9th December 2019

Attn: Caitlin O'Neill

Rio Tinto Iron Ore

152-158 St Georges Tce

Perth, WA 6000

Dear Caitlin,

Biologic conducted molecular systematics analysis (DNA barcoding) of 44 subterranean fauna (stygofauna and troglofauna) specimens collected from Rio Tinto's Hope Downs 1 (HDOW1) Project in November 2019. Since the time of publication of the report for molecular systematics analysis (Biologic 2019), some of the sequences derived from HDOW1 have been included in additional regional genetic comparisons with other and/or new sequences. This has resulted in further genetic alignments which may be of interest to Rio Tinto in relation to the HDOW1 project, including:

1. Hemiptera: *Nisia* OES16 (LN36535 and LN33789). Sequences from this Operational Taxonomic Unit (OTU) have been found to occur within a large clade containing many specimens from the Greater Brockman (GBO) area. The COI divergence between the GBO and HDOW1 sequences is between 3.7 and 4.4%, which is considered to represent the same species. There appears to be a strong population level difference between the average divergence of GBO sequences (0.8% COI), and HDOW1 vs GBO sequences (average 4.0%), which may reflect their geographical separation, but is below the species threshold applied at present.

2. Polyxenida: Lophoproctidae (LN38435): Genetic divergences within this taxon appear to be very gradational throughout the region and thus it is difficult to define consistent species thresholds. There is a chance that there could all be one large, regionally widespread OTU with divergences ranging up to 12% (average 8.7%). However, we are hesitant to accept this interpretation (with a very high level of COI divergence) without further genetic or morphological evidence. Therefore, as a precaution the current interpretation splits two widespread clades at approximately 9-10% COI divergence, with the HDOW1 sequence aligning to other sequences collected from GBO, Robe Headwaters, West Turner Syncline, Mesa G, and Paraburdoo. The closest individual match to LN38435 is 8.0% from Robe Headwaters, which is borderline high population-level divergence or low species-level divergence. Given anecdotal evidence of widespread/ cosmopolitan Lophoproctidae specimens occurring throughout subterranean

habitats in the Pilbara region, we are reasonably comfortable with this interpretation; however, further work is required to derive valid species divergence thresholds at COI in this taxon.

3. Zygentoma: Ateluridae sp. (LN39280). The HDOW1 sequence aligned with a Zygentoma OTU from West Angelas at 6.7% (12s), and also at a slightly higher divergence, with *Dodecastyla* sp. WAM-ZYGA001 from Paraburdoo (average 8.5% 12s). Owing to the ecological interpretation of Ateluridae as soil fauna/ inquiline inhabitants of termite nests, and therefore likely troglophiles/ trogloxenes, this level of divergence is regarded as indicative of a single, widely occurring OTU, with divergent populations at these different locations.

The current interpretations of OTUs and species thresholds are limited to the available genetic sequence data and may be subject to change with incorporation of further morphological, ecological, or genetic information. In particular, further work using a multiple gene approach combined with morphological taxonomy may be required to determine specific, taxonomically valid species divergence thresholds across the various subterranean taxa occurring in the Pilbara region. The current results may also be affected by the general constraints and limitations of subterranean fauna studies such as incomplete sampling, unequal sub-sampling for genetic analyses, taxonomic and ecological uncertainties, and low detection rates for some taxonomic groups.

If you have any queries or would like to discuss details further, please do not hesitate to contact myself or Nihara Gunawardene (nihara@biologicenv.com.au).

Yours sincerely,

Shae Callan,
Principal Zoologist

Executive Summary

Rio Tinto is evaluating the potential development of additional iron ore deposits at Hope Downs 2 (HD2), approximately 80 km northwest of Newman, in the Pilbara region of Western Australia. The HD2 Proposal (the Proposal) comprises three above water table (AWT) deposits; Baby Hope (BH), Bedded Hilltop (BHT) and HD2, as well as supporting infrastructure. Stantec Australia Pty Ltd (Stantec), was commissioned to undertake a desktop review and Level 2 stygofauna survey (the Survey) for the Proposal. The main objective of the Survey was to define the stygofauna values within the Survey area, to enhance and contextualise the level of knowledge at a local scale.

Sample Effort and Survey Adequacy

A total of 88 stygofauna haul net samples were collected from 57 sites during the Survey; 52 in Phase 1 (October/November 2018, late dry season) and 36 in Phase 2 (March/April 2019, late wet season) (**Table** ES-1). The Survey area encompassed the BH, BHT and HD2 deposit areas together with regional reference sites from the Weeli Wolli calcrete and riparian zone. Sampling effort exceeded the minimum recommended regulatory requirement of 40 samples for the Survey area.

Table ES-1: Stygofauna sample effort during the Survey.

Deposit Area	Phase 1 Samples (n)	Phase 2 Samples (n)	Total Samples (n)	Total Sites (n)
BH	21	8	29	23
BHT	11	10	21	11
HD2	14	11	25	16
Regional	6	7	13	7
Total	52	36	88	57

Stygofauna Findings

A total of four stygofauna specimens were recorded during the two field phases of the Survey. All specimens were Paramelitidae amphipods collected from a single site in the BHT area, within the alluvial/colluvial detritals and calcrete along Pebble Mouse Creek. The four specimens were identified as *Pilbarus* 'sp. Biologic-AMPH001' using morphological and DNA sequencing techniques. Genetic analysis suggested that *Pilbarus* 'sp. Biologic-AMPH001' may represent a new operational taxonomic unit (OTU) or taxon, only known from the Survey area. However, this may be an artefact of limited sampling or available sequences for comparison.

The presence of prospective habitat (alluvial/colluvial detritals and calcrete), together with previous amphipod records from the area, suggest *Pilbarus* 'sp. Biologic-AMPH001' may have a broader distribution along the Pebble Mouse and Weeli Wolli drainage lines. No stygofauna were collected from the Banded Iron Formation (BIF)-hosted groundwaters sampled from the BH, BHT and HD2 deposit areas during the Survey.

Conclusion

The results of this Survey indicated that stygofauna diversity and abundance within the Survey area are likely to be low. During the Survey, BHT deposit area yielded one stygofauna taxon, a potentially new paramelitid amphipod *Pilbarus* 'sp. Biologic-AMPH001', associated with alluvial/colluvial detritals and calcrete along Pebble Mouse Creek. These results were consistent with previous collections from the the Survey area, limited an amphipod and a Bathynellacean from colluvial/alluvial detritals of Pebble Mouse Creek.

Although apparently restricted to the Survey area based on genetic sequencing, it is likely that *Pilbarus* 'sp. Biologic-AMPH001' is distributed more broadly in prospective habitat along the Pebble Mouse and Weeli Wolli drainage lines. BIF geology within the BHT, BH and HD2 deposits did not yield any stygofauna, suggesting these habitats are not conducive to stygofauna within the Survey area, Additionally, hydrogeological conceptualisation indicated that the BIF aquifers are compartmentalised and expected to have limited connectivity with the more prospective, shallow groundwaters of the drainage lines. Sample effort for the Survey area was sufficient to meet regulatory guidance, with the BHT deposit area characterised by higher stygofauna values in comparison to the remaining areas.

Glossary

alluvium – sediment deposited by a stream or river

aquatic – relating to water

aquifer – a body of permeable rock or sediment capable of storing groundwater

arid – a region characterised by a severe lack of available water, to the extent that the growth and development of biota is hindered or prevented

bedrock – consolidated rock attached to the earth's crust

biodiversity – the diversity of biota in a particular environment or region

calcrete – carbonate deposits that form in arid environments, as a result of groundwater evaporation

cave – a subsurface cavity of sufficient size that a human could enter

dissolved oxygen – a measure of the amount of gaseous oxygen dissolved in a solution; oxic = > 3 mg/L; dysoxic = 0.3 to 3.0 mg/L; suboxic = < 0.3 mg/L levels

distribution range – the overall geographic area that a species is known to occur in

divergence – degree of separation from a common ancestor

diversity – a combination of species richness and abundance

drawdown – the lowering of the adjacent water table or piezometric surface as a result of groundwater extraction

electrical conductivity – an estimate of the total dissolved salts in a solution, or salinity

endemic – having a distribution restricted to a particular geographic region

epigean – pertaining to the surface zone

fractured rock – a rock formation characterized by separation or discontinuity, usually as a result of geological stress (e.g. faulting)

geological ages (e.g. Cainozoic) – distinct time periods within the geological history of the earth

groundwater – water occurring below the ground surface

habitat – an ecological or environmental area that is inhabited by a particular animal or plant species

hypogean – pertaining to the subterranean zone

hyporheic zone – spatially fluctuating ecotone within the bed of a river or stream between surface and groundwater. Considered important component of groundwater ecosystems and involved in the 'interstitial highway', forming hyporheic corridor linking associated aquifers.

invertebrates – animals lacking vertebrae

karst – a region of limestone or other soluble rock, characterized by distinctive features such as caves, caverns, sinkholes, underground streams and springs

lineage – a group of organisms related by descent from a common ancestor

molecular – pertaining to the genetic characteristics of an organism or group

morphology – the specific form and structure of an organism or taxon

morphospecies – a general grouping of organisms that share similar morphological traits, but is not necessarily defined by a formal taxonomic rank

palaeoriver, palaeochannel, palaeodrainage – a remnant of a stream or river channel cut in older rock and filled by the sediments of younger overlying rock

relictual – having survived as a remnant

salinity – the concentration of all dissolved salts in a solution. The salinity level classification *sensu* Hammer (1986): freshwater = salinity less than 5 mS/cm (3 ppt); hyposaline = salinity ranging from 5–30 mS/cm (3–20 ppt); mesosaline = salinity ranging from 30–70 mS/cm (20–50 ppt); hypersaline = salinity equal to or greater than 70 mS/cm (50 ppt)

semi-arid – a climatic region that receives low annual rainfall (250 – 500 mm)

species – a formal taxonomic unit defining a group or population of organisms that share distinctive characters or traits, are reproductively viable and/or are otherwise identifiable as a related group

species richness – the number of species present in a particular habitat, ecosystem or region

standing water level (SWL) – the depth to groundwater from a particular reference point (e.g. in a monitoring bore)

stygal – pertaining to groundwater habitat or biota

stygobite – an obligate aquatic species of groundwater habitats

stygobiont – another term used to describe obligate inhabitants of groundwater systems

stygofauna – a general term for aquatic groundwater fauna

stygophile – an aquatic species that temporarily or permanently inhabits groundwater habitats

stygoxene – an aquatic species that has no fixed affinity with groundwater habitats, but may nonetheless occur in groundwater habitats

sympatry / sympatric – two or more species that are considered to exist in the same or overlapping geographic area and may regularly interact with, or encounter, each another (without interbreeding)

taxon (singular), taxa (plural) – an identifiable group of organisms, usually based on a known or inferred relationship or a shared set of distinctive characteristics

void – a pore space in the rock or stratum

1. Introduction

Rio Tinto is evaluating the potential development of additional iron ore deposits at Hope Downs 2 (HD2), approximately 80 km northwest of Newman, in the Pilbara region of Western Australia (**Figure 1-1**). The HD2 Proposal (the Proposal) comprises three above water table (AWT) deposits; Baby Hope (BH), Bedded Hilltop (BHT) and HD2, as well as supporting infrastructure. Ore is will be transported to the existing processing plant at Hope Downs 1 (HD1). Stantec was commissioned by Rio Tinto in 2018 to undertake a desktop review and Level 2 stygofauna survey (the Survey) for the Proposal.

1.1 Scope and Objectives

The main objective was to define the stygofauna values present within the Survey area by undertaking a desktop review and Level 2 comprehensive survey (dry and wet seasons) to enhance and contextualise the level of knowledge at a local scale.

To address the objective, the following were completed:

- desktop assessment including database searches, literature review, habitat evaluation and characterisation (local and regional scale), and assessment of the likelihood of the occurrence significant species and/or communities in the Survey area;
- two phases of field surveys for stygofauna within the Survey area; and
- reporting and mapping of the diversity and distribution of stygofauna species recorded from this and previous surveys in the Survey area and surrounds.

The objective and the survey methods were aligned with relevant regulatory guidelines, comprising:

- Environmental Protection Authority (2016a). Technical Guidance Sampling Methods for Subterranean Fauna Survey (equivalent to EPA 2007 Guidance Statement No. 54A Sampling Methods and Survey Considerations for Subterranean Fauna in Western Australia); and
- Environmental Protection Authority (2016b). Technical Guidance Subterranean Fauna Survey (equivalent to EPA 2013 EAG 12 Environmental Assessment Guideline for Consideration of subterranean fauna in environmental impact assessment in Western Australia).

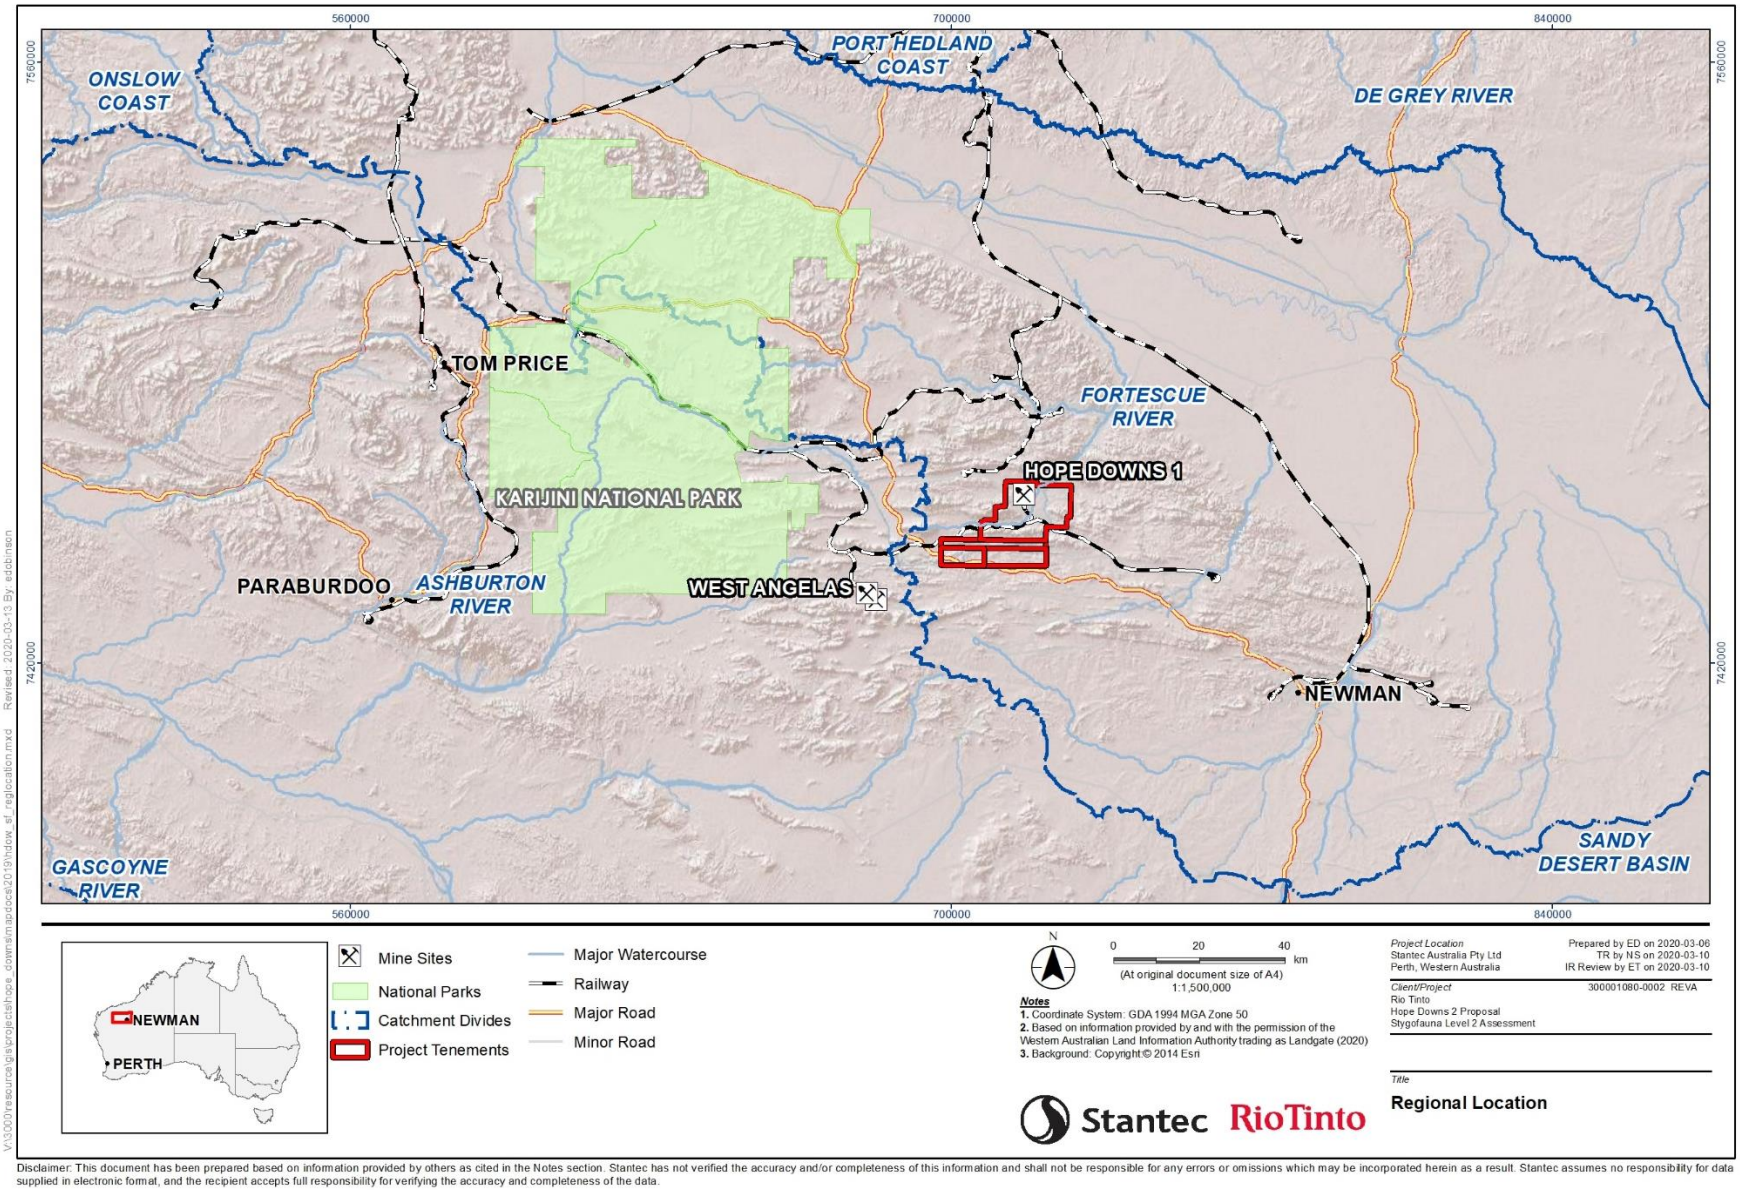

Figure 1-1: Regional location of the Survey.

2. Existing Environment

2.1 Biogeographical Context

The Survey area is located in the Hamersley subregion (PIL03) within the southern section of the Pilbara bioregion (**Figure 2-1**). The subregion is 5,634,727 ha in size and classified as a Desert and Xeric Shrubland ecoregion, characterised as a mountainous area of Proterozoic sedimentary ranges and plateaux that are extensively dissected by gorges (Kendrick 2001). The vegetation of the subregion mainly consists of low mulga woodland over grasses on fine textured soils in valley floors, with *Eucalyptus leucophloia* over *Triodia brizoides* on skeletal soils of the ranges (Department of the Environment and Energy 2019a; Kendrick 2001).

The subregion hosts the headwaters of three of the main drainage systems in the Pilbara; the northern portion drains into the Fortescue catchment; the southern portion drains into the Ashburton catchment; and the western portion drains into the Robe catchment (Kendrick 2001) (**Figure 1-1**). The subterranean fauna values of the subregion are known to be high, with alluvial and calcrete aquifer systems and banded iron formations (BIF) supporting diverse stygofauna and troglofauna assemblages (Halse *et al.* 2014; Kendrick 2001).

Land within the subregion is mainly used for native pasture grazing, with smaller areas classified as unallocated Crown land (UCL), Crown and Aboriginal reserves, as well as mining and small urban centres (Kendrick 2001). Adjacent to the Survey area, exploration activities and active mining are associated with the HD1 mine.

2.2 Regional Hydrology and Hydrogeology

The Survey area is located within the upper reaches of the Weeli Wolli Creek catchment, which forms part of the Fortescue River Basin. The Weeli Wolli catchment covers an area of approximately 4,770 km^2, underlain by formations of the Hamersley Group, encompassing dolomite, shale and ironstone, with minor felsic volcanics and intrusives, dolerite dykes and sills (Environmental Protection Authority 2018). The Survey area also intersects Pebble Mouse Creek, a major tributary of Weeli Wolli Creek with a sub-catchment area of 340 km^2 (Rio Tinto Iron Ore 2014). The BH and BHT deposits lie either side of the shallow and broad (2 km wide) Pebble Mouse Creek valley, where a relatively well-defined creek drains in a north-easterly direction into Weeli Wolli Creek (Rio Tinto Iron Ore 2014).

The karstic dolomite of the Wittenoom Formation (Paraburdoo member) form a regionally important aquifer (Environmental Protection Authority 2018; Johnson and Wright 2003). Groundwaters also occur in the West Angela Member (Wittenoom Formation) and within fractured Marra Mamba Iron Formation, where mineralisation or structural features increase permeability. Aquifers exist in association with alluvium, pisolite and calcrete, with the latter units forming significant groundwater systems (Johnson and Wright 2003). Regional groundwater flow is generally from south-west to north-east, following the surface water drainage.

2.3 Climate

The climate of the Hamersley subregion is classified as semi-desert tropical. The area receives an average of 300 mm rainfall, the majority of which occurs during the wet season, linked to cyclonic or tropical low weather events (Kendrick 2001). Winter rainfall (early to mid-dry season) also occurs but to a lesser extent. The nearest Bureau of Meteorology (BOM) weather stations to the Survey area with reliable long-term and recent climatic data, are Marillana (station number 5009) and Newman Aero (station number 7176). Marillana station, approximately 55 km northeast of the Survey area, provided long-term rainfall records. Newman Aero, approximately 85 km south-east of the Survey area, provided long-term temperature trends.

The mean long-term annual rainfall recorded at Marillana is 328 mm with the majority falling between January to March (**Figure 2-2**) (Bureau of Meteorology 2019). The annual rainfall in 2018 was below average, totalling 281 mm. February and June were exceptions, the latter receiving more than four times the monthly rainfall average. The annual rainfall total in 2019 was also well-below average, with only 150 mm received. The minimum and maximum temperatures recorded in 2018 and 2019 were largely consistent with the mean temperatures recorded since 1997 at Newman Aero, although the maximum and minimum temperatures were comparatively higher between March to early May (Bureau of Meteorology 2019).

Phase 1 of the Survey was undertaken in the late dry season between 26 October and 03 November 2018 (**Figure 2-3**). Phase 2 of the Survey was completed in the late wet season between 29 March and 04 April 2019 (**Figure 2-3**). In 2019, total rainfall recorded at Marillana preceding Phase 2 was approximately 120 mm, amounting to 80% of total rainfall received in 2019 (**Figure 2-3**).

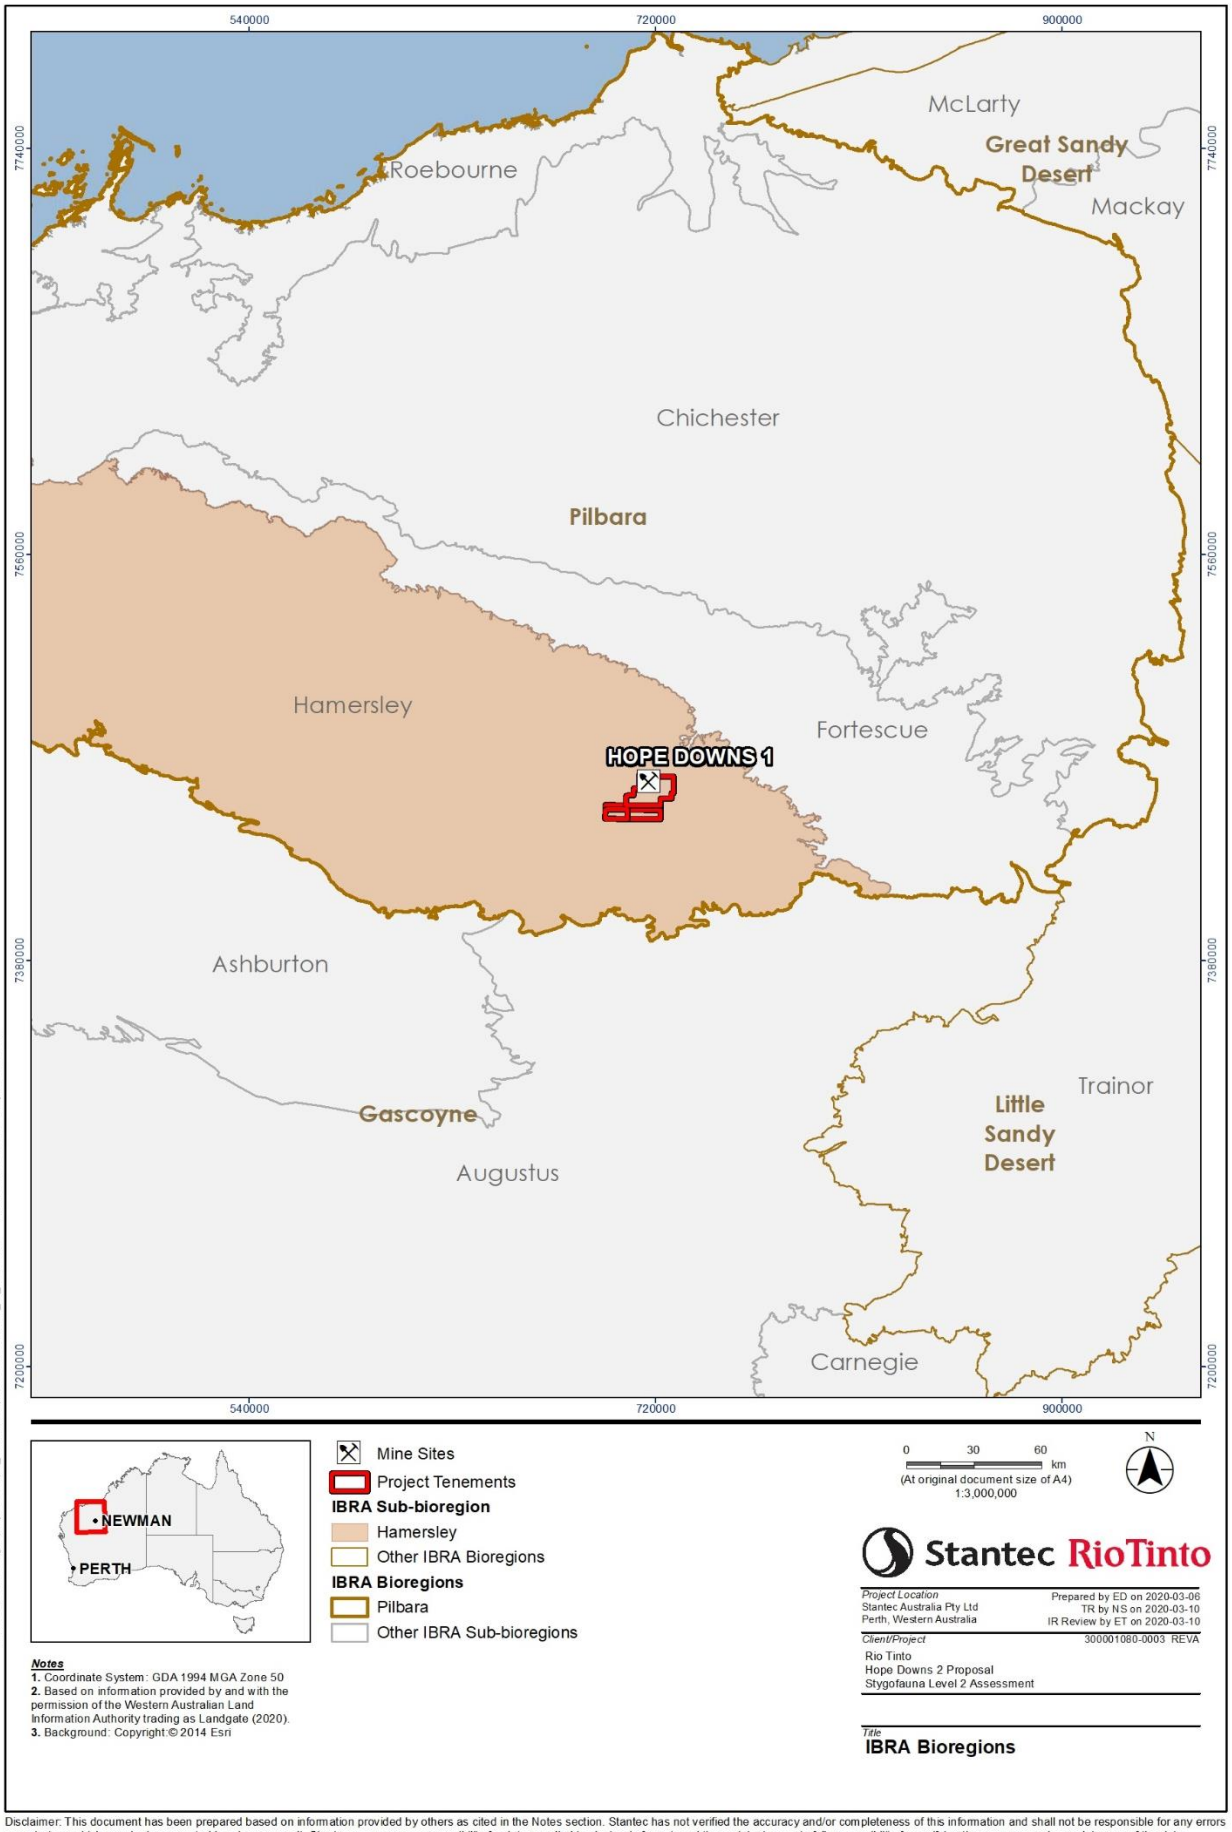

Figure 2-1: Location of the Survey area within the IBRA Hamersley bioregion.

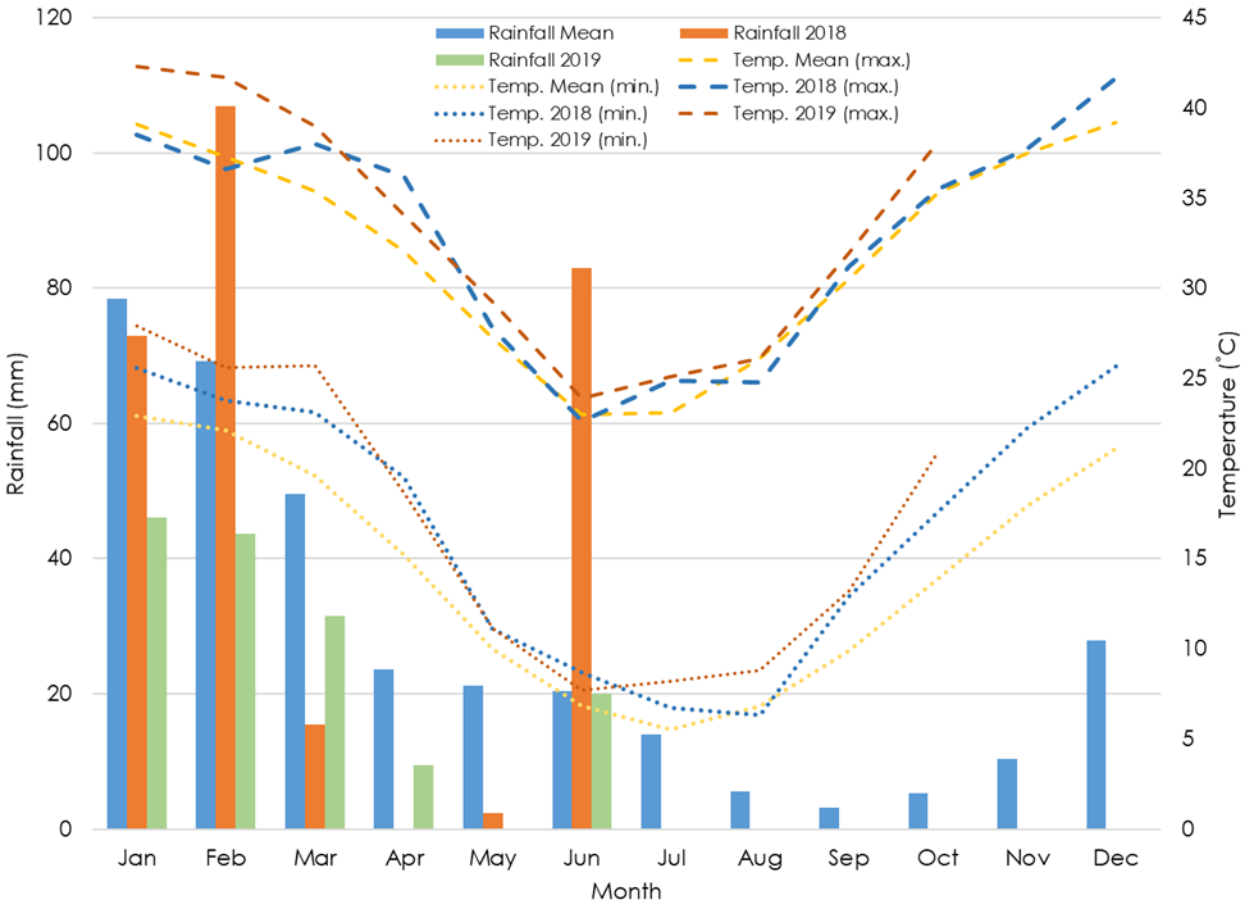

Figure 2-2: Long-term average monthly rainfall for Marillana Weather Station (5009; 1937 to 2019), and long-term average monthly minimum and maximum temperatures for Newman Weather Station (007176; 1972 to 2019) compared to 2018 and 2019 data (Bureau of Meteorology 2019).

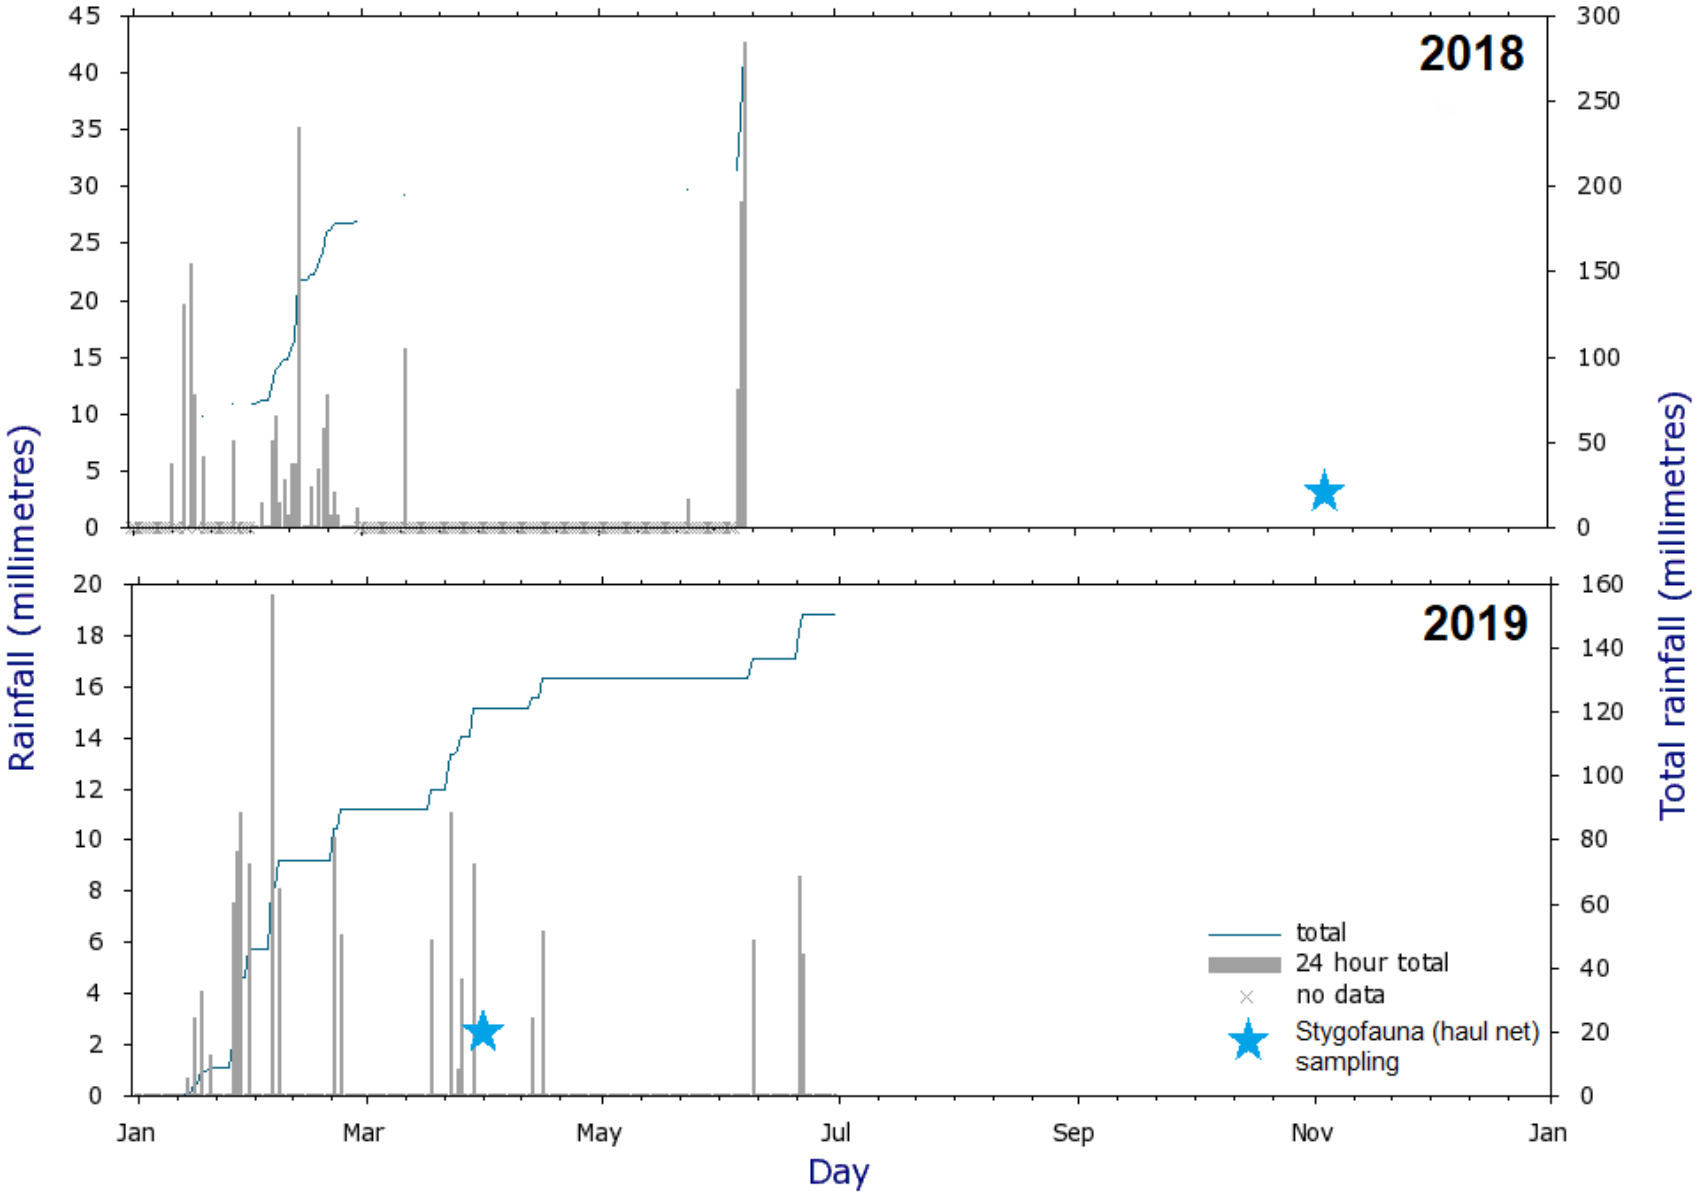

Figure 2-3: Daily rainfall data recorded for Marillana (Station:5009) in 2018 and 2019 (Bureau of Meteorology 2019).

3. Subterranean Fauna

Subterranean fauna inhabit underground environments and are often relictual forms of surface dwelling (epigean) groups. They can be divided into stygofauna and troglofauna: the former are aquatic, occupying groundwater systems, with the latter persisting in air-filled voids. Both groups often display evolutionary adaptations according to their subterranean existence, including reduced pigmentation, poorly functioning or non-existent eyes, and the presence of extended locomotory and sensory appendages. Subterranean fauna comprise invertebrate and vertebrates, with the former prevalent in Western Australia (Culver and Pipan 2009; Environmental Protection Authority 2016b). Both stygofauna and troglofauna include short-range endemic (SRE) species that have geographically restricted ranges of less than 10,000 km^2 and are considered vulnerable to extinction (Harvey *et al.* 2011; Harvey 2002).

3.1 Stygofauna

Stygofauna predominantly comprise crustaceans (such as ostracods, copepods, amphipods and syncarids), while other invertebrate stygofauna groups can include gastropods (snails), insects, water mites and worms. In Western Australia, studies have shown that calcrete and alluvial aquifers associated with palaeodrainage channels of the arid and semi-arid zones can contain rich stygofauna communities. Specifically the Pilbara region stands out as a global hotspot for stygofauna diversity (Humphreys 2008). Stygofauna can be classified according to their level of dependency on the subterranean environment:

stygoxenes are animals that enter groundwaters passively or accidentally;

stygophiles inhabit groundwaters on a permanent or temporary basis; and

stygobites are obligate groundwater dwellers.

3.2 Habitat

Prospective habitat for stygofauna is dependent on the presence of sub-surface crevices, fractures and voids of suitable size and connectivity to satisfy biological requirements. Adequate interconnected spaces and associated high permeability allows for movement of stygofauna. These spaces can also provide pathways for the infiltration of resources such as dissolved oxygen and nutrients, key factors influencing subterranean fauna (Humphreys 2008; Strayer 1994). Geologies with suitable secondary porosity can include karst, calcrete, coarse alluvium, fractured rock, pisolites and thin rocky regoliths (Halse *et al.* 2002; Humphreys 2006;2008; MWH 2016b;c; Outback Ecology 2014).

3.3 Relevant Legislation and Risk

Subterranean fauna are protected under State and Federal legislation, governed by three Acts comprising:

- *Biodiversity Conservation Act 2016* (WA) (BC Act);
- *Environmental Protection Act 1986* (WA) (EP Act); and
- *Environment Protection and Biodiversity Conservation Act 1999* (Cth) (EPBC Act).

The development and operation of mines in Western Australia poses several key risks to subterranean fauna and their habitat, including:

- direct removal of, or disturbance to, habitats through mining excavation;
- lowering the water table through groundwater abstraction for pit dewatering and supply; and
- altering water quality parameters, to levels which may exceed species tolerance limits.

Mining proposals that will potentially impact on groundwater, or hypogean habitats that support subterranean fauna, require environmental impact assessment (EIA) to ensure mining operations do not threaten the viability of significant species or communities. Proponents must demonstrate that any species existing within potential mine-related impact zones also occur outside of this area. For taxa restricted to impact zones, a suitable management plan must be developed, which includes ongoing monitoring of subterranean fauna to ensure the persistence of the species.

3.4 Regulatory Survey Adequacy Guidelines

The EPA (2016a,b) stipulates that the appropriate level of survey effort depends on the likely presence of subterranean fauna, the degree of impact proposed, and adequacy to reliably inform decisions as part of the EIA process in relation to the EPA's objective. The EPA objective for the environmental factor of subterranean fauna is to protect subterranean fauna so that biological diversity and ecological integrity are maintained (Environmental Protection Authority 2016c).

The EPA (2016a) recommends that for a Level 2 (baseline) stygofauna survey in an area that is prospective for stygofauna, a minimum of 40 net haul samples should be collected over at least two survey seasons from within proposed impact areas. The minimum survey effort relates to proposed impacts across interconnected habitat.

4. Methods

4.1 Desktop Review

4.1.1 Database Search and Lists

Searches of both Commonwealth and State databases were undertaken as part of the desktop review for the Survey. These focused on identifying threatened or priority ecological communities (TEC's and PEC's) and stygofauna taxa recorded from within or near the Survey area. Search areas were either from a central point in the Survey area or a designated rectangular search area (**Table 4-1**, **Figure 4-1**). Database and internet information sources included:

- Department of Biodiversity, Conservation and Attractions (DBCA) TEC/PEC database was searched for TEC's and PEC's occurring within a 50 km radius of the Survey area (Department of Biodiversity Conservation and Attractions 2019b);
- Western Australian Museum's (WAM) Arachnida, Myriapoda, Crustacea, Mollusca and Insecta collection databases were searched for subterranean fauna (Western Australian Museum 2018a;b;c;d);
- Atlas of Living Australia (ALA) (Atlas of Living Australia 2020); and
- NatureMap of Western Australia (Department of Biodiversity Conservation and Attractions 2020).

The following Federal and State government lists were also assessed against the database results, to identify any threatened or priority subterranean fauna that may occur within the search area:

- BC Act Specially Protected Species List (Department of Biodiversity Conservation and Attractions 2018);
- EPBC Act Threatened Ecological Communities (TEC) List (Department of the Environment and Energy 2019b); and
- EPBC Act Threatened Fauna List (Department of the Environment and Energy 2019c).

Table 4-1: Defined area and coordinates of database searches for the Survey.

WAM Collections	80 km square	NW corner @ 22.694628°S, 118.630309 E SE corner @ 23.422667 S, 119.422871 E
ALA		

4.1.2 Literature Review

A literature review was conducted to gather existing information on stygofauna from within the vicinity of the Survey area. The review included technical reports, scientific journal articles and government publications. The literature review focussed on drainage and palaeochannel systems associated with or adjacent to the Survey area, as well as BIF ridge systems within approximately 40 km of the Survey area.

4.1.3 Stygofauna Habitat Characterisation

A review of geological and hydrogeological information was undertaken to characterise potential stygofauna habitat and assess stygofauna prospectivity in the Survey area. Information reviewed included bore logs, hydrogeological cross section diagrams and mapping of interpreted aquifer extent provided by Rio Tinto and mapped geological units (surface and bedrock).

4.2 Stygofauna Survey

4.2.1 Field Personnel and Fauna Licences

The field survey methods and sampling effort aligned with EPA technical guidance (Environmental Protection Authority 2016a;b). A Regulation 17 licence to collect fauna for scientific purposes was obtained from the DBCA prior to the field surveys (Licence Number 08-003053-1). Personnel involved in the field sampling for both phases were Dr Nicholas Stevens (BSc Hons. (Zoology), PhD; 20+ years' experience) and Emma Dobinson (BSc Hons. (Marine Biology), MRes (Ecology, Evolution and Conservation); 5+ years' exp.

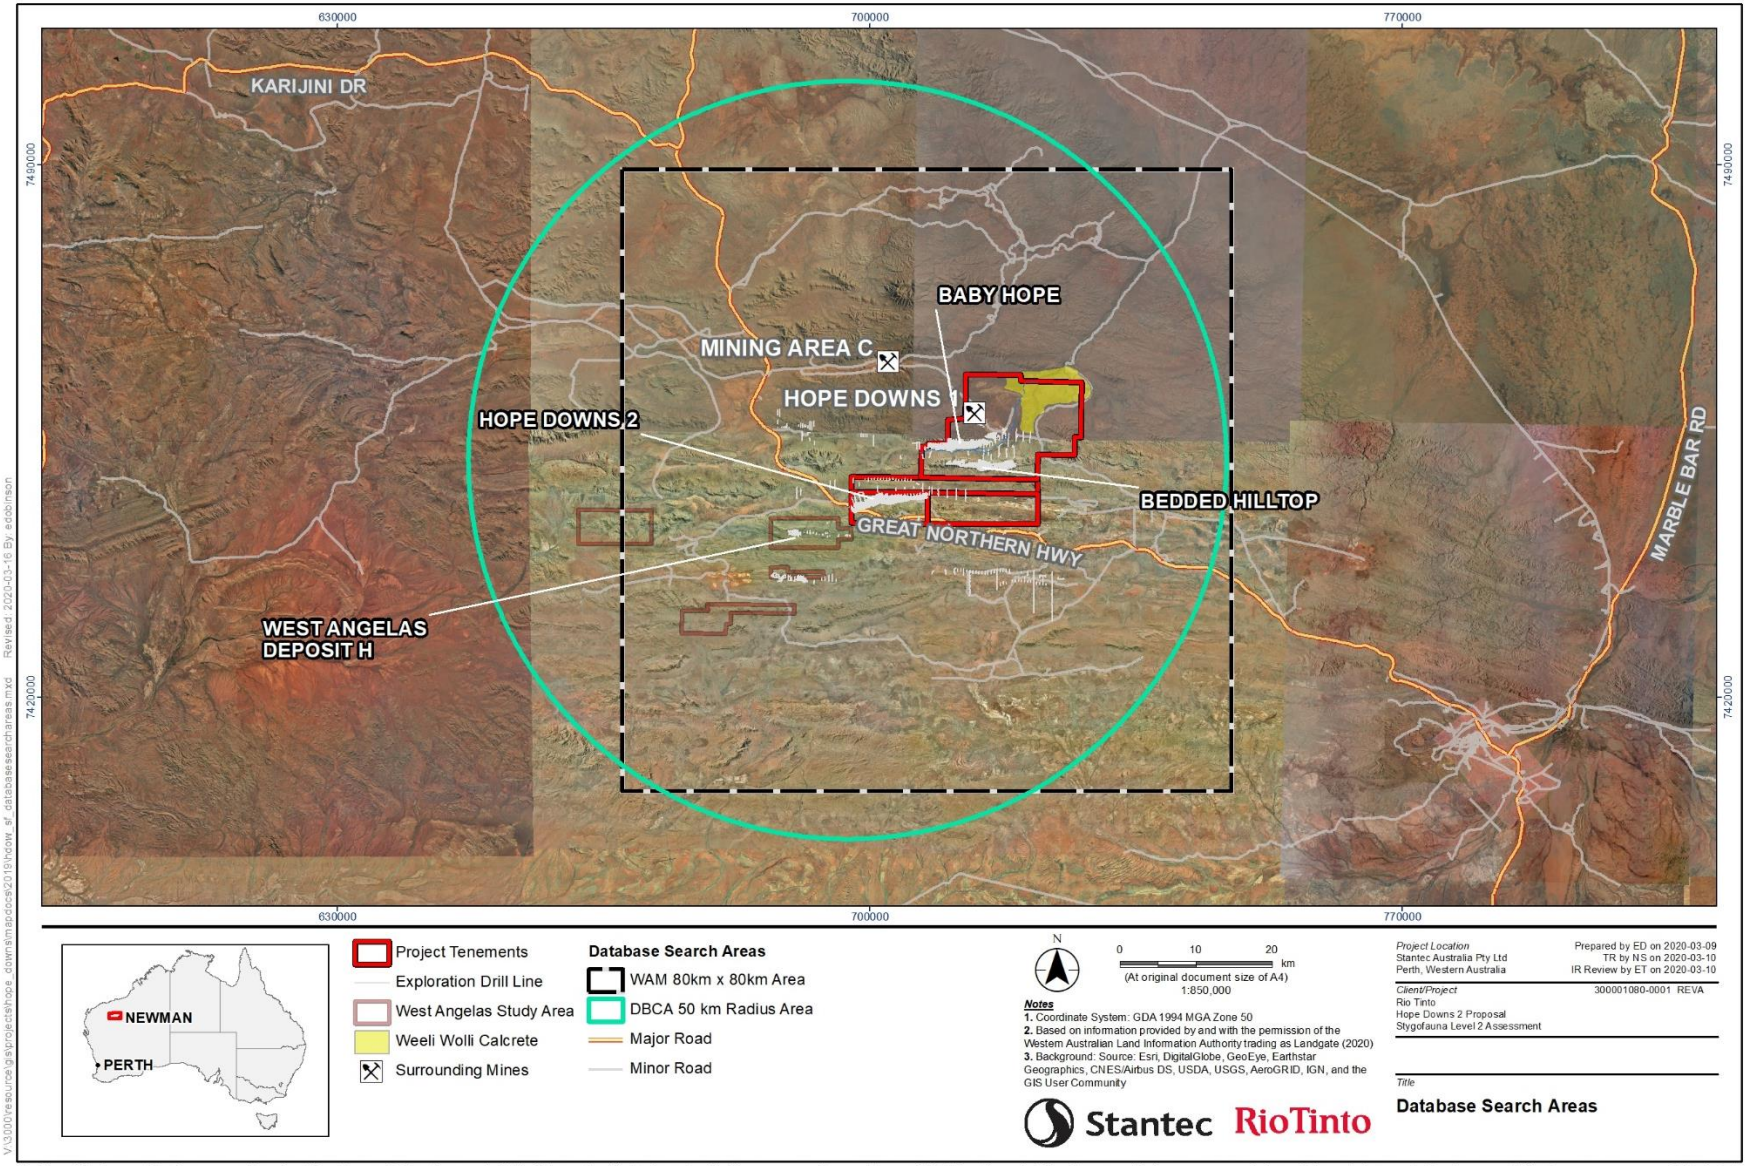

Figure 4-1: Database search areas for the Survey.

4.2.2 Survey Effort

The Survey comprised a total of 88 stygofauna net haul samples collected from 57 sites across two phases of field surveys: Phase 1 (October-November 2018, late-dry season) and Phase 2 (March-April 2019, late-wet season) (**Table 4-2, Figure 4-2, Appendix A).** This incorporated sites from within the BH, BHT and HD2 deposits area and regional reference sites in the Weeli Wolli Creek calcrete and riparian zone; referred to as the Survey area. Representative site images are presented in **Appendix A**.

The majority of samples (75) were collected from the deposit areas, with 13 samples collected from regional reference sites. The survey effort for the Survey area meets the minimum number of 40 impact samples for a Level 2 baseline stygofauna survey, as long as there is habitat connectivity (Environmental Protection Authority 2016a).

Table 4-2: Stygofauna sample effort for the Survey.

Deposit Area	Phase 1 Samples (n)	Phase 2 Samples (n)	Total Samples (n)	Total Sites (n)
BH	21	8	29	23
BHT	11	10	21	11
HD2	14	11	25	16
Regional Reference	6	7	13	7
Total	52	36	88	57

4.2.3 Net Haul Sampling

Stygofauna samples were collected from a combination of drill holes, monitoring bores and production bores (referred to as 'sites') using haul nets, which have been found to be the most efficient retrieval method (Allford *et al.* 2008). Sampling was consistent with the procedures outlined in the EPA (2016a) technical guidance. The sampling method was as follows:

- samples were collected using two weighted haul nets with mesh sizes of 150 µm and 50 µm (each net was fitted with a collection vial with a base mesh of 50 µm);
- the 150 µm net was lowered first, near the bottom of the site;
- once at the bottom, the net was gently raised up and down to agitate the sediments;
- the net was then raised slowly, to minimise the 'bow wave' effect that may result in the loss of specimens, filtering stygofauna from the water column on retrieval;
- once retrieved, the collection vial was removed, and the net contents emptied into a 2 L polyethylene sample container;
- this process was repeated three times alternating with three samples with the 50 µm net;
- the 2 L sample container comprising the contents of all six net hauls was elutriated through a decontaminated 50 µm net into a 250 mL polyethylene vial, with the contents preserved with 100% undenatured ethanol;
- to prevent cross-contamination, all sampling equipment was decontaminated after each site using a Decon 90 (2 to 5% concentration) after each site and then rinsed with water;
- samples were placed into eskies with ice bricks in the field, prior to being transferred into a refrigerated environment on-site at the end of each field survey day; and
- on completion of each field survey, samples were couriered to the Stantec laboratory in Perth, where they were stored in 100% ethanol, at approximately minus 20°C.

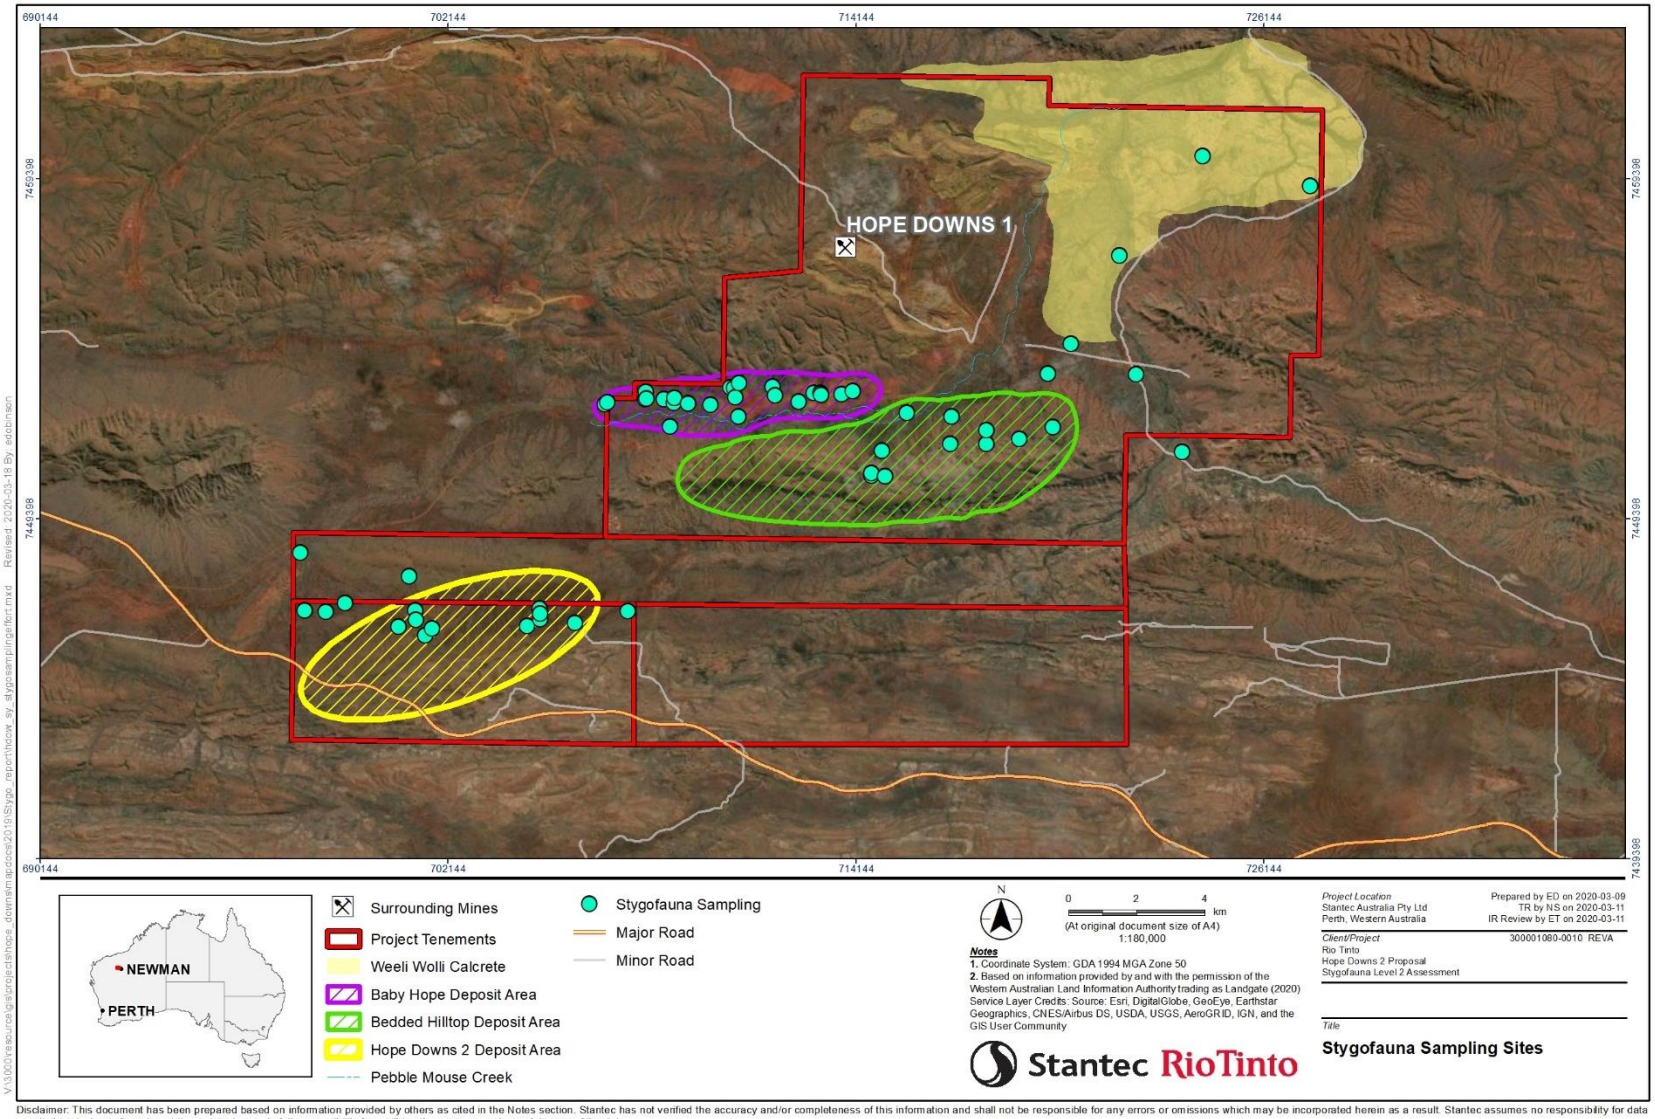

Figure 4-2: Stygofauna sampling effort for the Survey.

4.2.4 Sorting and Identification of Specimens

Preserved stygofauna samples collected from the two phases of the field surveys were sorted manually using Leica MZ6, MZ7.5, M80 and M205C stereomicroscopes within the Stantec laboratory by Emma Dobinson, Jake Daviot and Thomas de Silva (aquatic and subterranean fauna scientists). Once sorted, any potential subterranean fauna specimens found were preserved in 100% ethanol (preserving DNA for sequencing) and stored at minus 20°C. Higher taxonomic resolution was provided by Dr Nicholas Stevens of Stantec to identify stygofauna species, using published and unpublished keys and taxon descriptions. Undescribed taxa were assigned morphospecies names based on morphological features.

4.2.5 DNA Sequencing

Material from two stygofauna specimens was sent to Biologic Environmental for genetic analysis. The molecular analysis provided a comparison to identifications based on morphological characters, including juvenile specimens. Genetic analysis also allows for the alignment of morphospecies with any described and/or previously sequenced taxa.

4.2.6 Limitations

Fewer stygofauna samples were collected (88) than originally proposed (150) for the Survey, due to the lack of suitable and accessible sites. The number of sites in the vicinity of the proposed development that intercept the water table is limited. Many of the bores sampled in Phase 1 in the BH active mining area had been destroyed by pre-mining stripping of the eastern portion prior to the Phase 2 field survey. Many other sites sampled during Phase 1 were no longer accessible during Phase 2, due to the recent installation of fixed electronic monitoring equipment.

The availability of suitable reference sites from the non-resource area was limited, with few sites present beyond the BIF. The seemingly restricted distributions of subterranean fauna species to within a specific resource target habitat type can largely be an artefact of the disproportionate sampling effort conducted between likely impact areas and reference areas.

Every effort was made to accurately assess the taxonomy, distribution and conservation significance of collected stygofauna specimens using in-house data collections, publications, publicly available reports, and information provided by specialist taxonomists. However, assessment was limited by available information.

5. Results

5.1 Desktop Review

5.1.1 Database Searches

A search of the DBCA's threatened and ecological communities database identified two priority ecological groundwater communities within a 50 km radius of the Survey area; Weeli Wolli Spring Community North and Weeli Wolli Spring Community South (Department of Biodiversity Conservation and Attractions 2019b). The area, encompassing the Weeli Wolli Spring and sections of the Weeli Wolli Creek is known to support a high diversity of stygofauna, likely attributed to the large-scale calcrete and alluvial aquifer system associated with the watercourse (Department of Biodiversity Conservation and Attractions 2019a). Both PECs are classified as Priority 1, a ranking allocated to poorly known ecological communities of restricted distribution (Department of Environment and Conservation 2013). The 5 km buffer zone associated with the Weeli Wolli Spring Community South PEC overlaps with the eastern portion of the Survey area, including the BHT deposit (**Figure 5-1**, **Figure 5-2**).

An area of 6,400 km^2 around the Survey area was investigated during searches of the WAM Arachnida, Myriapoda, Crustacea, Mollusca and Insecta databases (**Figure 4-1**). A total of 367 stygal crustaceans, and eight stygal arachnids, were identified during these searches (**Figure 5-1**, **Figure 5-2**, **Appendix B**). Crustacea records comprised primarily Copepoda (98 records), Amphipoda (91 records) and Isopoda (81 records), with Ostracoda (49 records) and Syncarida (48 records) less-well represented (**Appendix B**). All eight Arachnida records belonged to the Acari (water mite) group (**Appendix B**). No records of stygal Insecta, Myriopoda or Mollusca were found (Western Australian Museum 2018a;c;d). Most records were from subterranean fauna environmental baseline studies for iron ore projects such as Greater West Angelas, Hope Downs 1, Yandicoogina, Mining Area C and South Flank. Records were typically highest within the alluvial/colluvial habitats, particularly in association with the Marillana and Weeli Wolli Creek systems (**Figure** 5-2).

A search of the DBCA's NatureMap database found 34 potential stygofauna taxa within a 40 km radius of the Survey area, with representatives from Copepoda (three taxa), Ostracoda (13 taxa), Oligochaeta (three taxa), Amphipoda (6 taxa), Syncarida (one taxa), Rotifera (one taxa) and Acari (seven taxa) (Department of Biodiversity Conservation and Attractions 2020). The majority of these were from the regional Pilbara stygofauna survey conducted by Halse *et al.* (2014). A search of the ALA database for the Survey area did not return any additional stygofauna records (Atlas of Living Australia 2020).

5.1.2 Literature Review

Previous sampling within or near the Survey area has been undertaken for two Projects; Rio Tinto Yandicoogina (Yandi) Operations and Rio Tinto Hope Downs Project (Biota 2006, Biota 2015). Additionally in 2011 Bennelongia conducted the Weeli Wolli Creek catchment stygofauna assessment on behalf of BHP (Bennelongia 2013). Sampling for Yandi in 2009 identified stygofauna from six bores in or adjacent to the Survey area. Over 20 stygofauna specimens were recorded from the following groups; Amphipoda, Copepoda, Bathynellacea, Isopoda and Ostracoda, with identification to class or order only (Biota 2015). Each site was located in the vicinity of the Pebble Mouse or Weeli Wolli Creeks within calcrete mapped surface geology (**Figure 5-3**). The mapped bedrock units included Wittenoom Formation, Mount McRae Shale and Mount Sylvia Formation (**Figure 5-4**).

The Weeli Wolli Creek Catchment assessment by Bennelongia (2013) comprised sampling of 64 sites across the Upper Weeli Wolli Creek catchment, Lower Weeli Wolli Creek catchment, and Rhodes Ridge area, with 111 samples collected. Of these, 60 samples were collected from the Upper Weeli Wolli Creek catchment area, adjacent to the BH and BHT deposits. In total, 459 stygofauna specimens recorded from the Weeli Wolli Creek catchment area, comprising 23 stygofauna taxa from six higher order groups (Nemtaoda, Ostracoda, Copepoda, Amphipoda, Isopoda and Oligochaeta). The catchment is described as primarily dominated by Hamersley Group rocks alongside areas of Tertiary detritals and calcrete in the palaeochannel creeklines. All bores sampled for during the assessment were situated upon palaeochannel aquifers and calcrete formations, which are well known as prospective stygofauna habitat. Coordinates for individual taxa records are not provided, and so it is uncertain whether any of the stygofauna taxa were recorded from within the BHT or BH deposit areas.

The assessment for Hope Downs, undertaken between 2002 and 2004 (Biota 2006), identified stygofauna from alluvium, colluvium (detritals), calcrete and Marra Mamba Iron Formation mapped surface geology (**Figure 5-3**). The mapped bedrock units comprised Wittenoom and Weeli Wolli Formations, Mount McRae Shale, Mount Sylvia Formation, Brockman Formation and Marra Mamba Iron Formation (**Figure 5-4**).

Over 600 stygofauna specimens were collected from 30 sites during the Hope Downs assessment (Biota 2006). Most of these specimens were recorded from saturated alluvium and calcrete associated with Weeli Wolli Creek. Sampling in the Survey area was limited to two sites (**Figure 5-3, Figure 5-4**). One of these sites, near Pebble Mouse Creek witin the BH deposit area, yielded a bathynellacean (family Parabathynellidae). Two specimens of the amphipod Paramelitidae sp. 2 were collected from the second site, located north of the BHT banded iron formation (BIF) ridge towards Pebble Mouse Creek. The mapped surface geologies for these specimen records were colluvium (bathynellacean) and Wittenoom Formation (Paramelitidae sp. 2) (**Table** 5-1**, Figure 5-3, Figure 5-4**).

Paramelitidae sp. 2 has been recorded during a number of surveys in the Pilbara region (Biota 2010a;b; Outback Ecology 2009). During the Hope Downs surveys, this taxon was documented along a distance of approximately 40 km, from the BHT area near Pebble Mouse Creek northwards past the confluence of Weeli Wolli and Marillana Creeks (**Table 5-1**, **Figure 5-3**, **Figure 5-4**) (Biota 2006). The isopod *Pygolabis* 'weeliwolli' also demonstrated the broader distribution of taxa within the Weeli Wolli catchment. Morphological identification in conjunction with genetic analysis indicated a distribution in excess of 20 km, along the drainage (**Figure** 5-3**, Figure 5-4**) (Biota 2006). The distribution of these taxa highlights the interconnectivity of habitat along the Weeli Wolli drainage system, supported by the mapped extent of alluvial/colluvial detritals, calcrete and underlying units (**Figure 5-3**, **Figure 5-4**).

The bathynellacean recorded from the BH deposit area was only identified to family level (Parabathynellidae), and so its broader distribution is uncertain. Several representatives from the family Parabathynellidae have been recorded across the Weeli Wolli Creek catchment (Biota 2015, Bennelongia 2013). Biota (2015) recorded 62 Parabathynellidae specimens from at least eight taxa from the lower Weeli Wolli Creek and Marillana Creek areas between 2011 and 2015. Of these, five were singletons having only been recorded from a single site. Despite the records of these singletons amongst the Parabathynellidae, Biota (2015) suggest that most taxa from the Weeli Wolli Creek catchment are unlikely to be restricted in distribution, given the relatively large distance that separate some specimens of the same species (>9 km), and the catchment-wide distribution of other constituents of the the stygal community (particularly larger crustaceans such as Paramelitidae sp. 2).

Similar trends have been found on a wider regional scale, with the results of various studies for iron ore projects indicating the greatest diversity and abundance of stygofauna occurs within detritals (alluvium, colluvium) and calcrete units along drainage lines (**Figure 5-2**) (Biota 2015; MWH 2014; Subterranean Ecology 2012). In contrast, sampling within the BIF units has tended to yield little or no stygofauna (Biota 2008; ecologia Environment 2013; MWH 2016a; Subterranean Ecology 2008a).

For example, two surveys by Subterranean Ecology (2008, 2009) assessed the Area C Packsaddle deposits for stygofauna, located immediately to the north-west of the Survey area. The first of these surveyed Deposit 1, 2 and 3 in 2008. A total of 37 sites were sampled across two phases, however, only a single species of enchytraeid oligochaete was collected from two bores, located within the Packsaddle 3 deposit. The survey effort at Packsaddle Deposits 4 to 6 in 2009 consisted of 45 sites and 96 samples, again yielding only enchytraeid oligochaetes from a single bore. The host rock geology of the region is BIF with little to no voids or pore spaces, with a low water table constituting unfavourable stygofauna habitat.

There are several exceptions, where diverse stygofauna communities have been recorded from both alluvial/calcrete aquifers and BIF hosted groundwaters. A survey of Callawa Ridge, as part of the Cundaline and Callawa mining assessment, found a moderately diverse stygofauna assemblage. However, this was attributed to a perched aquifer system with a reasonable degree of hydraulic connectivity to the De Grey River system aquifers (Subterranean Ecology 2008a). At Hope Downs 4, diverse and abundant communities were primarily recorded in superficial alluvial and calcrete deposits associated with Coondiner Creek (**Figure 5-2**). A speciose community also occurred at an orebody site that intersected heavily mineralised Dales Gorge Member; folded to the surface and with a relatively shallow depth to groundwater (Outback Ecology 2009).

While several deposits at West Angelas did not yield any stygofauna (Biota 2008; ecologia Environment 2013; Rio Tinto 2018), moderate stygofauna diversity was documented within and/or near Deposits C and D (Biologic 2016; Rio Tinto 2018). The primary habitats in the area were identified as mineralised Marra Mamba Iron Formation, Wittenoom Formation and overlying weathered regolith, alluvial/colluvial detritals, pisolite and calcrete. The superficial hydrogeological units along the drainage lines were also considered to provide connectivity of stygofauna habitat beyond the study area (Biologic 2016;2017; Rio Tinto 2018).

Table 5-1: Summary of previous stygofauna records from the Survey area and associated mapped geology

Taxon	Reference	Deposit Area	Wider Distribution	Mapped surface Geology	Mapped Bedrock Geology
Amphipoda Paramelitidae					
Paramelitidae sp. 2	Biota (2006)	BHT	Weeli Wolli & Marillana Creek catchments	Wittenoom Formation	Wittenoom Formation
Syncarida Parabathynellidae					
Parabathynellidae sp.	Biota (2006)	BH	Unknown	Alluvium	Wittenoom Formation

5.2 Stygofauna Habitat Characterisation

5.2.1 Bedded Hilltop

The BHT deposit forms part of a distinct ridge landform system, occurring in association with the mineralised Dales Gorge Member of the Brockman Iron Formation. The deposit dips beneath the colluvial and alluvial detrital deposits to the north, within the Pebble Mouse Creek valley. A localised and mostly isolated aquifer (the Mineralised Brockman Aquifer) occurs within the Brockman Iron Formation where the orebody mineralisation extends below the local water table (Rio Tinto 2019) (**Figure 5-5**). The surrounding regionally extensive Wittenoom Aquifer encompasses colluvial and alluvial detritals, weathered rock and karst features (**Figure 5-5**).

The Mineralised Brockman Aquifer is predominantly separated from the Wittenoom Aquifer by the Mount McRae Shale (**Figure 5-5**). The latter primarily outcrops, surrounding the orebody and the associated aquifer. The exception is a small area of interpreted connection between the Mineralised Brockman Aquifer and Wittenoom Aquifer in the central northern portion of the deposit, where the Mount McRae Shale subcrops below the water table (Rio Tinto 2019) (**Figure 5-5, Figure 5-6**).

The BHT aquifers (Mineralised Brockman and Wittenoom Aquifers) are bounded by outcropping unmineralized Marra Mamba Formation (MacLeod and Nammuldi Members) to the north and outcropping Mount McRae Shale to the south; the relatively impermeable units forming a discontinuity of groundwater flow. A north-west to south-east trending dyke forms the eastern boundary, separating the BHT aquifers from the aquifer associated with HD1 to the east. The interpreted aquifer boundaries are expected to compartmentalise the groundwaters from surrounding aquifers, forming a mostly isolated system. In hydrogeological terms, outflow is likely to be negligible, potentially occurring through groundwater overtopping or through the low permeability dykes along the eastern boundary (Rio Tinto 2019). However, biological data suggests a degree of groundwater flow between the adjacent aquifers (Biota 2006).

The water table in the BHT deposit area occurs at approximately 594 m AHD. This corresponds to groundwater depths of between 25 to 100 m bgl, reflecting the wide variation in surface elevation. The greatest depths to groundwater are associated with the BIF ridge. Groundwaters in the northern section of BHT, along Pebble Mouse Creek, are comparatively shallow, ranging from 30 m bgl in the west to 25 m bgl in the east (Rio Tinto 2019). In contrast, along the ridge, the distance to groundwater is greater, typically around 50 to 60 m bgl and ranging up to 100 m bgl (Rio Tinto 2019).

Groundwaters associated with the BHT BIF ridge are considered unlikely to host stygofauna communities. Surveys in the broader region have predominantly recorded stygofauna from the superficial alluvium or calcrete aquifers of the Weeli Wolli drainage system, with few records from the elevated BIF ridges (Biota 2006;2008; MWH 2014; Subterranean Ecology 2008a;2012). Exceptions, where diverse stygofauna have been collected from both alluvial or calcrete aquifers of drainage systems and BIF deposit areas, generally tend to reflect shallow depths to groundwater and/or degrees of hydraulic connection between the aquifers (Outback Ecology 2009; Subterranean Ecology 2008a).

Groundwaters along Pebble Mouse Creek represent the most prospective habitat for stygofauna in the BHT area, supported by previous amphipod records (Biota 2006)(**Figure 5-3**). This reflects the presence of favourable hydrogeological units, examples of which include gravelly clay and calcrete (**Appendix C**), with alluvial/colluvial detritals and associated units spanning a considerable distance along the drainage lines (**Figure 5-3**). In addition, the water table is comparatively shallow (25 to 30 m bgl). Depth to groundwater is recognised as a likely constraint on stygofauna abundance and diversity (Halse *et al.* 2014; Strayer 1994). Extensive sampling across the Pilbara region yielded low numbers of stygofauna from groundwaters in excess of 30 m bgl (Halse *et al.* 2014). Work in eastern Australia also found an inverse relationship between groundwater depth and stygofauna diversity (Hancock and Boulton 2008).

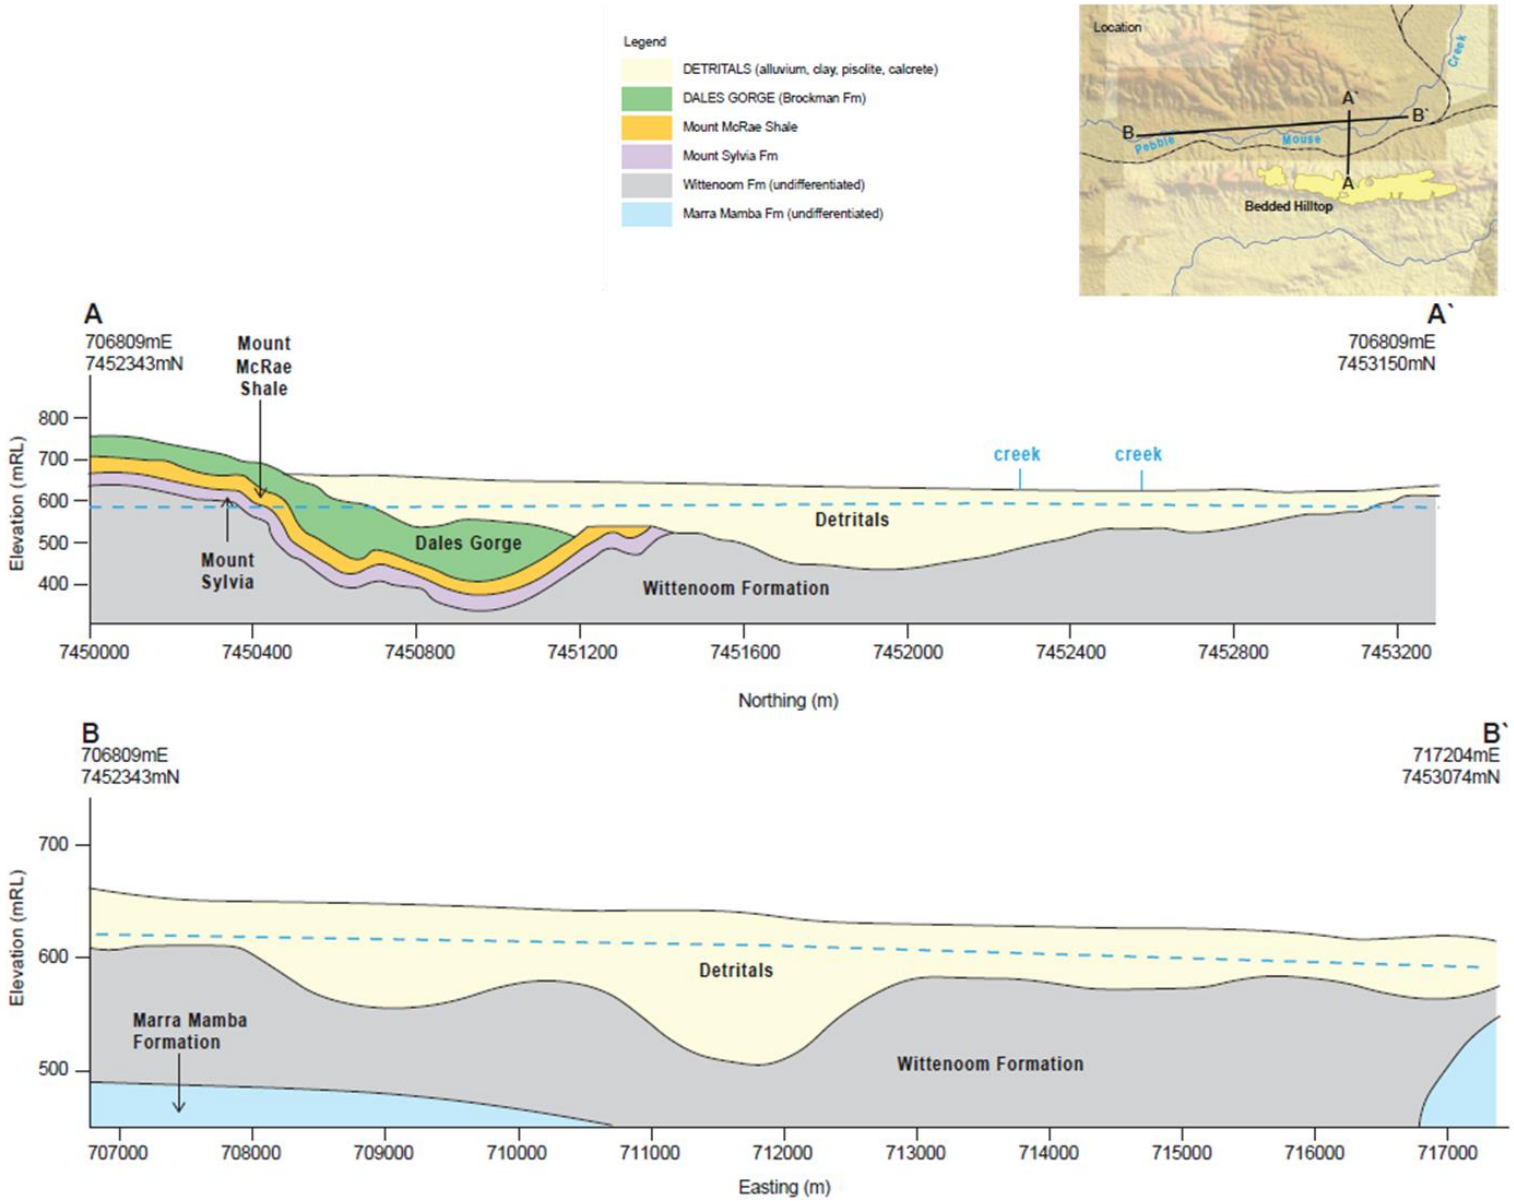

Figure 5-5: Hydrogeological cross sections of the BHT deposit (image supplied by Rio Tinto).

5.2.2 Baby Hope

The BH deposit occurs within the mineralised Marra Mamba Formation on the northern margin of the broad, shallow Pebble Mouse Creek valley (Rio Tinto 2015). The groundwaters are primarily hosted within the Wittenoom Formation (Rio Tinto 2015), extending into the overlying detritals in some sections (**Figure 5-6, Appendix E**). The natural water table at the deposit is approximately 50 m bgl, corresponding with 595 m AHD in the west to 585 m AHD in the east. However, dewatering of the adjacent HD1 deposit has lowered the groundwaters in the eastern portion by at least 5 m (Rio Tinto 2015).

A zone of low permeability silica to the west of BH forms an interpreted boundary to the Wittenoom Aquifer, indicated by a 20 m head difference. The aquifer is bounded to the east by a pair of dykes. Consistent with this, groundwater levels on the eastern side have decreased from 570 to 540 m AHD, in response to dewatering of the HD1 deposit, while depth to groundwater on the western side has remained relatively stable (Rio Tinto 2019).

The depth to groundwaters in the northern portion of the BH deposit area (≥50 m bgl) are considered sub-optimal for stygofauna. However, the alluvial/colluvial detritals to the south, towards Pebble Mouse Creek, represent more favourable habitat as groundwater is <50 m bgl. This was supported by the collection of a bathynellacean in the BH area, approximately 200 m from Pebble Mouse Creek (Biota 2006). It is likely that the groundwaters immediately adjacent to Pebble Mouse Creek are the primary habitat for stygofauna, with habitat continuity, largely alluvium, implied by mapped geology (**Figure 5-3**).

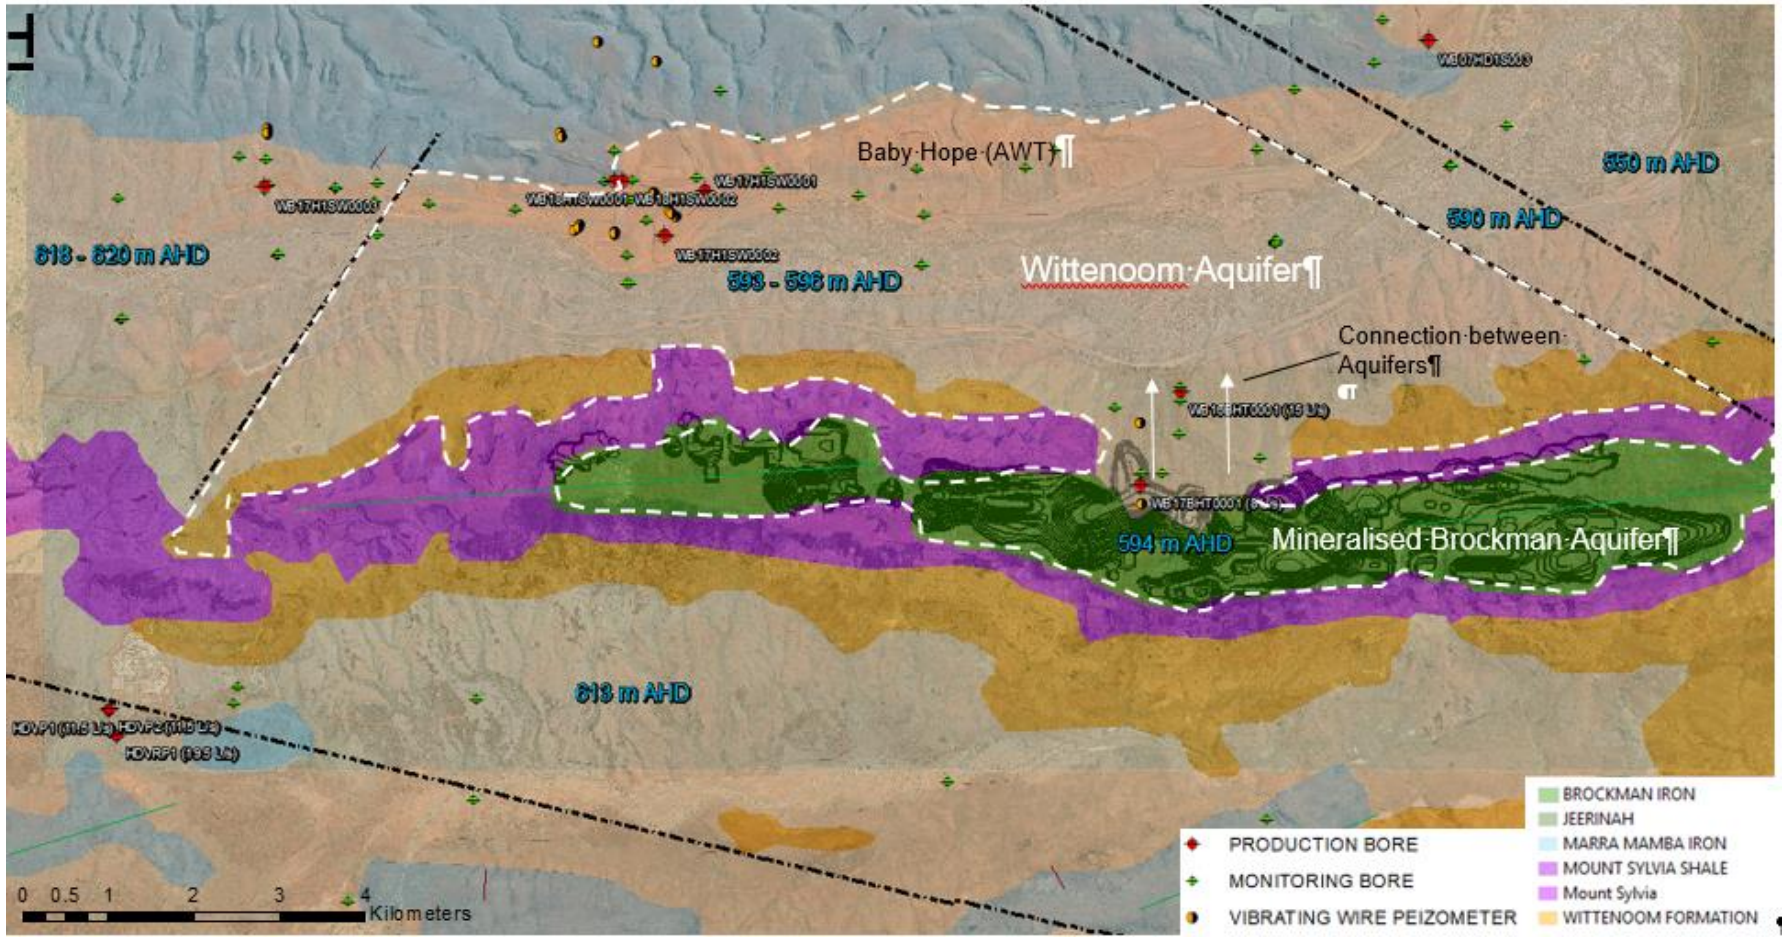

Figure 5-6: Interpreted extent of the aquifer in the BHT deposit area (supplied by Rio Tinto). Groundwater levels are shown in blue text.

5.2.3 Hope Downs 2

The HD2 deposit is located between Pebble Mouse Creek and Weeli Wolli Creeks, in an area of low hills. The deposit is associated with the Marra Mamba Formation and overlying detritals. The water table occurs within the Marra Mamba and abutting Wittenoom Formation, generally below the base of the detritals (**Figure 5-7**). Hydrogeological conceptualisation infers that groundwaters within the Marra Mamba Iron Formation are hydraulically connected to the adjacent Wittenoom Formation, largely forming a single aquifer (Wittenoom Aquifer) (Rio Tinto 2019) (**Figure 5-7**,**Figure 5-8**).

Secondary permeability within the Wittenoom Formation (Bee Gorge and Paraburdoo Members) is likely related to weathering and potential karst features. For the West Angela Member and underlying Marra Mamba Iron Formation, secondary permeability is expected to reflect mineralisation and fractures (Rio Tinto 2019).

The Wittenoom Aquifer in the HD2 area is bounded by outcropping unmineralized Marra Mamba Iron Formation to the north and south. A regionally extensive south-west to north-east trending dyke forms a boundary to the west. To the east, a folded zone of low permeability silica (north-east) and a dyke (south-east) compartmentalise groundwater flow. Groundwater discharge, albeit at a very slow rate, is likely to occur via groundwater flow through the eastern boundaries (low permeability silica and dyke) (Rio Tinto 2019).

The groundwaters of the elevated HD2 deposit area are considered unlikely to support stygofauna. The deposit is located higher in the catchment comparative to BHT and BH and is likely to have limited connection to the more prospective, shallow groundwaters further along the drainage lines. Depth to groundwater is also considered a limiting factor, with the water table at the HD2 deposit typically ranging between 60 to 80 m bgl. Depth to groundwater in the area decreases along the Pebble Mouse and Weeli Wolli Creeks (~40 m bgl), however still exceeds the values typically associated with diverse stygofauna communities (Halse *et al.* 2014). It is also unclear whether these groundwaters are hosted within the alluvial/colluvial detrital deposits or underlying weathered rock.

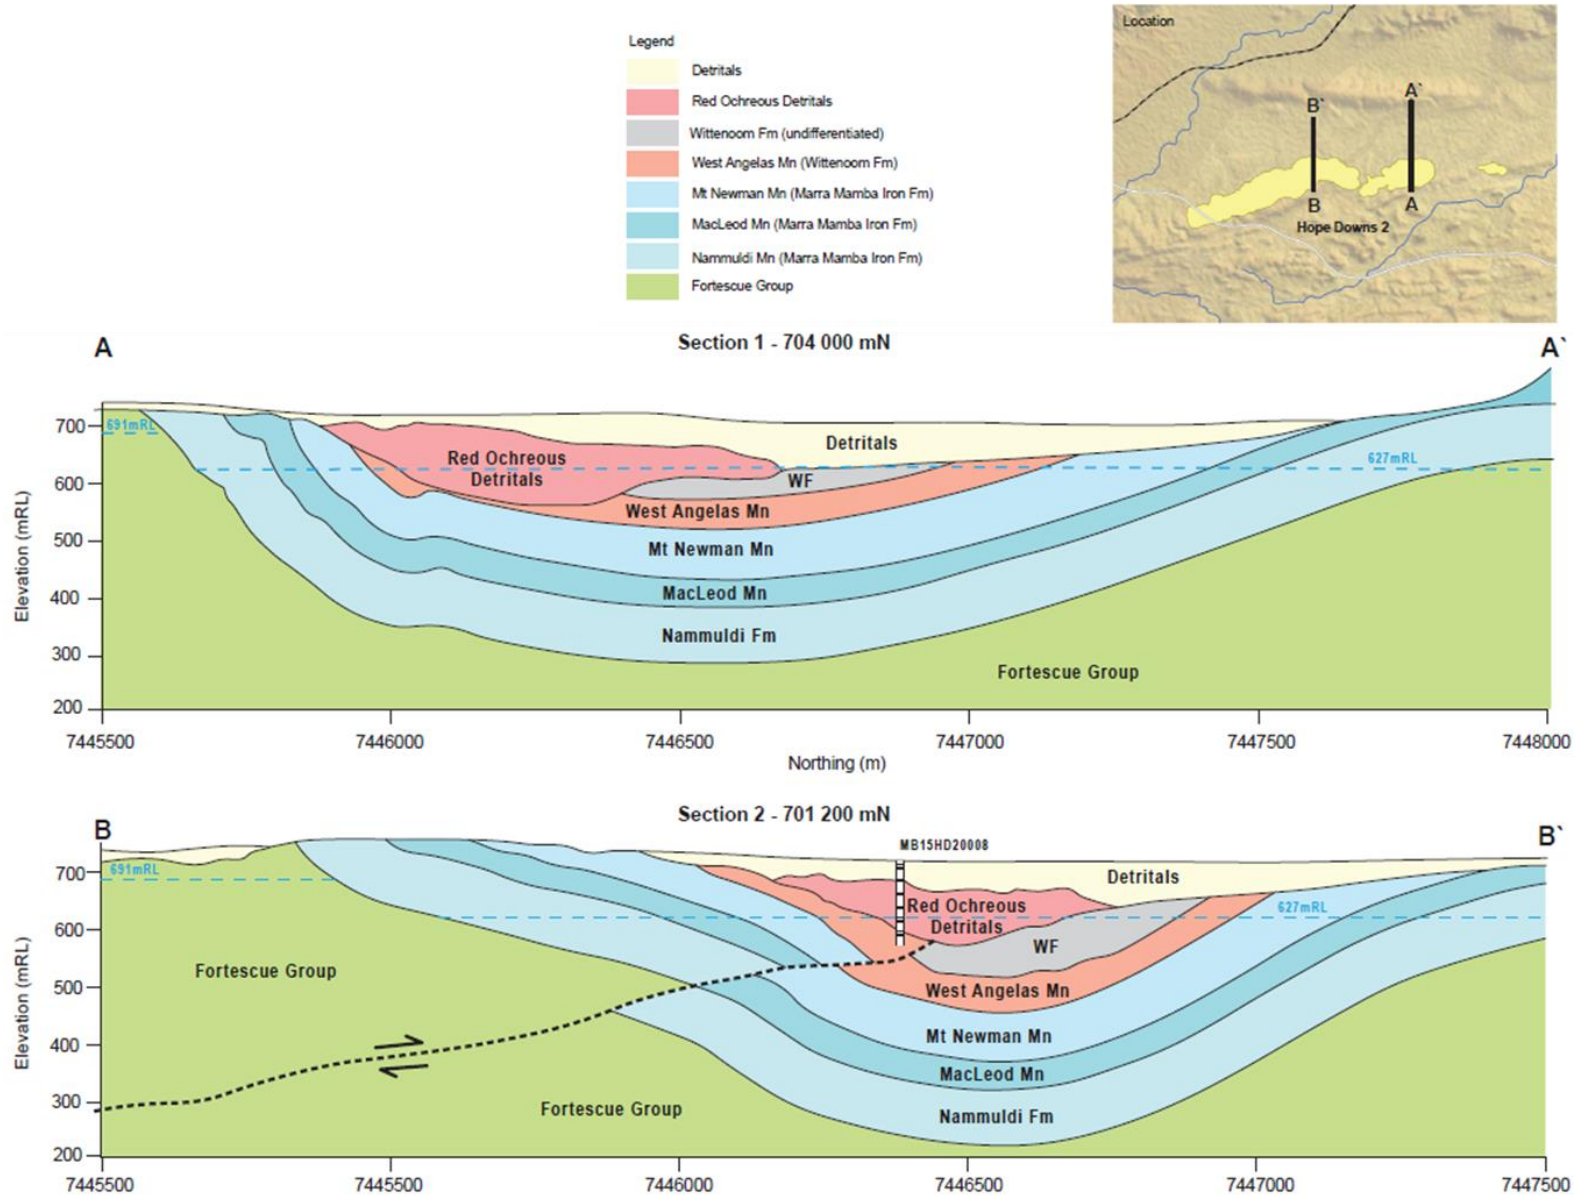

Figure 5-7: Hydrogeological cross sections of the HD2 deposit (supplied by Rio Tinto).

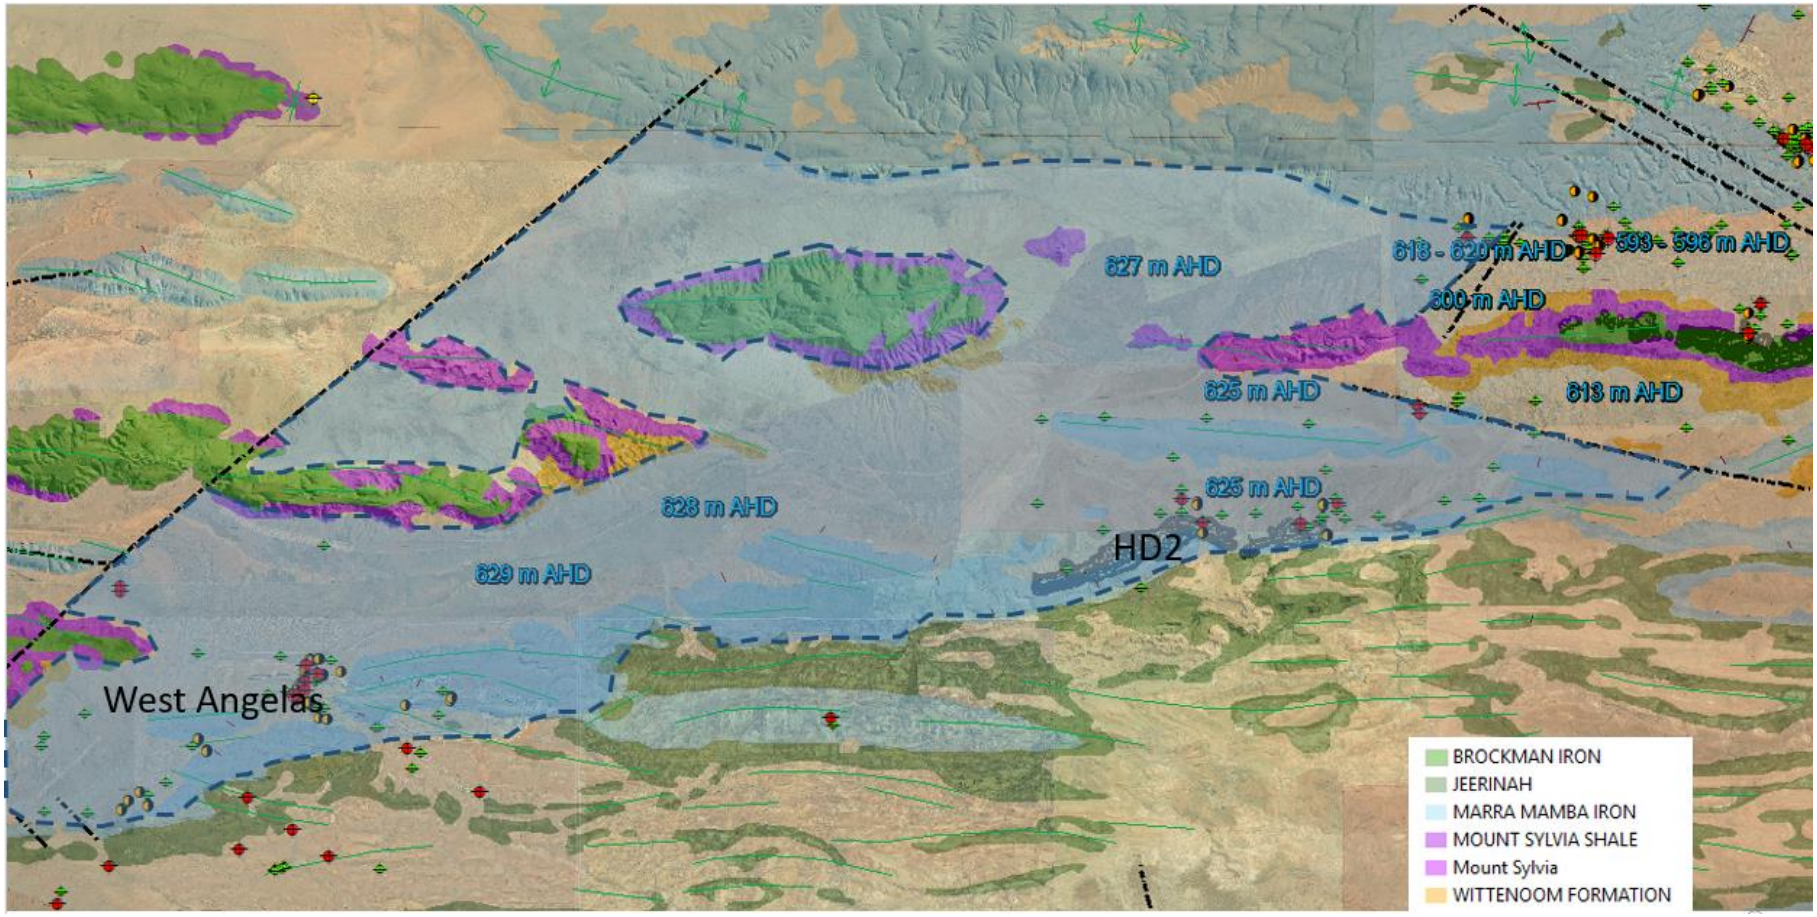

Figure 5-8: Interpreted extent of the aquifer in the HD2 deposit area (supplied by Rio Tinto).

5.3 Stygofauna Survey

5.3.1 Groundwater Properties

The standing water levels (SWL) within the deposit areas ranged from 27.0 to 108.0 m bgl, while at regional reference sites, ranged from 45.1 m bgl to 65.5 m bgl (**Figure 5-9, Appendix F)**. The shallowest depth to groundwater was recorded at site MB16HD1SW0006 (27 m bgl), within the Pebble Mouse Creek valley channel. In contrast, the greatest depth to groundwater (108 m bgl) was recorded at site RC18HD20071, in the elevated HD2 deposit area (**Figure 5-9, Appendix F**).

The mean SWL was highest at HD2 (75.4 m bgl), followed by BHT (53.4 m bgl) and BH (51.3 m bgl), in comparison to the mean SWL of 53.3 m bgl at regional reference sites (**Figure 5-9, Appendix F**). Between Phase 1 (late dry season) and Phase 2 (early wet season), there was a slight decrease in mean SWL at BH (- 4.5 m) and BHT (-2.4 m), whereas mean SWL increased between phases at HD2 (+3.3 m) and regional reference sites (+2.4 m) (**Figure 5-9, Appendix F**).

The groundwater salinity (measured as electrical conductivity; EC) across the deposit areas was classified as freshwater (Hammer 1986), ranging from 200 to 1,362 µS/cm (**Figure 5-9, Appendix F**). Mean EC was highest at BHT (993 µS/cm), followed by HD2 (894 µS/cm) and BH (657 µS/cm). Freshwater conditions were also characteristic of the regional reference sites (ranging from 214 to 1,027 µS/cm, with a mean 788 µS/cm) (**Figure 5-9, Appendix F)**. While stygofauna have been recorded from salinities in excess of 100,000 µS/cm (Outback Ecology 2011b, 2012a), significant stygofauna communities are typically associated with values below approximately 80,000 µS/cm (Environmental Protection Authority 2016a).

Groundwater pH across the deposit areas ranged from 6.4 (circumneutral) to 9.4 (alkaline), with means of between 7.0 to 7.6 across the deposits. In comparison, groundwater pH at the regional reference sites ranged from 6.5 to 7.5, with a similar mean of 7.1 (**Figure 5-9, Appendix F**). The pH values of groundwaters across the Survey area (deposit and regional reference sites) are within the range considered suitable for stygofauna. The most diverse stygal communities are often associated with calcareous environments between pH 7.2 and 8.2 (Humphreys 2008). However, while low pH can restrict stygofauna distribution, some ostracods have been documented from pH as low as 4.4 (Reeves *et al.* 2007).

Dissolved oxygen (DO) levels recorded within the deposit areas ranged from 0.8 mg/L to 6.2 mg/L. Mean DO levels were also similar across the deposit areas; 2.6 mg/L at BH, 2.4 mg/L at BHT and 2.3 mg/L at HD2. The DO at regional reference sites ranged from 0.8 mg/L to 3.0 mg/L, with a mean of 1.8 mg/L (**Figure 5-9, Appendix F**). DO concentrations are often patchy in the subterranean environment, commonly ranging from suboxic (<0.3 mg/L) to oxic (>3 mg/L) over temporal and spatial scales. Given this variability, stygofauna tend to be more resistant to low levels of oxygen than their surface water counterparts (Malard and Hervant 1999, Strayer 1994). While concentrations below 5 mg/L may adversely affect surface water biota for example, stygofauna are known to occur in sub-oxic conditions well below 1 mg/L (Chapman and Kimstach 1996, Humphreys 2008).

The groundwater properties represented by the basic suite of physicochemical parameters measured during the Phase 1 and Phase 2 field surveys, indicate conditions are suitable to support stygofauna across the Survey area. Based on these results, groundwater quality was considered unlikely to represent a barrier to stygofauna.

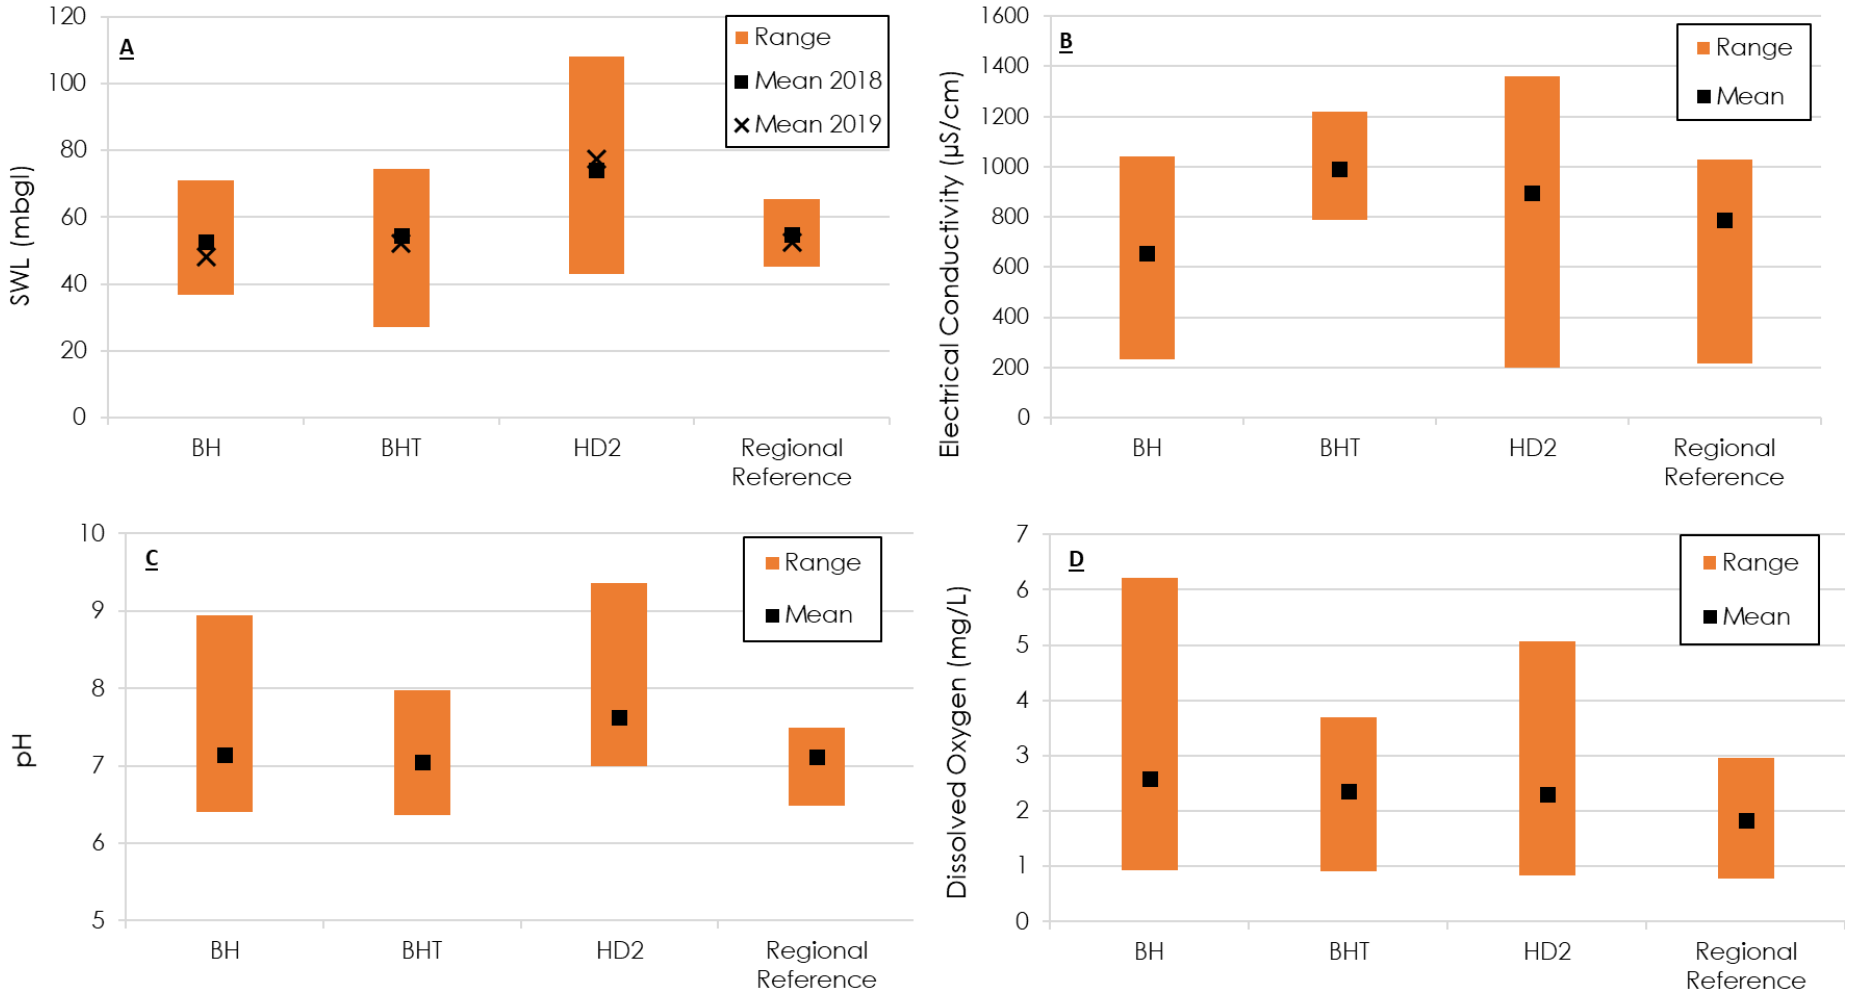

Figure 5-9: Groundwater properties (A) SWL, (B) EC, (C) pH, and (D) DO, indicating ranges and means across the Survey area.

5.3.2 Stygofauna Findings

A total of four stygal amphipod specimens were collected during the two field phases of the Survey. This comprised one specimen in Phase 1 (2018) and three specimens in Phase 2 (2019) (

Table 5-2**, Plate 5-1**). All four specimens were collected from site MB16HD1SW0006 within the BHT deposit area. This site is located immediately north of the BHT landform, along the alluvial/colluvial channel associated with Pebble Mouse Creek, underlain by Wittenoom Formation (**Figure 5-10, Figure 5-11, Figure 5-12**). The bore log also indicates the presence of calcrete in the superficial strata at this site (**Appendix D**).

The specimen collected from MB16HD1SW0006 in Phase 1 was a juvenile that would not reliably key to a described genus or family. Specimens from Phase 2 were identified as the *Pilbarus* OES12 (nr *millsi*) (Paramelitidae) based on morphological characteristics. DNA sequencing of two specimens (the Phase 1 juvenile and a tissue sample from a mature Phase 2 specimen), indicated there was negligible divergence between their lineages (<0.1% CO1), with all specimens considered to belong to *Pilbarus* OES12 (nr *millsi*) (Biologic code Biologic-AMPH001), herein referred to as *Pilbarus* 'sp. Biologic-AMPH001' (**Appendix G**).

Sequences of the specimens did not closely align with any Amphipoda sequences from available regional databases, including between 27-29% divergence CO1 divergence from Paramelitidae sequences from Weeli Wolli and Marillana Creeks (Biologic 2019). Therefore, based on available results to date, *Pilbarus* 'sp. Biologic-AMPH001' may represent a new operational taxonomic unit (OTU) or taxon, known only from the Survey area (Biologic 2019).

No stygofauna were collected from the BIF-hosted groundwaters sampled from the BH, BHT and HD2 deposit areas during the Survey. Similarly, the samples collected from the regional reference sites of the Weeli Wolli calcrete system and Weeli Wolli Creek riparian zone did not yield stygofauna (**Figure 5-10**,**Figure 5-11**,**Figure 5-12**, **Appendix A**).

Table 5-2: Summary of stygofauna results

Taxon	Identification Method	Collection Site	Abundance			Deposit Area	Sample Depth (m bgl)	Mapped Geology
			Phase 1	Phase 2	Total			
Amphipoda Paramelitidae

6. Discussion

The results of this Survey indicated that stygofauna diversity and abundance within the Survey area are likely to be low. The only taxon collected, the paramelitid amphipod *Pilbarus* 'sp. Biologic-AMPH001', occurred at one site within the BHT deposit area. This site was to the north of the BHT landform, in strata that intersected alluvium, pisolite, gravelly clay and calcrete, with groundwaters of suitable quality. These findings align with previous sampling in the Survey area and surrounds (Biota 2006, Biota 2015), which identified alluvial/colluvial detritals and calcrete along the Pebble Mouse and Weeli Wolli Creeks as the core habitat for stygofauna. This includes the previous collection of a bathynellid (Parabathynellidae sp.) from the Pebble Mouse Creek alluvials within the BH deposit.

Additionally, Biota (2006) collected the amphipod Paramelidiate sp. 2 from Wittenoom Formation, immediately adjacent Pebble Mouse Creek alluvials within the BHT depost area. The regionally extensive Wittenoom Aquifer encompasses colluvial and alluvial detritals, weathered rock and karst features, and is predominantly separated from the Mineralised Brockman Aquifer by the Mount McRae Shale.

Contrastingly, the BIF geology across the BH, BHT and HD2 deposits did not yield any stygofauna. This was also consistent with previous surveys in the broader region, indicating limited prospectivity within the BIF (Biota 2008, ecologia Environmental 2013, MWH 2016a, Subterranean Ecology 2008a). HD2, in particular, is located higher in the catchment, with greater depth to groundwaters. Additionally, hydrogeological conceptualisation suggests that the aquifers associated with the BHT and BH deposits are compartmentalised from the adjacent HD1 aquifer, and are expected to have limited connectivity with the more prospective, shallow groundwaters of the drainage lines, likely providing limited dispersal pathaways and creating sub-optimal conditions for stygofauna.

The limited distribution of *Pilbarus* 'sp. Biologic-AMPH001' during this Survey was likely an artefact of the low number of accessible sites available for sampling proximal to Pebble Mouse Creek. In this instance, biological and physical surrogates can assist in determining likely taxon distribution (Environmental Protection Authority 2016b). The former focuses on the distribution of similar taxa, while investigating the extent of geological habitat can act as a physical surrogate.

Based on mapped geology, the alluvial/colluvial detrital and calcrete habitat supporting *Pilbarus* 'sp. Biologic-AMPH001' extends along the Pebble Mouse and Weeli Wolli drainage lines. Similarly, the distribution of the amphipod Paramelitidae sp. 2, recorded during the Hope Downs surveys (Biota 2006) was also found to predominantly occur along the drainage lines over a distance of approximately 40 km. It is presumed that larger stygal crustaceans such as Paramelitidae sp. 2, which are known to utilise surface and hyporheic waters as well as groundwaters, are distributed within catchments during flood events (Biota 2015).

Genetic analysis indicated that *Pilbarus* 'sp. Biologic-AMPH001' may represent a new operational taxonomic unit (OTU) or taxon, known only from the Survey area. Sequences from the analysed specimens did not closely align with any known Amphipoda sequences from available databases, including Paramelitidae from Yandi and Weeli Wolli (Biologic 2019). However, this may also reflect limited sampling and available genetic sequences for comparison. The continuity of prospective habitat, supported by the geology, and the extent of a similar taxon, Paramelitidae sp. 2, suggest that *Pilbarus* 'sp. Biologic-AMPH001' may have a broader distribution along the drainage lines.

There were no stygofauna recorded at the regional reference sites within the Weeli Wolli calcrete or Weeli Wolli Creek riparian zone during the Survey, despite a number of records from within the vicinity over time (Biota 2006, Biota 2015). However, approximately half of the BHT deposit lies within the 5 km buffer of the Weeli Wolli Spring Community South PEC. This area is known to support a high diversity of stygofauna, attributed to the large-scale calcrete and alluvial aquifer system associated with the Weeli Wolli spring.

7. Conclusion

The Survey indicated that the BHT deposit area hosted one stygofauna taxon, a potentially new paramelitid amphipod *Pilbarus* 'sp. Biologic-AMPH001'. This species occurred in groundwaters of suitable quality, associated with prospective habitat comprising alluvial/colluvial detritals and calcrete, along Pebble Mouse Creek. These results were consistent with previous surveys of the area, whereby a bathynellacean was also recorded within alluvial/colluvial detritals of the Pebble Mouse Creek drainage, and an amphipod (Paramelitidae sp. 2) was recorded from the Wittenoom Aqifer immediately adjacent Pebble Mouse Creek. While apparently restricted to within the Survey area based on genetic sequencing, it is likely that *Pilbarus* 'sp. Biologic-AMPH001'is distributed more broadly in suitable habitat along the drainage lines. BIF geology within the BHT, BH and HD2 deposits are not considered prospective for stygofauna. Sample effort for the

Survey area was sufficient to meet regulatory guidance, with the BHT deposit area characterised by higher stygofauna values in comparison to the remaining areas, particularly where it intersects the surficial alluvial/colluvials of the Pebble Mouse Creek drainage, as well as the 5 km buffer of the Weeli Wolli Spring Community South PEC.

Appendix C Geological Codes for Mapped Geological Units.

Table C-1: Descriptions of bedrock geology codes relevant to the Survey area.

Code	Unit Name	Description
A-FAU-BBO	Bunjinah Formation	Pillowed and massive basaltic flows; basaltic breccia and basaltic volcanic sandstone; minor chert; amygdaloidal basalt flows occur in upper parts of formation; metamorphosed.
A-FO-OD	Fortescue Group	Dolerite dyke or sill.
A-HAD-KD	Wittenoom Formation	Thinly bedded dolomite and dolomitic shale, with minor black chert, shale, banded iron formation and sandstone.
A-HAM-CIB	Marra Mamba Iron Formation	Chert, banded iron-formation, mudstone, and siltstone; minor carbonate; metamorphosed.
A-HAU-XSL-CI	Mount McRae Shale and Mount Sylvia Formation	Mudstone, siltstone, chert, banded iron-formation, and dolomite; metamorphosed.
A-FOJ-XS-B	Jeerinah Formation	Siliciclastic sedimentary rocks, mafic volcanic rocks and minor felsic volcanic rocks; local carbonate rocks, chert, and dolerite sills.
A-FO-OD	Fortescue Group	Dolerite dyke or sill.
P_-HAB-CIB	Brockman Iron Formation	Banded iron-formation, chert, mudstone, and siltstone; metamorphosed.
P_-HAO-CI	Boolgeeda Iron Formation	Fine-grained, finely laminated iron-formation, mudstone, siltstone, and chert; metamorphosed.
P_-HAJ-XCI-OD	Weeli Wolli Formation	Banded iron-formation (commonly jaspilitic), mudstone, siltstone, and numerous dolerite sills; metamorphosed.
P_-HAW-FR	Woongarra Rhyolite	Rhyolite, rhyodacite, rhyolitic breccia, and banded iron-formation; metamorphosed.
P_-TK-S	Turee Creek Group	Mudstone, siltstone, sandstone, conglomerate, dolomite; minor diamictite, limestone and iron formation; intruded by Balgara Dolerite sills.

Table C-2: Descriptions of surface geology codes relevant to the Survey area.

Code	Unit Name	Description
Ad	Fortescue Group - mafic intrusions	Metadolerite, dolerite, gabbro; medium to coarse grained, massive grey-green rock, usually foliated.
Al	Wittenoom Formation	Calcitic dolomite, interbedded chert and shale in upper and lower parts, volcaniclastic sandstone
As	Mount McRae Shale and Mount Sylvia Formation	Interbedded shale, chert, banded iron-formation.
Ac	Marra Mamba Iron Formation	Chert, ferruginous chert, jaspilite, banded iron-formation, minor shale, siltstone, mudstone.
Ab	Bunjinah Formation	Pillowed and massive basaltic flows; basaltic breccia; and basaltic volcanic sandstone; minor chert; amygdaloidal basalt flows occur in upper parts of formation; metamorphosed.
Aw	Jeerinah Formation	Shale, sandstone, siltstone, mudstone, dolomite, local microbanded chert, jaspilite, conglomerate; fine-grained massive rhyolite; mafic tuff with local accretionary lapilli and agglomerate; thin basalt/dolerite and andesitic basalt flows.
Czk	Calcrete	Pisolitic, nodular or massive calcrete; ferruginous inclusions; calcareous cementing of bedrock and transported materials; locally with intercalated chalcedony; as low mounds, in playa lakes, or as valley calcrete; locally dissected and karstified.
Czl	Ferruginous duricrust 38498	Ferruginous duricrust, laterite; pisolitic, nodular, vuggy; may include massive to pisolitic ferruginous subsoil, mottled clays, magnesite, reworked products of ferruginous and siliceous duricrusts, calcrete, gossan; residual ferruginous saprolite
Czz	Silcrete 42026	Silcrete, silicified gravel, siliceous duricrust, siliceous breccia; opaline silica, jasperoidal chalcedony, local chrysoprase caprock over ultramafic rock
Czs	Sand plain 38499	Sand or gravel plains; may include some residual alluvium; quartz sand sheets commonly with ferruginous pisoliths or pebbles; local clay, calcrete, laterite, silcrete, silt, colluvium
Czi	Millstream Formation	Dolomite, calcareous dolomite, calcrete; with silcrete, clay, chert breccia, and local basal conglomerate.
Lc	Brockman Iron Formation	Banded iron-formation, chert, mudstone and siltstone.

Code	Unit Name	Description
Lf	Woongarra Rhyolite	Rhyolite, rhyodacite, rhyolitic volcaniclastic breccia and banded iron formation.
-Pd	Mafic, ultramafic, intermediate intrusions 74431	Dolerite, gabbro, norite, pyroxenite, peridotite, diorite, tonalite; locally metamorphosed; rare biotite rock, amphibolite
Qa	Alluvium	Channel and flood plain alluvium; gravel, sand, silt, clay, locally calcreted.
Qrc	Colluvium	Colluvium, sheetwash, talus; gravel piedmonts and aprons over and around bedrock; clay-silt-sand with sheet and nodular kankar; alluvial and aeolian sand-silt-gravel in depressions and broad valleys in Canning Basin; local calcrete, reworked laterite.
Qt	Lake deposits 38492	Lake and swamp deposits; mud, silt, evaporites, limestone; minor sand, peat

Appendix D Bore Log from Bedded Hilltop.

MB16HD1SW0006

HOLE DETAILS
PROJECT: Hope Downs 1
LOCATION: Hope Downs

EASTING: 715630.437
NORTHING: 7452497.757
ELEVATION: 620.737 mAHD

Shallow 40m monitoring bore in a cluster of 5 monitoring bores, designed to enable discrete sampling of groundwater from specific depths for age profiling, and also to sample gas from discrete locations at 5 depths, all above the current SWL.

Depth (mbgl)	Geology	Lithology	Lithological Description	Gamma Log	Field Notes	Well Design	Well Construction
0	Detritals		SILTY GRAVEL (ALLUVIUM): Red/brown to blue/grey, poorly sorted, fine to massive "pebble sized". Angular to well rounded gravel of predominantly BIF/Ironstone and Chert, with well rounded pisoliths (to 20%) and fine silt.	0 150	Cement/Bent Grout Gas inlet: 5m Cement/Bent Grout Gas inlet: 10m Cement/Bent Grout Gas inlet: 15m Cement/Bent Grout Gas inlet: 20m Cem/Bent Grout Bentonite Seal Gas inlet: 25m SWL 28.13m bToC on 11/11/2016 Cement/Bent Grout Penetration Rates: 10-42m : 15mins/rod Drilled to 42m to allow for fallback.		0-2m - 200mm uPVC collar Fine sand over Gravel pack 1.6-3.2mm Fine sand over Gravel pack 1.6-3.2mm Fine sand over Gravel pack 1.6-3.2mm Fine sand over Gravel pack 1.6-3.2mm Fine sand over Gravel pack 1.6-3.2mm -1 - 38m: 50mm CL 18 PVC blank casing Fine sand over Gravel pack 1.6-3.2mm 38-40m : 50mm CL18 PVC slotted casing
5							
10			CLAY(Pisolite): Dark red-brown, soft to medium plasticity clay with minor fine pisolitic gravel. Very soft/sticky 16-20m.				
15							
20			PISOLITIC CLAYEY GRAVEL: Dark brown to red-brown, f/med grained, rounded pisolitic gravel with minor ironstone in med plasticity clay.				
25			GRAVELLY LIMONITIC CLAY: Yellow/mustard to khaki and brown, soft low plasticity clay with fine, matrix supported gravelly sediment (goeth/shale). Minor Quartz.				
30			CALCRETE/CALCAREOUS CLAY: Off-white to yellow/khaki, fine to med sub-angular to sub-rounded chips of calcrete, majority clast-supported in calcareous clay (med to firm, to 30mm diameter)				
35			LIMONITIC CLAY: Yellow/mustard soft/sticky grading to high plasticity (34-36m). Pred clay, with minor gravelly fragments.				
40			CLAYEY GOETHITIC GRAVEL: Grey/brown to khaki, fine-med, angular to sub-rounded, platy fragments of goethitic gravel (semi-consolidated) in soft to med clay. Highr plasticity and % clay 40-42m.

Appendix G Molecular Analyses (Biologic 2019).

Hope Downs 1
Subterranean Fauna
Molecular Systematics Analysis

Biologic Environmental Survey

Report to Stantec Pty Ltd

November 2019

1 INTRODUCTION

Stantec Pty Ltd (Stantec) commissioned Biologic Environmental Survey (Biologic) to undertake a molecular systematics analysis (DNA barcoding) of 44 subterranean fauna (stygofauna and troglofauna) specimens collected from Rio Tinto's Hope Downs 1 (HDOW1) Project (the Study Area).

1.1 Aims and objectives

The aims and objectives of the molecular systematics analysis were to:

- Undertake DNA sequencing of 44 subterranean fauna specimens to obtain barcoding sequences of the mitochondrial gene Cytochrome Oxidase I (COI; Hebert *et al.* 2003), and the nuclear gene 12S for Zygentoma specimens;
- Investigate the interspecific and intraspecific relationships between sequences of each higher taxonomic group (i.e. use the results of the DNA analysis to indicate how many different species/ OTUs are likely to occur within each genus or relevant higher taxon, based on published species-thresholds); and
- Investigate the relationships between sequences from the HDOW1 specimens and relevant previous sequences from the wider Pilbara region, using available DNA databases (i.e. compare the results of the current analysis with accessible DNA databases to assess whether any of the species/ OTUs from the Study Area have been collected previously or more widely beyond the Study Area).

This document reports the methods and results of the molecular systematics analysis. Any remaining specimen material has been returned to Stantec, and sequence data has been incorporated within the Rio Tinto (RTIO) molecular sequence database and uploaded to GenBank as per Rio Tinto requirements.

2 METHODS

2.1 Sub-sample preparation

A total of 44 subterranean fauna specimens collected from the HDOW1 Study Area by Stantec, were sent to Biologic for molecular systematics analysis. The specimens belonged to seven different classes comprising 11 orders, nine families, and eight genera, based on morphological identifications conducted by Stantec.

Where whole specimens were submitted, Biologic undertook tissue preparation by removing a leg, briefly drying off the ethanol, and placing the tissue in ATL buffer. Where tissue was submitted, these were briefly dried and placed in ATL buffer at Biologic's laboratories. In all instances, greatest care was taken to decontaminate all tools and equipment between samples, using bleach and repeated rinsing in deionised water. Table 2.1 provides morphological identification details for each specimen included in the analysis.

Table 2.1: Specimens and tissue samples included in the analysis (ordered by taxon and lot number).

2.2 DNA extraction, amplification and sequencing

DNA extraction and sequencing methods followed Cullen and Harvey (2017, 2018), as follows:

Subsampled tissue was placed directly into ATL buffer for extraction using the *QIAGEN DN-easy* extraction kit. 20µl of proteinase K was added and incubated overnight at 56°C, immediately prior to extraction. DNA samples were amplified by Polymerase Chain Reaction (PCR) using Folmer PCR primers (LCO1490, HCO2198; Folmer *et al.* 1994) to assess the variability of COI for taxa other than Zygentoma. Zygentoma samples were amplified using 12S primers (12Sai, 12Sbi; Simon *et al.* 1994).

Resulting PCR product was sequenced by the Australian Genomic Research Facility (AGRF) Perth node. Specimen records, extraction data, PCR results, and DNA sequence data were managed using GENEIOUS v 10.1.2 (Kearse *et al.* 2012) with the Biocode plugin (http://www.mooreabiocode.org).

2.3 Analysis of sequence alignments/ divergence

Raw sequence data were edited and assembled in GENEIOUS. Consensus sequences were BLASTed against GenBank to determine nearest matches within the target higher taxonomic group. The consensus sequences were then aligned using MAFFT (Multiple Alignment using Fast Fourier Transform) algorithm (Katoh *et al.* 2002). Trees were constructed on resulting alignments using the Geneious Tree Builder using Tamura-nei Genetic Distance Model and Neighbour-joining as the Tree Build Method. Sequence data obtained using the 12S primers were edited, aligned and resulting consensus sequences BLASTed against GenBank. Regional sequences were obtained from RTIO's molecular sequence database as well as genetic data from accessible previous reports (Helix Molecular Solutions) and were included in the tree building analyses.

Lineages determined in this study were defined using molecular data with reference to morphological identifications undertaken by Stantec. These designations were specific to each higher taxon and the level of taxonomic certainty involved. Fauna-specific thresholds for determining species-level divergence were used wherever possible, based on published literature and available previous reports.

Where fauna-specific thresholds from literature or reports were not available, the assessment used average divergence thresholds for related groups or higher taxa developed by broad-level studies (e.g. Hebert *et al.* 2003).

Based on the number of specimens within each taxonomic level, DNA comparisons were typically conducted at the order level as follows:

- Amphipoda (2 specimens, plus regional comparisons);
- Blattodea (20 specimens, plus regional comparisons);
- Chilopoda (1 specimen, plus regional comparisons);
- Diplura (1 specimen, plus regional comparisons);
- Hemiptera (6 specimens, plus regional comparisons);
- Palpigradi (2 specimens, plus regional comparisons);
- Pauropoda (1 specimen, plus regional comparisons);
- Polyxenida (1 specimen, plus regional comparisons);
- Pseudoscorpiones (1 specimen, plus regional comparisons);
- Schizomida (8 specimens, plus regional comparisons); and
- Zygentoma (1 specimen, plus regional comparisons).

2.4 Constraints and Limitations

The analysis was constrained by the breadth of data available to undertake comparisons, the accessibility of pre-existing regional sequences, and the success rate of genetic sequencing, which can be affected by specimen collection, preservation, and storage methods, as well as contamination. Our understanding is that best practises were followed during specimen collection, preservation, and storage, prior to specimens arriving at Biologic. All care was taken to ensure that the risks of laboratory contamination, data handling issues, and specimen management issues were minimised within Biologic's laboratories throughout the subsampling, processing and genetic analysis. This was largely reflected in the results, with a low rate of sequence failure (5/44 sequences, or 11%) and no contaminated samples detected.

The databases used for regional comparisons were limited to Genbank, the RTIO molecular sequence database, and available data from previous genetic reports conducted for RTIO (by Helix Molecular Solutions). While these sequence databases, in combination, comprise a large portion of the subterranean fauna genetic work that has been undertaken for RTIO in the Pilbara region, it is acknowledged that there may be many other relevant sequences from third party project areas nearby or elsewhere in the region that were not available for comparison at the time of the study.

DNA barcoding using the mitochondrial gene COI, while useful for explaining genetic differences between closely-related or moderately-related species, is limited in its ability to resolve deeper phylogenies/ relationships between taxa at higher taxonomic levels (e.g. genus, family, order). In the current study, phylogenetic relationships between species/ OTUs at >25% COI divergence are treated with caution. If further resolution of deeper phylogeny is important for project goals, this could be investigated using a multiple gene approach.

3 RESULTS AND DISCUSSION

3.1 Amphipoda

Two specimens of Amphipoda (LN35584 and LN35145) were successfully sequenced from Baby Hope, from bores MB16SW0006 and MB16HD1SW0006 respectively. The two sequences showed a negligible level of divergence within their lineage (`Biologic-AMPH001`), indicating a single OTU (<0.1% COI). Stantec's morphological identifications of one of these specimens revealed a paramelitid amphipod, *Pilbarus* OES12 (nr *millsi*). The genetic results indicate that both specimens can be considered to belong to this taxon. Figure 3.1 shows a neighbour joining tree based on a comparison of 38 Amphipoda sequences from the available regional databases while Appendix 1 shows pairwise comparisons of sequences from the Study Area vs the sequence databases.

The sequences from the Study Area were not closely aligned (26%-45% COI) with any of the sequences included in these comparisons, suggesting that *Pilbarus* OES12 (nr millsi) has not been sequenced from elsewhere in the region (Figure 3.1, Appendix 1). There was a relatively high level of divergence (27%-29% COI) from previous specimens in the same taxonomic group, including *Pilbarus* and *Yilgarus* sequences from Paraburdoo/ Turee Creek, and Paramelitidae sequences from Yandi and Weeli Wolli. However, the average divergence compared to other Amphipoda taxa was the same or even higher; 29%-35% divergence from Bogidiellidae at Paraburdoo and Robe Valley, 39%-40% from *Nedsia* and Eriopsidae from Paraburdoo and Robe Valley, and 45% from Niphargidae at Tods Bore (Appendix 1).

Further genetic and morphological work may be required to validate the phylogenetic relationships of the current sequences with *Pilbarus* OES12 (nr millsi). Nevertheless, based on current results, Lineage `Biologic-AMPH001`/ *Pilbarus* OES12 (nr millsi) appears to represent a new/ unique OTU currently known only from the Study Area.

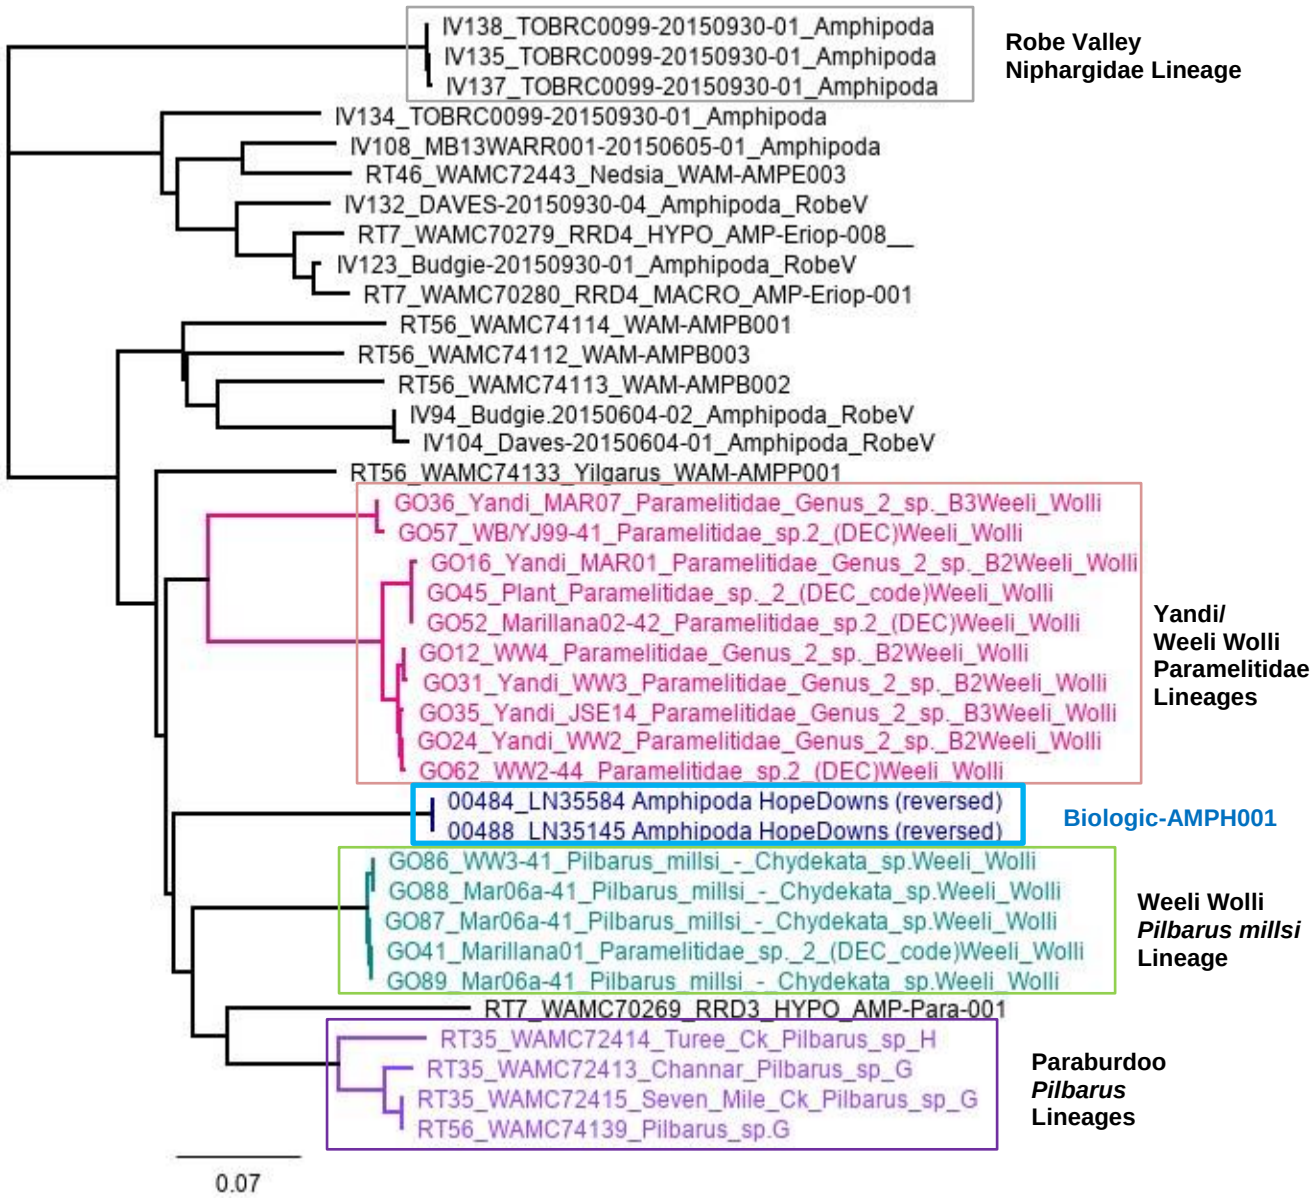

Figure 3.1. Neighbour Joining tree of Amphipoda haplotypes included in the analysis. Lineages from the Study Area are indicated by blue text.

3.2 Blattodea

All 20 specimens of Blattodea from Bedded Hill Top and Hope Downs 2 were successfully sequenced. Local comparisons revealed four lineages (intraspecific variability <3% COI), representing three to four potential OTUs (Table 3.1, Figure 3.2):

- *Nocticola* `Biologic-BLAT001` (LN34133, Hope Downs 2);
- *Nocticola* `Biologic-BLAT002` (LN33372, LN33532, LN34509, LN36536, and LN37718, Bedded Hill Top);
- *Nocticola* `Biologic-BLAT003` (LN33514, LN33574, LN35535, LN36514, LN36582, LN37412, and LN39408, Hope Downs 2 and Bedded Hill Top); and
- *Nocticola* `Biologic-BLAT004` (LN33391, LN35427, LN37424, LN37717, LN38726, LN34142, and LN38585, Bedded Hill Top).

Three of the four lineages (Biologic-BLAT002, BLAT003, and BLAT004) were well supported at COI divergences >8% (Appendix 2), indicating distinct species/ OTUs (based on average divergence thresholds Hebert *et al.* 2003). Lineage BLAT001 was only 7% different to BLAT002, indicating a borderline population/ species-level divergence, which may reflect geographical separation between Biologic-BLAT001 occurring in HD2 and BLAT002 in BHT. Nevertheless, based on a recent molecular study by Trotter *et al.* 2017 showing 3%-4% divergences between *Nocticola* species/ OTUs, 7% could be considered to indicate species-level divergence in *Nocticola*.

Table 3.1. Genetic results of *Nocticola* specimens from the Study Area (lineages represented by highlighted colours).

BHT	RC16BHT0291	*Nocticola* OES13	tissue	LN38585	BMR00485	004

The genetic results did not match the morphological identifications, which determined only two OTUs (*N*. OES12 and *N*. OES13). While the morphological identifications within Lineages BLAT001, BLAT002, and BLAT003 were consistent (within each respective lineage), the high COI divergence (36%-39%) between Lineages BLAT002 and BLAT003 (both morphologically identified as *N*. OES13) suggested cryptic morphology or further taxonomic work may be required (Appendix 2).

In addition, BLAT004 contained specimens morphologically identified as both *N*. OES12 and *N*. OES13 (Table 3.1), despite intraspecific variability <1.1% (COI). Lineage BLAT003 showed slight intraspecific variability (2%-3% COI), although this was not consistent between specimens from the two different sampling areas; therefore, it is uncertain whether there could be separated populations within this lineage (Appendix 2).

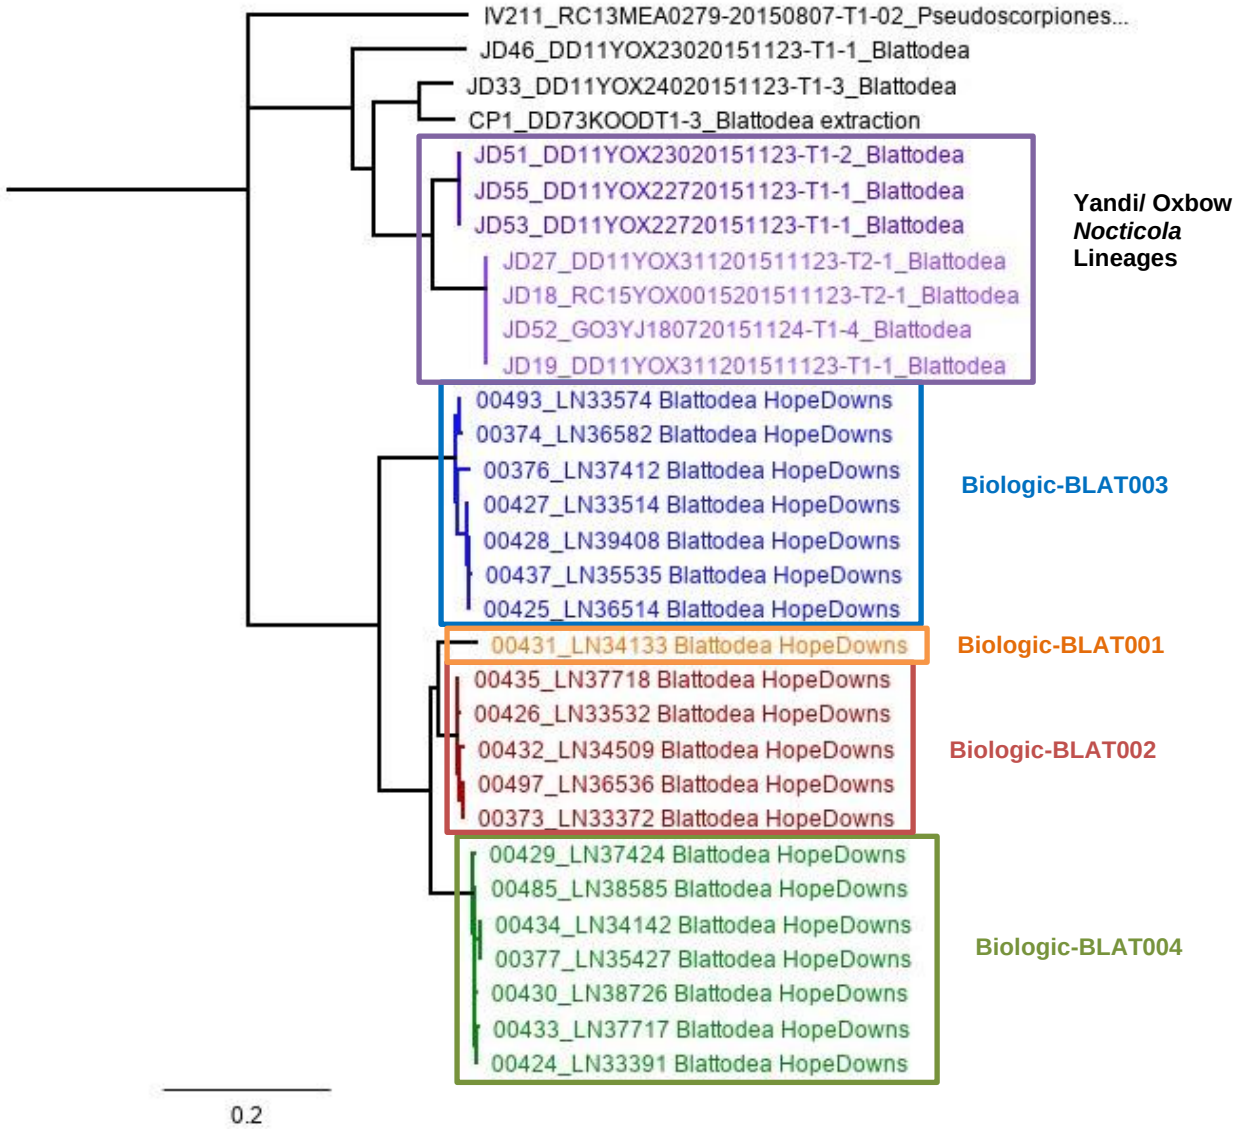

Figure 3.2. Neighbour Joining tree of Blattodea haplotypes (COI) included in the analysis. Lineages are indicated by coloured text.

In terms of sampling areas, Biologic-BLAT001, BLAT002, and BLAT004 were consistently collected from a single sampling area per lineage, while BLAT003 was collected in both Bedded Hill Top and Hope Downs 2. This suggests the potential for complicated evolutionary patterns such as allopatric and sympatric speciation, or multiple colonisations of subterranean habitats amongst the different OTUs of *Nocticola* from the Study Area.

Regional comparisons (Figure 3.2, Appendix 2) revealed that all sequences from the Study Area showed a high level of divergence (minimum 43% COI) from previous material based on a comparison of 11 regional sequences from the available databases. At this level of divergence all four lineages/ OTUs from the Study Area would be considered regionally unique (based on available sequences although further genetic (and potentially further morphological work) may be required to verify the deeper phylogenetic relationships.

3.3 Chilopoda

One specimen of Chilopoda (Scolopendromorpha sp.) (LN37426) was successfully sequenced at the COI gene (Biologic-CHIL001).

Regional comparisons (Figure 3.3) with previous sequences revealed a high COI divergence (min 21%) indicating that the lineage from the Study Area is not represented in the available sequence databases. This result was based on a comparison of 16 available subterranean Chilopoda sequences from the Pilbara region, and used the epigean species *Scolopendra mortisans* as an outgroup (Appendix 3).

Divergences were generally high between most lineages/ OTUs within the Chilopoda, excluding sequences likely representative of intraspecific variability (i.e. COI divergences below 3%) (Appendix 3). In this broader context the high divergences between Biologic-CHIL001 from the Study Area and other regional sequences was not considered out of trend with the rest of the group.

Based on comparisons with available databases, the Scolopendromorpha sp. `Biologic-CHIL001` collected from the Study Area appears to represent a new/ unique OTU that has not been sequenced elsewhere in the region.

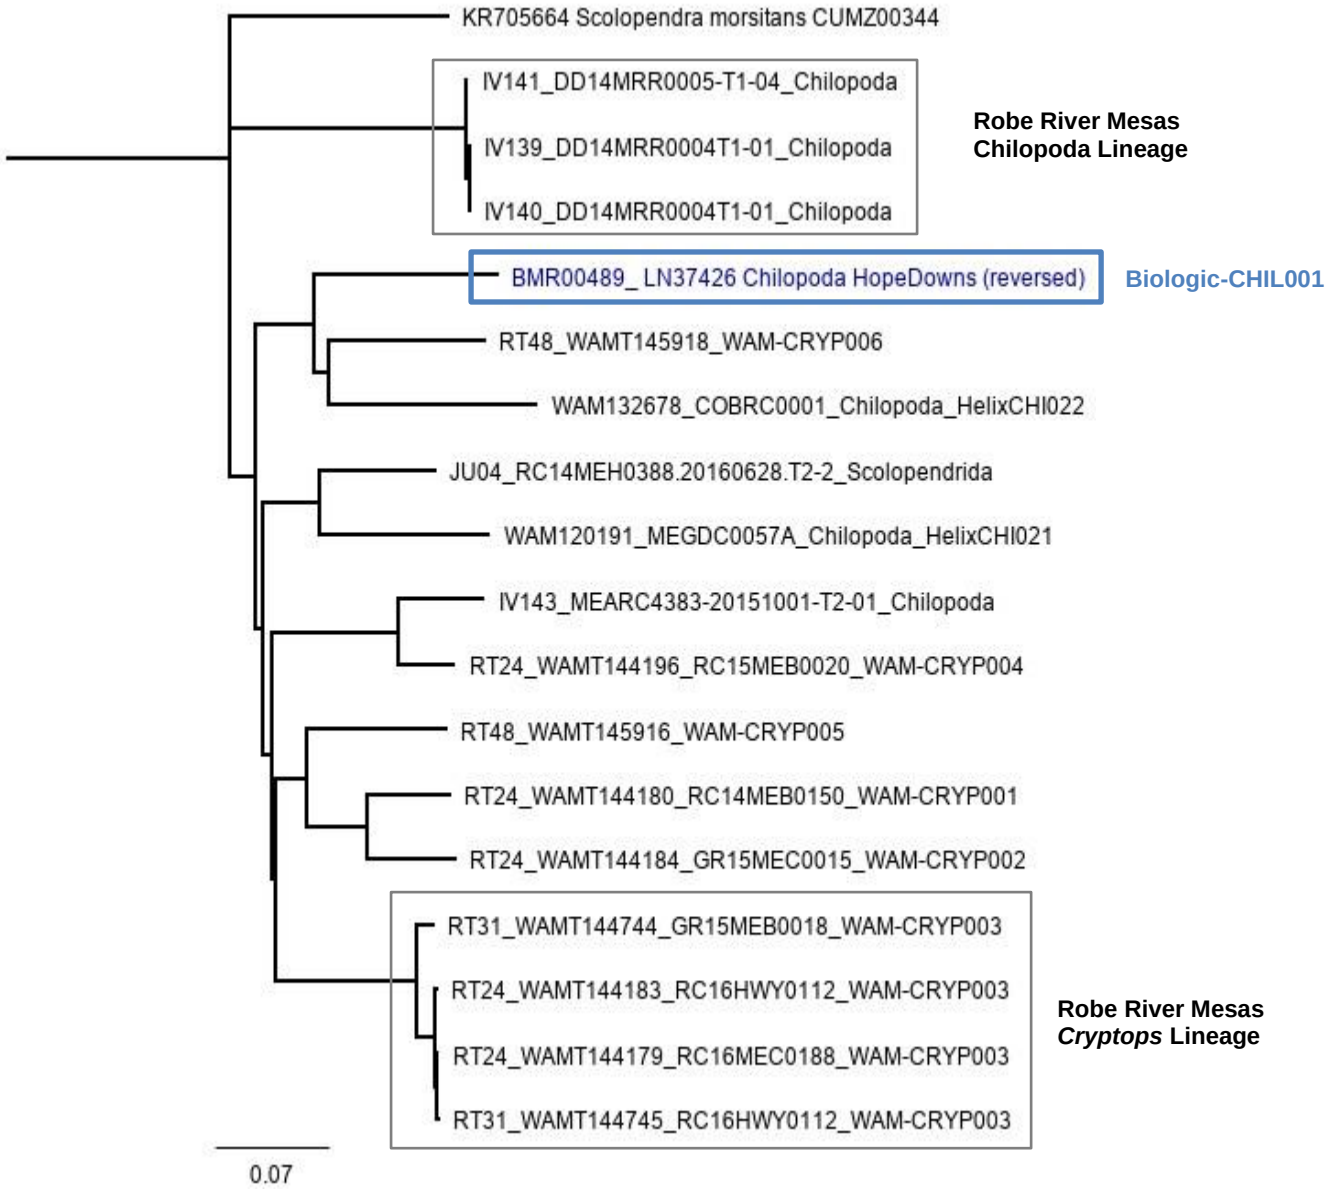

Figure 3.3. Neighbour Joining tree of Chilopoda haplotypes included in the analysis. Lineages from the Study Area are indicated by coloured text.

3.4 Diplura

One specimen of Diplura (LN33785; identified as *Indjapyx* OES7) was successfully sequenced (COI).

Regional comparisons (Figure 3.4) with previous sequences in Genbank and the RTIO databases revealed a high level of divergence (min 16% COI), indicating that Lineage DIPL001 from the Study Area is not represented elsewhere in the available sequence databases. This result was based on a comparison of 32 available Diplura sequences from the Pilbara region within the available sequence databases, and a Ptiliidae beetle was used as an outgroup (Figure 3.4, Appendix 4).

The dipluran sequenced from the Study Area (Lineage DIPL001) was closest to other diplurans identified as Japygidae, but at the high levels of divergence recorded (16%-19% COI), and due the lack of genus level identifications for most of the other sequences, further genetic or morphological information would be required to validate the phylogeny shown in Figure 3.4.

Indjapyx OES7 (Biologic-DIPL001) appears to represent a new/ unique OTU based on current comparisons with the available genetic databases.

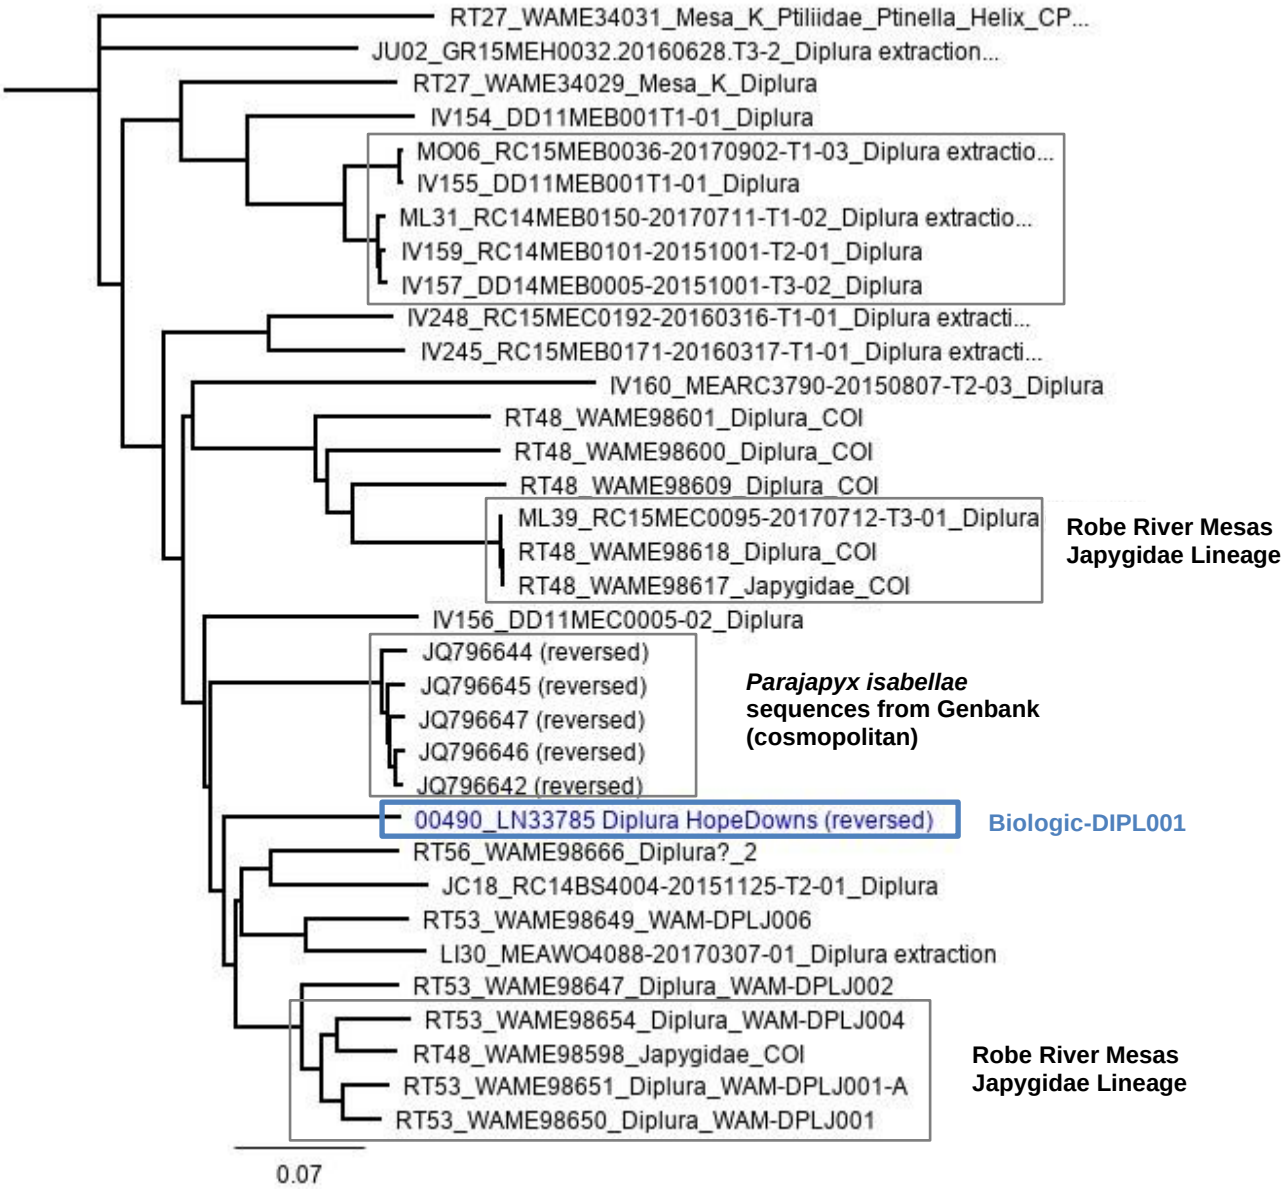

Figure 3.4. Neighbour Joining tree of Diplura haplotypes included in the analysis. Lineages from the Study Area are indicated by coloured text.

3.5 Hemiptera

Four of a total six specimens of Hemiptera from the Study Area were successfully sequenced (COI). Local comparisons revealed three well-supported lineages (intraspecific variability <1%), representing three distinct OTUs (Table 3.2, Figure 3.5):

- *Nisia* OES16 (HEMI001) (LN36535, 33789, Bedded Hill Top);
- *Phaconeura* HEMI002 (LN33774, Bedded Hill Top); and
- *Phaconeura* HEMI003 (LN35120, Bedded Hill Top);

These lineages each varied between 18% and 34% COI divergence (Appendix 5), indicating three highly divergent OTUs. Although morphological identifications (at Stantec) suggested that LN33774 and LN35120 belonged to the same morphospecies (*Phaconeura* OES15), the current genetic results revealed 18% (COI) divergence of Biologic-HEMI002 and HEMI003, indicating cryptic morphology or additional taxonomic work may be required.

Table 3.2. Genetic results of Hemiptera specimens (lineages represented by highlighted colours).

Area	Site Name	Morphospecies ID	No. of Individuals	Lot No. (LN)	BMR Code	HEMI Lineage
BHT	RC15BHT0267	*Nisia* OES16	1	LN36535	BMR00436	001
BHT	RC16BHT0222	*Nisia* OES16	1	LN33789	BMR00487	001
BHT	RC16HD10193	*Phaconeura* OES15	1	LN33774	BMR00486	002
BBH	RC14HD10072	*Phaconeura* OES15	1	LN35120	BMR00553	003

Regional comparisons (Figure 3.5 Appendix 5) revealed that each of the three lineages showed a high level of divergence (minimum 13-26% COI) from previously sequenced Hemiptera specimens. Specimens identified by Stantec as *Phaconeura* were clustered with other *Phaconeura* lineages, including one widespread OTU sampled at both Paraburdoo and West Angelas (P. WAM-PHAC001). However, at 13-14% COI divergence, *Phaconeura* sp. `Biologic-HEMI003` is regarded as a different OTU to *P*. `sp. WAM-PHAC001`, while *Phaconeura* `sp. Biologic-HEMI002` is regarded as different to another Paraburdoo taxon, P. `sp. WAM-PHAC002` (11-15% COI) (Appendix 5).

Nisia sp. Biologic-HEMI001 was highly divergent from all the available Meenoplidae sequences in the analysis (25-28% COI), although owing to the lack of genus level identifications for most of these sequences, further genetic (and/ or morphological work) may be required to validate these phylogenetic relationships.

Based on current results, the three Hemiptera OTUs from the Study Area do not appear to be represented elsewhere in the available databases.

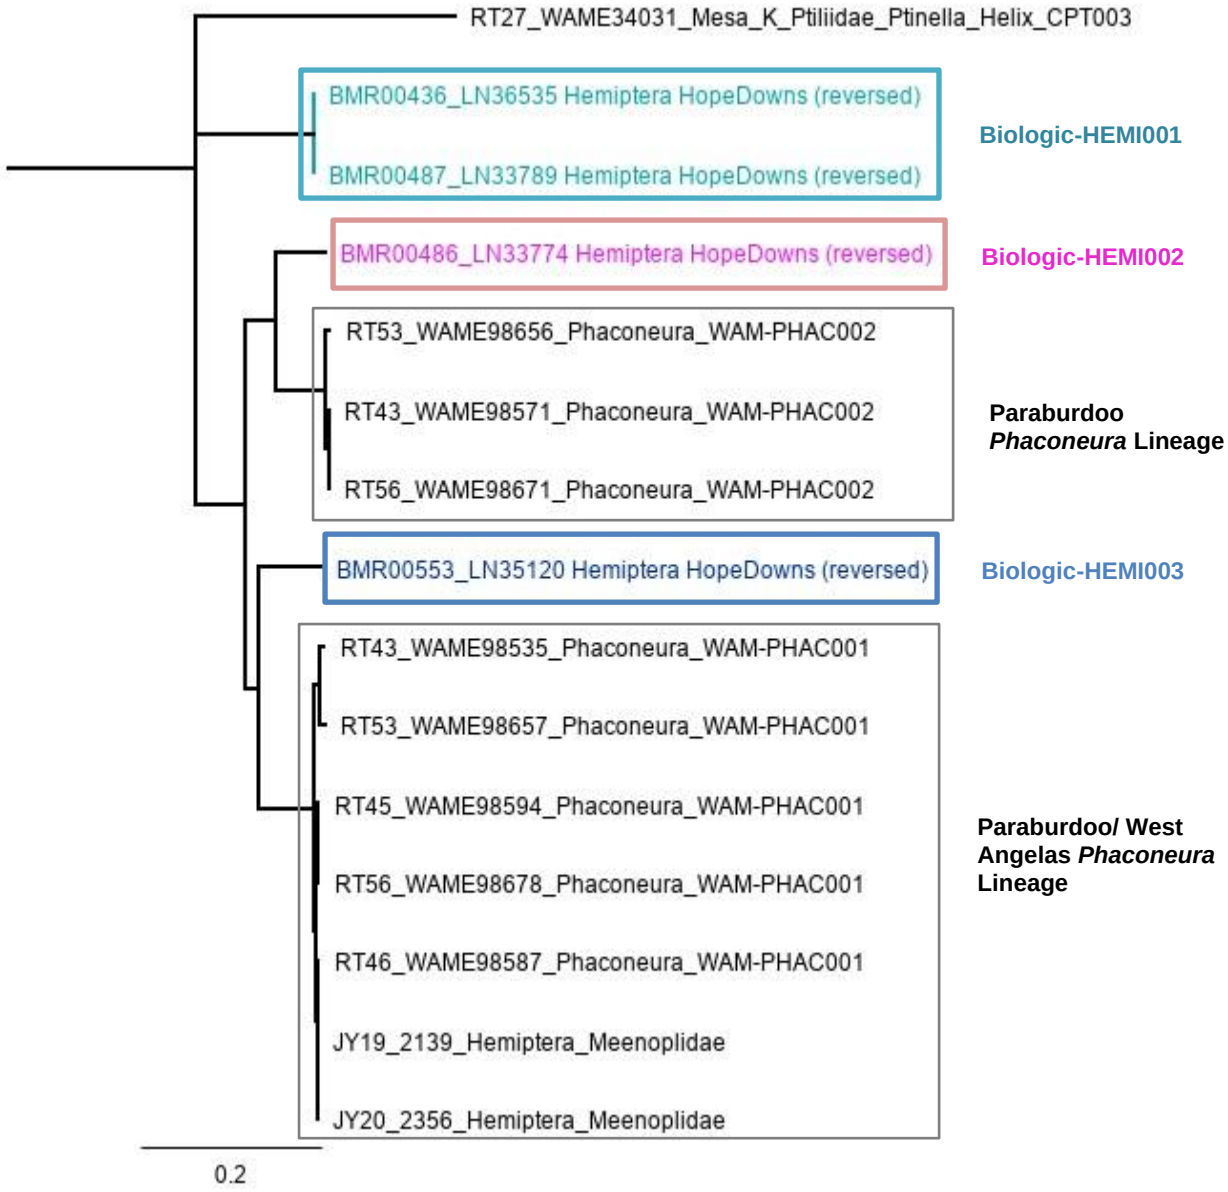

Figure 3.5. Neighbour Joining tree of Hemiptera haplotypes included in the analysis. Lineages from the Study Area are indicated by coloured text.

3.6 Palpigradi

One of the two specimens of Palpigradi (LN39264, identified as *Eukoenenia* OES2) was successfully sequenced (Lineage PALP001).

Regional sequences for this taxonomic group were very limited within the available databases, but the lineage from the Study Area was found to be 55-63% divergent (COI) from two other subterranean Palpigradi lineages collected at Paraburdoo (Figure 3.6, Appendix 6). A subterranean spider and an epigean spider sequence were used as outgroups in the analysis. At the high levels of divergence shown in this analysis, further genetic work (and potentially additional specimens/ sequences) would be required to verify the relationships between subterranean Palpigradi lineages from the region.

Based on the limited information currently available, *Eukoenenia* OES2 (Biologic-PAL001) does not appear to have been collected elsewhere to date.

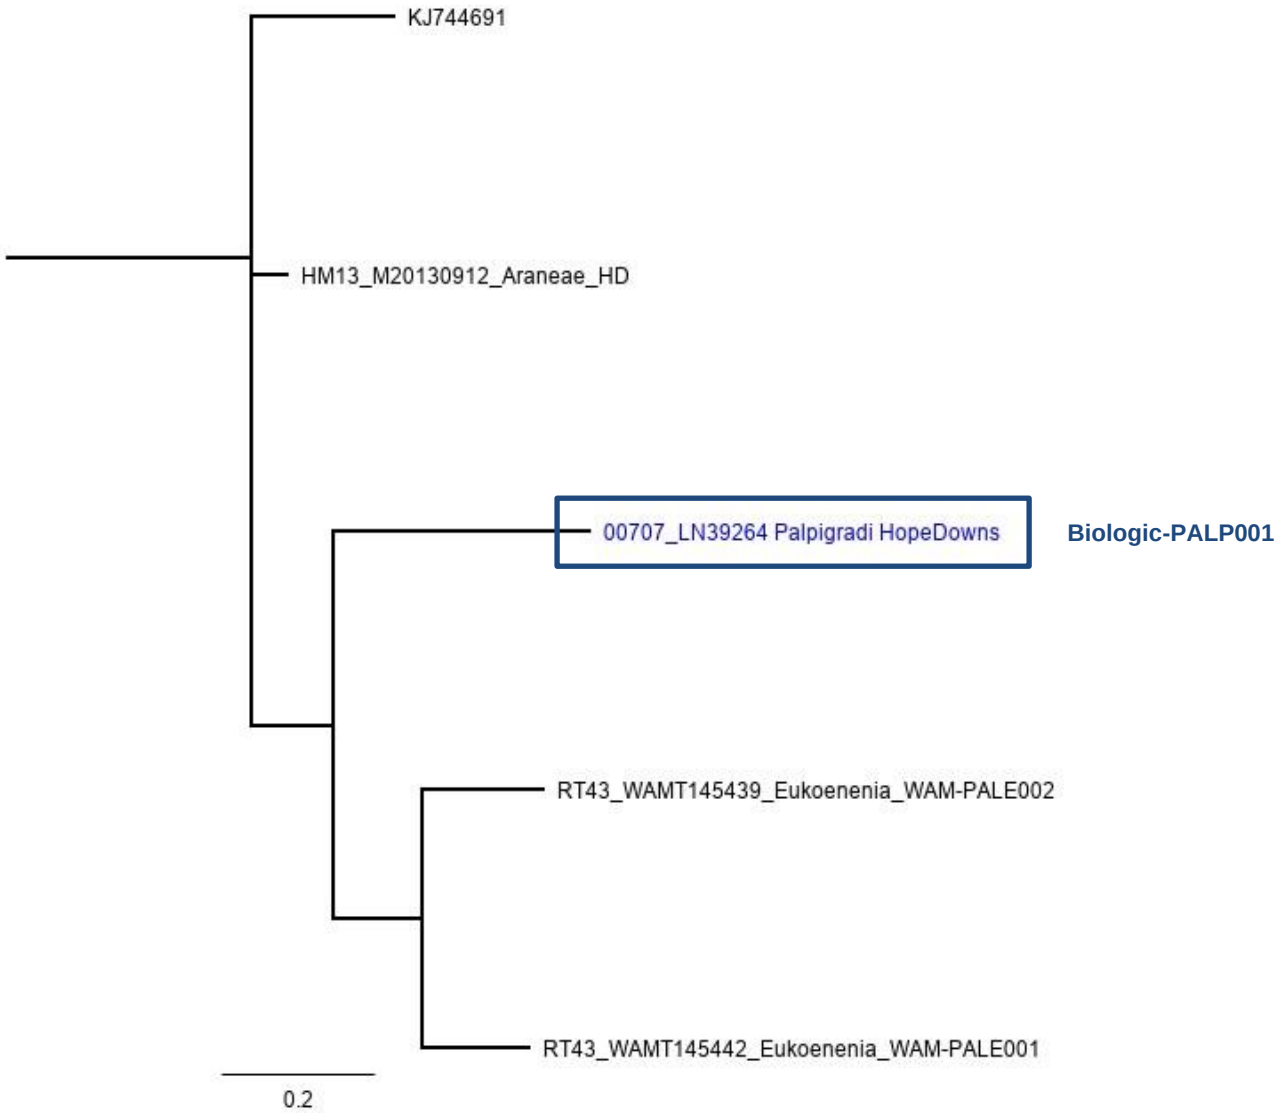

Figure 3.6. Neighbour Joining tree of Palpigradi haplotypes included in the analysis. Lineages from the Study Area are indicated by coloured text.

3.7 Pauropoda

One specimen of Pauropoda (LN35790) failed to sequence (COI). No further work was undertaken on this specimen.

3.8 Polyxenida

One specimen of Polyxenida (LN33785; Lophoproctidae sp.) was successfully sequenced (COI). Regional comparisons (Figure 3.7) were based on 25 available subterranean Polyxenida sequences from the Pilbara region (Appendix 7).

The analysis revealed a moderate level of divergence (9%-13% COI) with Polyxenida specimens collected at Robe Headwaters (S45), Cabbage Gum Bore (S12 and S31), Silvergrass (P3 and P1), and Western Range (P51 and P52). Based on average COI divergence thresholds of 8% (Hebert et al 2003), the sequence from the Study Area would still be considered to represent a distinct OTU (Biologic-POLYX001).

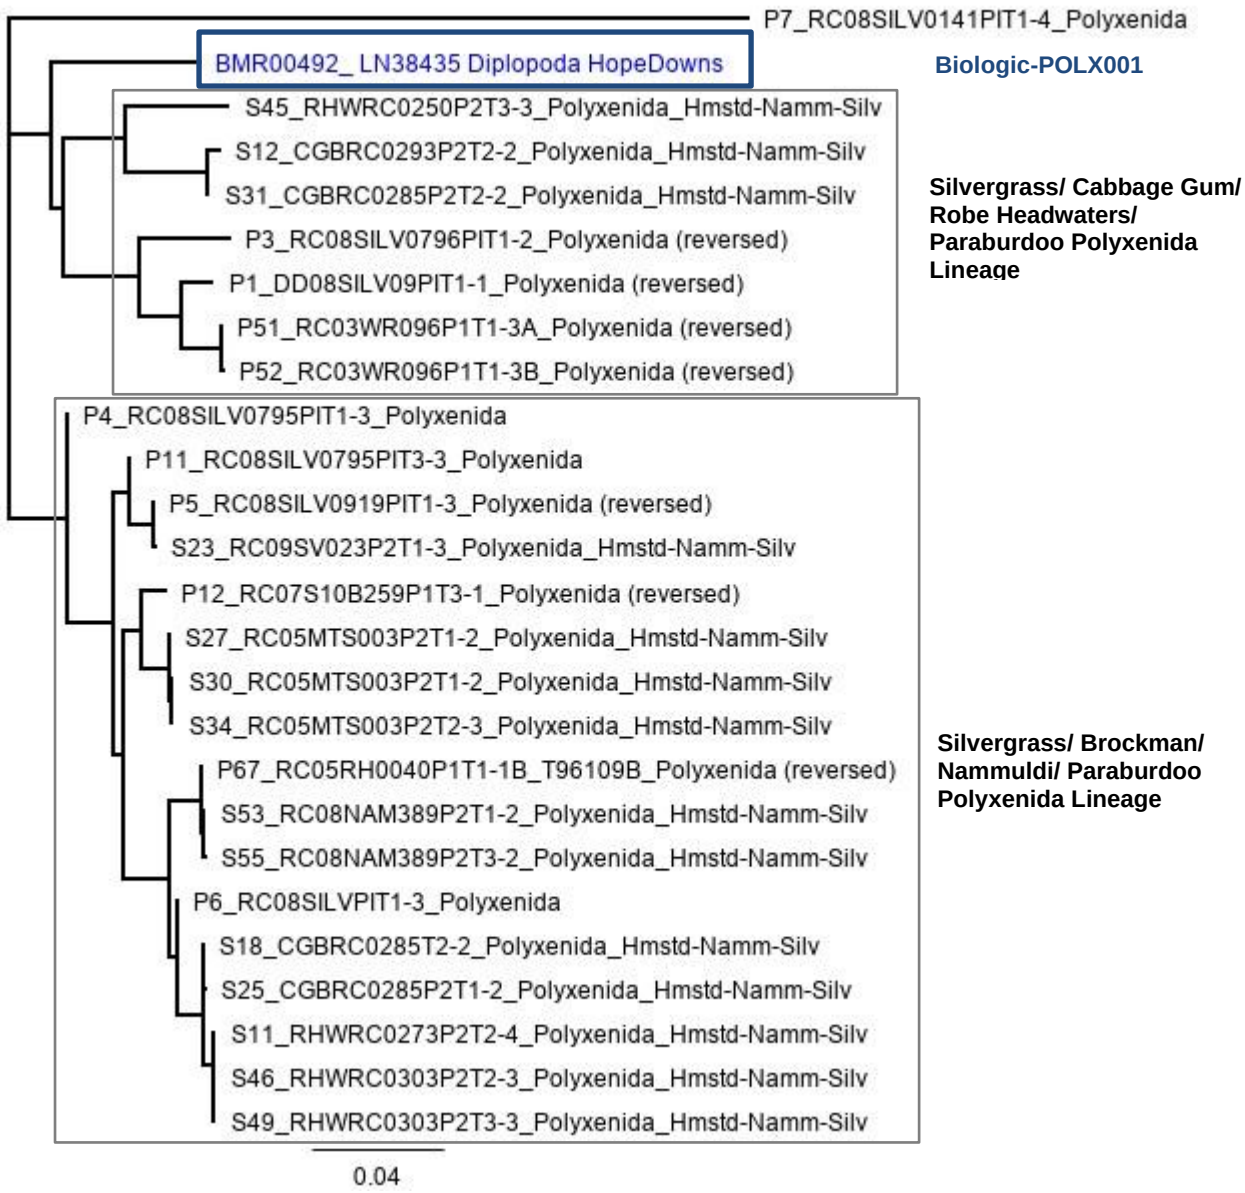

Figure 3.7. Neighbour Joining tree of Polyxenida haplotypes included in the analysis. Lineages from the Study Area are indicated by coloured text.

Although regionally widespread Lophoproctidae species are known to occur throughout the Pilbara region (i.e. the cosmopolitan species *Lophoturus madecassus,* which can be found in epigean and subterranean habitats), due to the lack of resolution in the accompanying morphological identifications, it is uncertain whether sequence material for this widespread species has been included in the current comparisons. However, it does appear that the most closely related lineages to the one collected at the Study Area have been recorded widely throughout the region.

Based on the currently available sequence information in the accessible databases, Lophoproctidae sp. (Biologic-POLYX001) does not appear to have been collected beyond the Study Area.

3.9 Pseudoscorpiones

One of the two specimens of Pseudoscorpiones (LN35130, identified as *Tyrannochthonius* OES20) was successfully sequenced at COI (Biologic-PSEU001). Figure 3.8 shows regional comparisons with 17 regional Chthoniidae sequences, and an *Aname* spider used as an outgroup.

Based on these regional comparisons, the Lineage PSEU001 from the Study Area was found to be highly divergent (19%-25% COI) from other sequences from Robe Valley (RT53 and RT48), and Paraburdoo (RT46) (Figure 3.8, Appendix 8). A subterranean spider and a subterranean Olpiidae sequence were used as outgroups in the analysis. Sequence data from the pseudoscorpion *Lagynochthonius* `sp. WAM-PSE096` previously collected from Baby Hope Downs were not available for genetic comparisons.

While the overall level of divergence between the sequence from the Study Area and other regional sequences in the same family was high, this was not considerably different from the range of divergences between *Tyrannochthonius* OTUs within the available databases (ranging from 12% to 24% COI, Appendix 8). In this broader context the high divergences between the lineage from the Study Area (Biologic-PSEU001) and other regional sequences was not considered out of trend with the range of divergences between other lineages in the genus.

Based on currently available information, *Tyrannochthonius* OES20/ Biologic-PSEU001 does not appear to have been collected elsewhere to date.

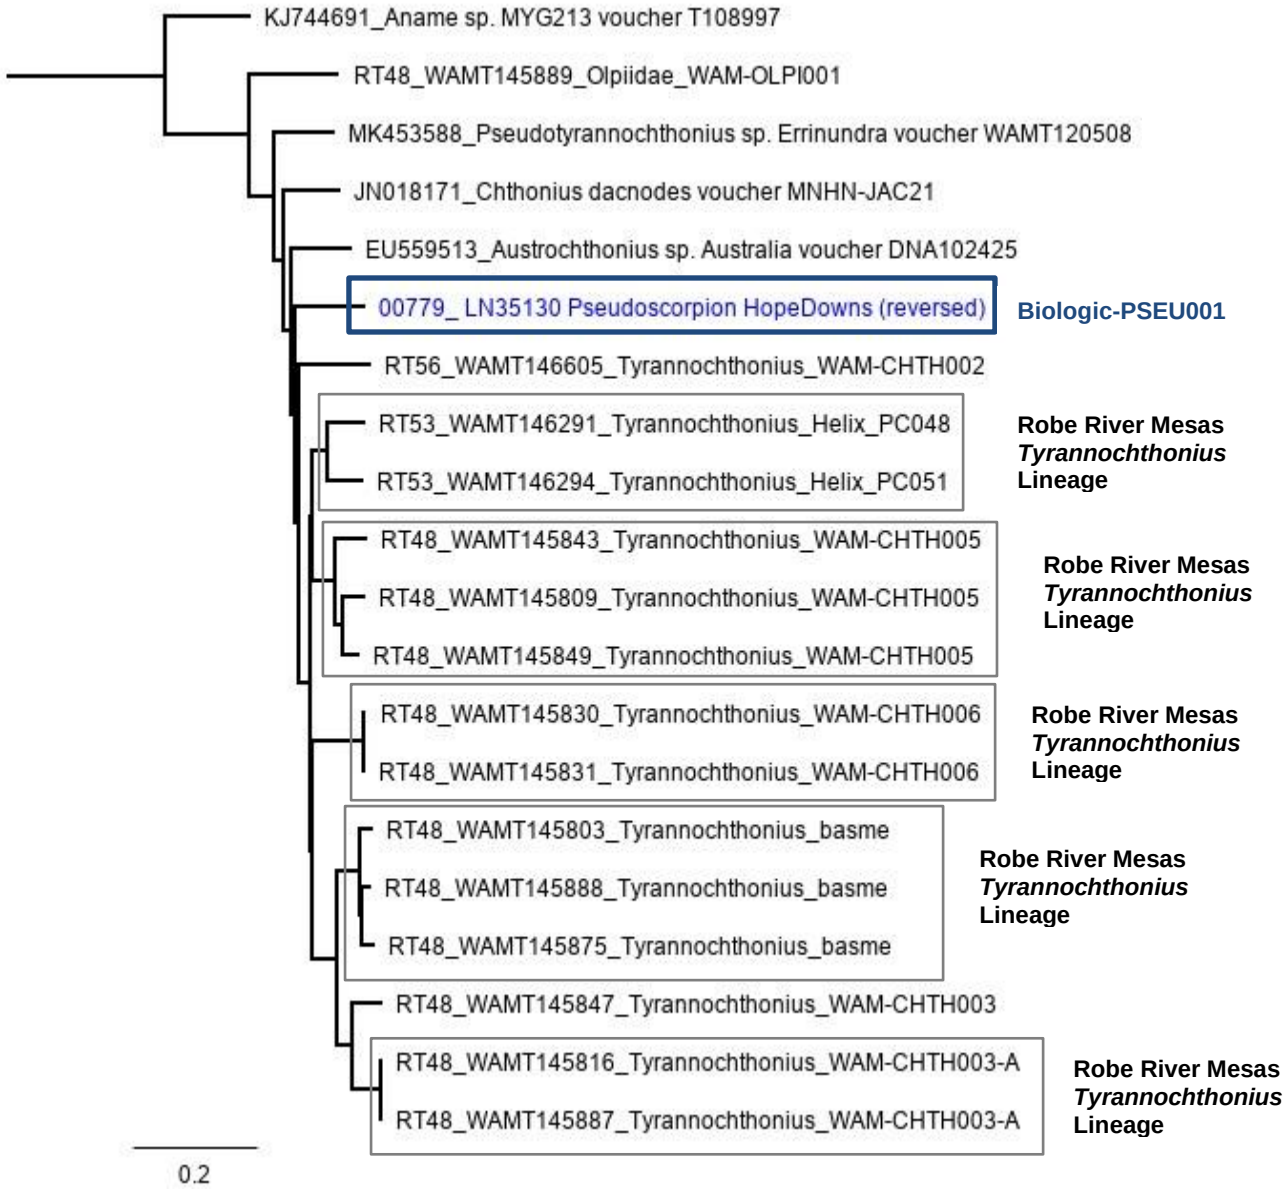

Figure 3.8. Neighbour Joining tree of Pseudoscorpiones haplotypes included in the analysis. Lineages from the Study Area are indicated by coloured text.

3.10 Schizomida

Eight specimens of Schizomida specimens were successfully sequenced at COI. Local comparisons revealed two potential lineages (intraspecific variability <1% COI, Appendix 9):

- Lineage A: LN35581, LN38567, LN33570, LN33590, and LN35572 from Bedded Hill Top; and
- Lineage B: LN37569, LN38573, and LN36580, also from Bedded Hill Top.

COI divergence between these lineages was only 6%- 7% (Appendix 9) and based on average COI divergence thresholds of 8% (Hebert et al 2003), these would be considered to represent a single OTU.

When compared to the sequences from specimens previously collected in the Hope Downs 1 South West area and Baby Hope Downs (Figure 3.9, Appendix 9), the two lineages are nested with the intraspecies variability within *Draculoides* sp. SCH068, as recently described by Abrams *et al.* (2019). Within the published sequences of *Draculoides* sp. SCH068, the current analysis showed variability between 3%-7% COI (Appendix 9). Current sequences within Lineage A varied from *D*. sp. SCH068 by 6%-9%, while sequences within Lineage B varied from *D*. sp. SCH068 by 2%-7% (Appendix 9). As stated above, Lineages A and B varied from each other by 6% - 7%.

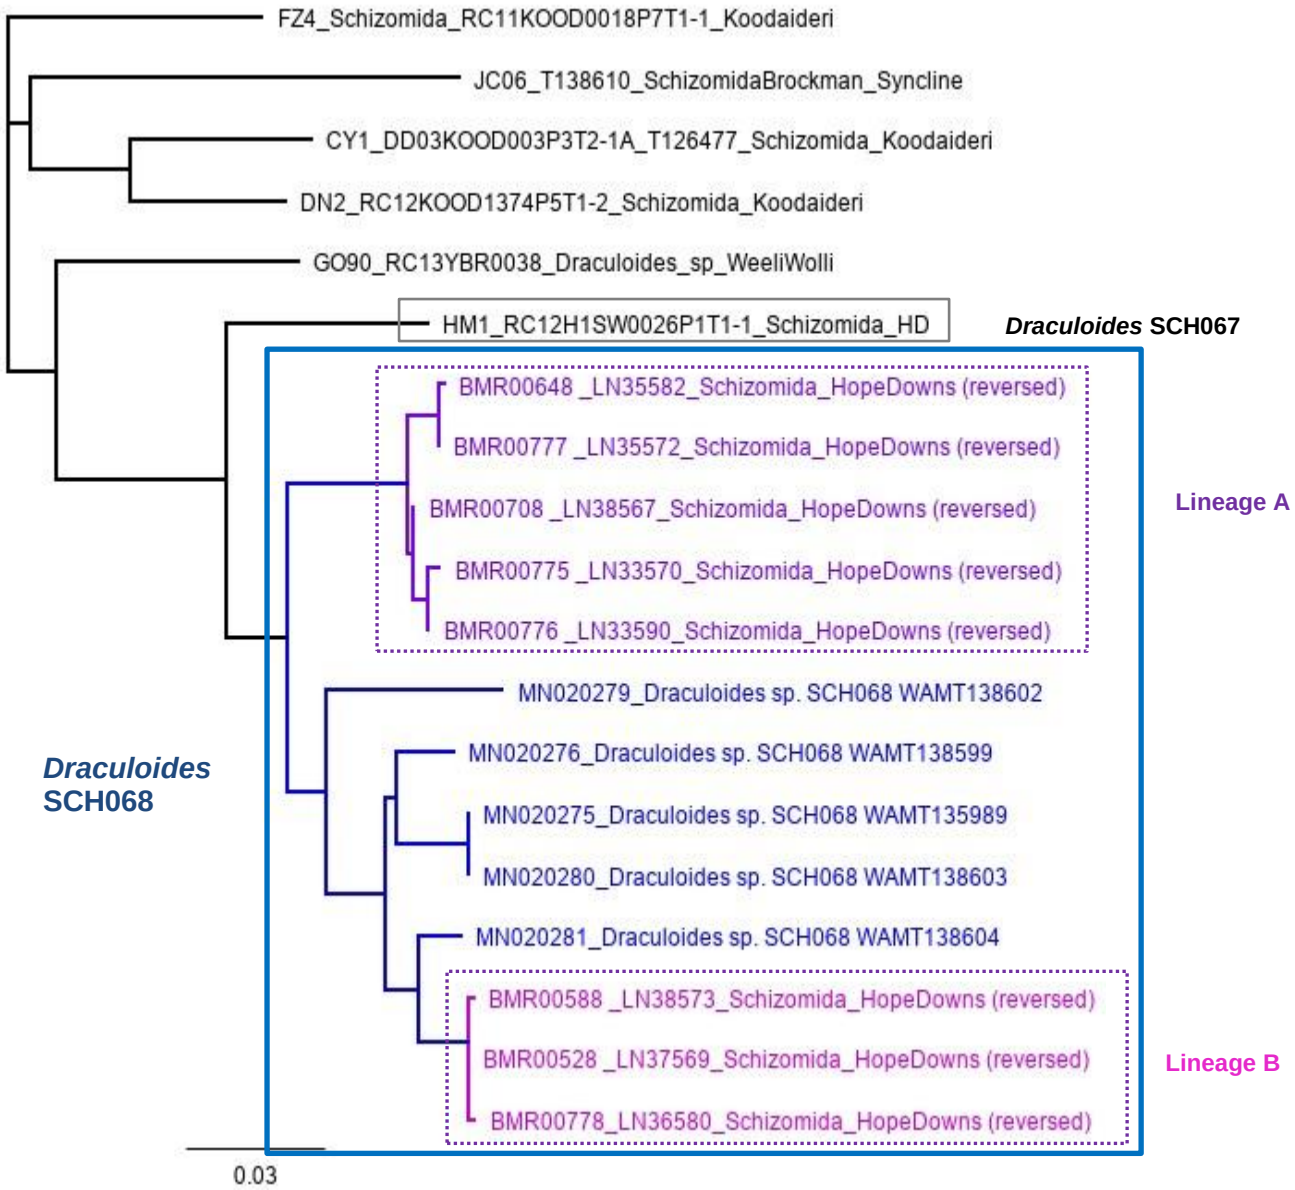

Figure 3.9. Neighbour Joining tree of Schizomida haplotypes included in the analysis. Lineages are indicated by coloured text.

The current analysis also suggests that Lineage A is also closely related to another OTU from Hope Downs 1 South West, *Draculoides* sp. SCH067 (Abrams *et al.* 2019). The average pairwise divergences of specimens in Lineage A vs SCH068 were 7% (SD 0.009), whereas Lineage A vs SCH067 was 8% (SD 0.004) (Table 3.3). This very marginal difference suggests that, even though both OTUs are quite similar to Lineage A, based on current sequences, Lineage A is closer to *Draculoides* sp. SCH068 (as in Figure 3.9).

Table 3.3: Average and standard deviation of COI divergences between lineages of Schizomida collected from the Hope Downs area, in the current analysis

	Lineage A (5)	Lineage B (3)	SCH068 (5)	SCH067 (1)
Lineage A (5)	1% (intra)	SD 0.003	SD 0.009	SD 0.004
Lineage B (3)	Ave 7%	0% (intra)	SD 0.017	SD <0.001
SCH068 (5)	Ave 7%	Ave 4%	4% (intra)	SD 0.004
SCH067 (1)	Ave 8%	Ave 10%	Ave 10%	n/a

Meanwhile, Lineage B was much more similar to *Draculoides* sp. SCH068 (COI divergence mean 4%, SD 0.017), which was within the same mean intraspecific variability as SCH068 itself (Table 3.3). Lineages A and B were also quite similar (COI divergence mean 7%, SD 0.003), indeed, the same average level of divergence as Lineage A vs SCH068, suggesting that Lineages A, B, and SCH068 can be regarded as the same OTU, albeit one with a relatively high level of intraspecific variability (mean 5%, range 0%-9%).

Based on the current results, all of the new sequences of Schizomida collected from the Study Area appear to align to the previously known OTU, *Draculoides* sp. SCH068. However, some of the divergences between the current lineages and the available sequence material for *Draculoides* sp. SCH068 and *Draculoides* sp. SCH067 were gradational/ marginal, therefore further genetic work using a multi-gene approach, potentially combined with morphological work as in Abrams *et al.* (2019) may be useful to validate the species-level phylogenetic relationships between these specimens.

3.11 Zygentoma

One specimen of Zygentoma (Atelurinae sp., LN39280) failed to sequence at COI, therefore analysis was conducted at 12S, following Smith *et al.* (2012). The specimen was successfully sequenced using 12S (Biologic-ZYGE001).

Based on comparisons with 20 regional Zygentoma sequences within the available databases, the lineage from the Study Area was found to be moderately divergent (8%-10% 12S) from a *Dodecastyla* OTU collected at Paraburdoo (*Dodecastyla* WAM-ZYGA001), and more highly divergent (19%-48% 12S) from other subterranean Zygentoma, several of which were morphologically identified as

Trinemura (Figure 3.10, Appendix 9). Smith *et al.* (2012) regarded sequences of *Dodecastyla* at 6.2% - 6.5% divergence (12S) as different species, therefore the lineage from Study Area would be considered distinct from *Dodecastyla* WAM-ZYGA001.

The current genetic results appear to confirm the morphological assessment, that the Zygentoma from the Study Area (ZYGE001) likely belongs to the Atelurinae (e.g. *Dodecastyla* sp.). This taxonomic group is commonly regarded as soil-dwelling (including inhabitants of termite nests), rather than troglobitic (Smith *et al.* 2012). While Biologic-ZYGE001 is closely related to *Dodecastyla* WAMZYGA001 sequenced at Paraburdoo, based on currently available information in the accessible databases, does not appear to have been collected elsewhere beyond the Study Area to date.

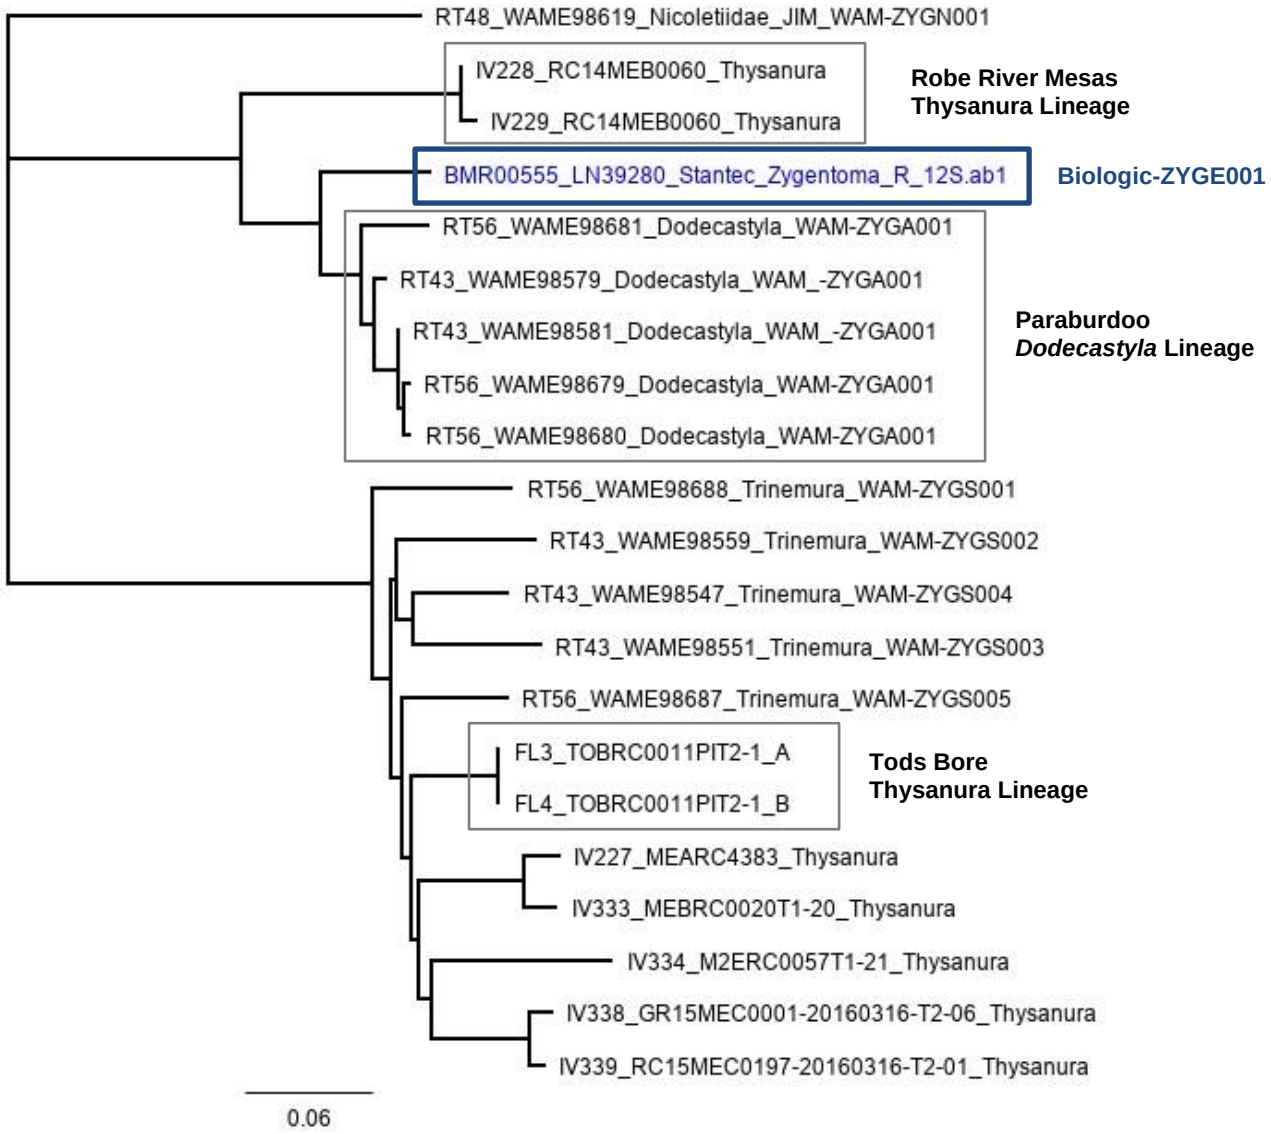

Figure 3.10. Neighbour Joining tree of Zygentoma haplotypes included in the analysis. Lineages from the Study Area are indicated by coloured text.

4 KEY FINDINGS

The molecular analysis of subterranean fauna from the HDOW1 Study Area resulted in the following key findings at the species/ OTU level:

- Amphipoda (CO1): 1 OTU, Biologic-AMPH001 (*Pilbarus* nr *millsi* OES12), regionally unique;
- Blattodea (CO1): 4 OTUs (formerly *Nocticola* sp. OES12 and OES13), Biologic-BLAT001, Biologic-BLAT002, Biologic-BLAT003, and Biologic-BLAT004, all regionally unique;
- Chilopoda (CO1): 1 OTU, Biologic-CHIL001 (Scolopendromorpha sp.), regionally unique;
- Diplura (CO1); 1 OTU, Biologic-DIPL001 (*Indjapyx* OES7), regionally unique;
- Hemiptera (CO1): 3 OTUs, Biologic-HEMI001 (*Nisia* OES16), Biologic-HEMI002 and Biologic-HEMI003 (the latter both formerly *Phaconeura* OES15), all regionally unique.
    - Two other specimens failed to sequence;
- Palpigradi (CO1): 1 OTU, Biologic-PALP001 (*Eukoenenia* OES2), regionally unique.
    - A second specimen failed to sequence;
- Pauropoda (CO1): failed to sequence;
- Polyxenida (CO1): 1 OTU, Biologic-POLX001 (Lophoproctidae sp.), regionally unique;
- Pseudoscorpiones (CO1): 1 OTU, Biologic-PSEU001 (*Tyrannochthonius* OES20).
- Schizomida (CO1): 1 OTU (*Draculoides* sp. SCH068),
    - Previously recorded OTU *Draculoides* sp. SCH068 encompasses Lineage A, Lineage B, and morphospecies *Draculoides* ?BH4/BH5;
- Zygentoma (12S): 1 OTU, Biologic-ZYGE001 (Ateluridae sp.), regionally unique.

Thank you for giving Biologic the opportunity to undertake this work. Please contact us if you have any further questions.

Sincerely,

Shae Callan

EXECUTIVE SUMMARY

This report presents an assessment of the potential impacts on surface water quantity and quality at Weeli Wolli Spring and Ben's Oasis from mining infrastructure proposed for the HD2 Proposal which includes deposits at Bedded Hilltop (BHT) and Hope Downs 2 (HD2). Weeli Wolli Spring and Ben's Oasis are located within the Weeli Wolli Creek catchment and are referred to as sensitive receptors due to their Aboriginal heritage and environmental significance.

A two-dimensional (2D) hydraulic model was developed to characterise the surface water flow regime of Weeli Wolli Creek and Pebble Mouse Creek (a major tributary of Weeli Wolli Creek) in their existing conditions. This regional model was used to quantify the total volume and peak flows estimated at the sensitive receptors. An operational mining scenario was also modelled to simulate estimated surface water flows once HD2 and BHT mining infrastructure had been constructed. Comparison of results from the two scenarios highlighted areas within Weeli Wolli Creek and Pebble Mouse Creek that experienced a change in maximum water depths due to mining infrastructure, in particular the addition of diversion drains at HD2 and a haul road crossing at Pebble Mouse Creek.

The water quality component of the assessment considered the potential for sediments at the Pebble Mouse Creek haul road crossing to be transported 14 km downstream and impacting Weeli Wolli Spring. A refined, localised 2D hydraulic model was developed focusing on flows within Pebble Mouse Creek at the location of the floodway crossing as well as the HD1 rail crossing (consisting of multiple culverts and located 4 km downstream of the floodway). Evaluation of velocities at these crossings and assumptions of sediment transport behaviour formed the basis of the water quality analysis.

Results from the regional model indicated that mining operations associated with the HD2 Proposal (including pits, dumps and drainage infrastructure) truncated approximately 3.5% of the total catchment reporting to Weeli Wolli Spring. This resulted in the loss of 1 % of the total runoff volume at the Spring and a reduction of the peak flow by 1.4 %, based on the 1:100 annual exceedance probability (AEP) 24 hour rainfall event. At Ben's Oasis, the catchment reporting to this location was truncated by 0.2 %, which resulted in a reduction to peak flow of 1.1%.

Results from the localised model indicated that during frequent (1:5 AEP) and rare (1:100 AEP) rainfall events, flood depths are increased on the upstream side of the floodway and rail culverts due to the attenuation and backwater impacts of these structures. Velocities modelled at these locations are observed to be lower on the upstream side as flow is throttled by the crossing obstruction, with a distinct increase in velocity at and immediately downstream of the crossing as flow is concentrated through the floodway or culvert.

The slight loss of runoff demonstrated through the regional modelling is expected to have little effect on the flow regime at either sensitive receptor and is therefore expected to have insignificant impact of the environmental and heritage values of Weeli Wolli Spring or Ben's Oasis. This is further reinforced by the fact that water levels in Weeli Wolli Spring are supplemented by Hope Downs 1 dewatering discharge and Ben's Oasis is a groundwater sustained system.

High flood depths and low velocities observed on the upstream side of the rail crossing in results from the local model support the increased deposition of sediment at the rail culvert inlets and most likely poor transport of sediment through the culverts. Therefore, sediment transported from haul road crossings over Pebble Mouse Creek is considered unlikely to impact water quality at Weeli Wolli Spring.

1. INTRODUCTION

The purpose of this report is to assess the potential surface water impacts to the sensitive receptors, Weeli Wolli Spring and Ben's Oasis, within the Weeli Wolli Creek catchment from the mining infrastructure proposed for the HD2 Proposal which includes deposits at Bedded Hilltop (BHT) and Hope Downs 2 (HD2).

The cumulative effects of mining and interventions resulting from the HD2 Proposal in the Weeli Wolli Creek catchment have the potential to alter the flooding characteristics and flooding frequency of the creek system. Activities such as construction of diversion structures and haul/access road crossings can potentially modify the existing surface flow regimes. Existing pits at HD1 and development of future pits for the HD2 Proposal may also truncate local catchments thus reducing flow contribution to Weeli Wolli Creek and its tributaries. These changes in surface flow regime may result in reductions to peak and total flow volumes, with the potential to impact water quality through a change in sediment loading.

Two-dimensional hydraulic modelling has been utilised to characterise the surface flow regime in Weeli Wolli Creek and assess the changes in surface water quantity and quality, in particular at Weeli Wolli Spring and Ben's Oasis.

2. REGIONAL HYDROLOGY

HD2 and BHT deposits are located within the upper reaches of the Weeli Wolli Creek catchment that forms part of the Fortescue River Region (BoM, 2021). Weeli Wolli Creek has a total catchment area of approximately 4,770 km^2 to Waterloo Bore gauging station and drains north to the Fortescue Marsh.

The upper reaches of the Weeli Wolli Creek catchment include Pebble Mouse Creek, a major tributary of Weeli Wolli Creek, which has a catchment area of 340 km^2. HD2 and BHT deposits are bisected by the Pebble Mouse Creek and Weeli Wolli Creek catchment divide and do not interact with the flood plains of either creek.

The Tarina gauging station (operated by DWER) is the closest stream flow gauge to the study area and is located on Weeli Wolli Creek, about 7 km downstream of Weeli Wolli Spring. The Weeli Wolli Creek catchment area reporting to the Tarina gauge is about 1,530 km^2 and this area is illustrated in Figure 1.

Table 1: Catchment areas of Weeli Wolli Creek

Catchment	Area	Downstream Location
Weeli Wolli Creek	4,770 km^2	Fortescue Marsh
Weeli Wolli Creek	1,530 km^2	Tarina gauging station
Weeli Wolli Creek	1,340 km^2	Weeli Wolli Spring
Weeli Wolli Creek	420 km^2	Ben's Oasis
Pebble Mouse Creek	340 km^2	Confluence with Weeli Wolli Creek

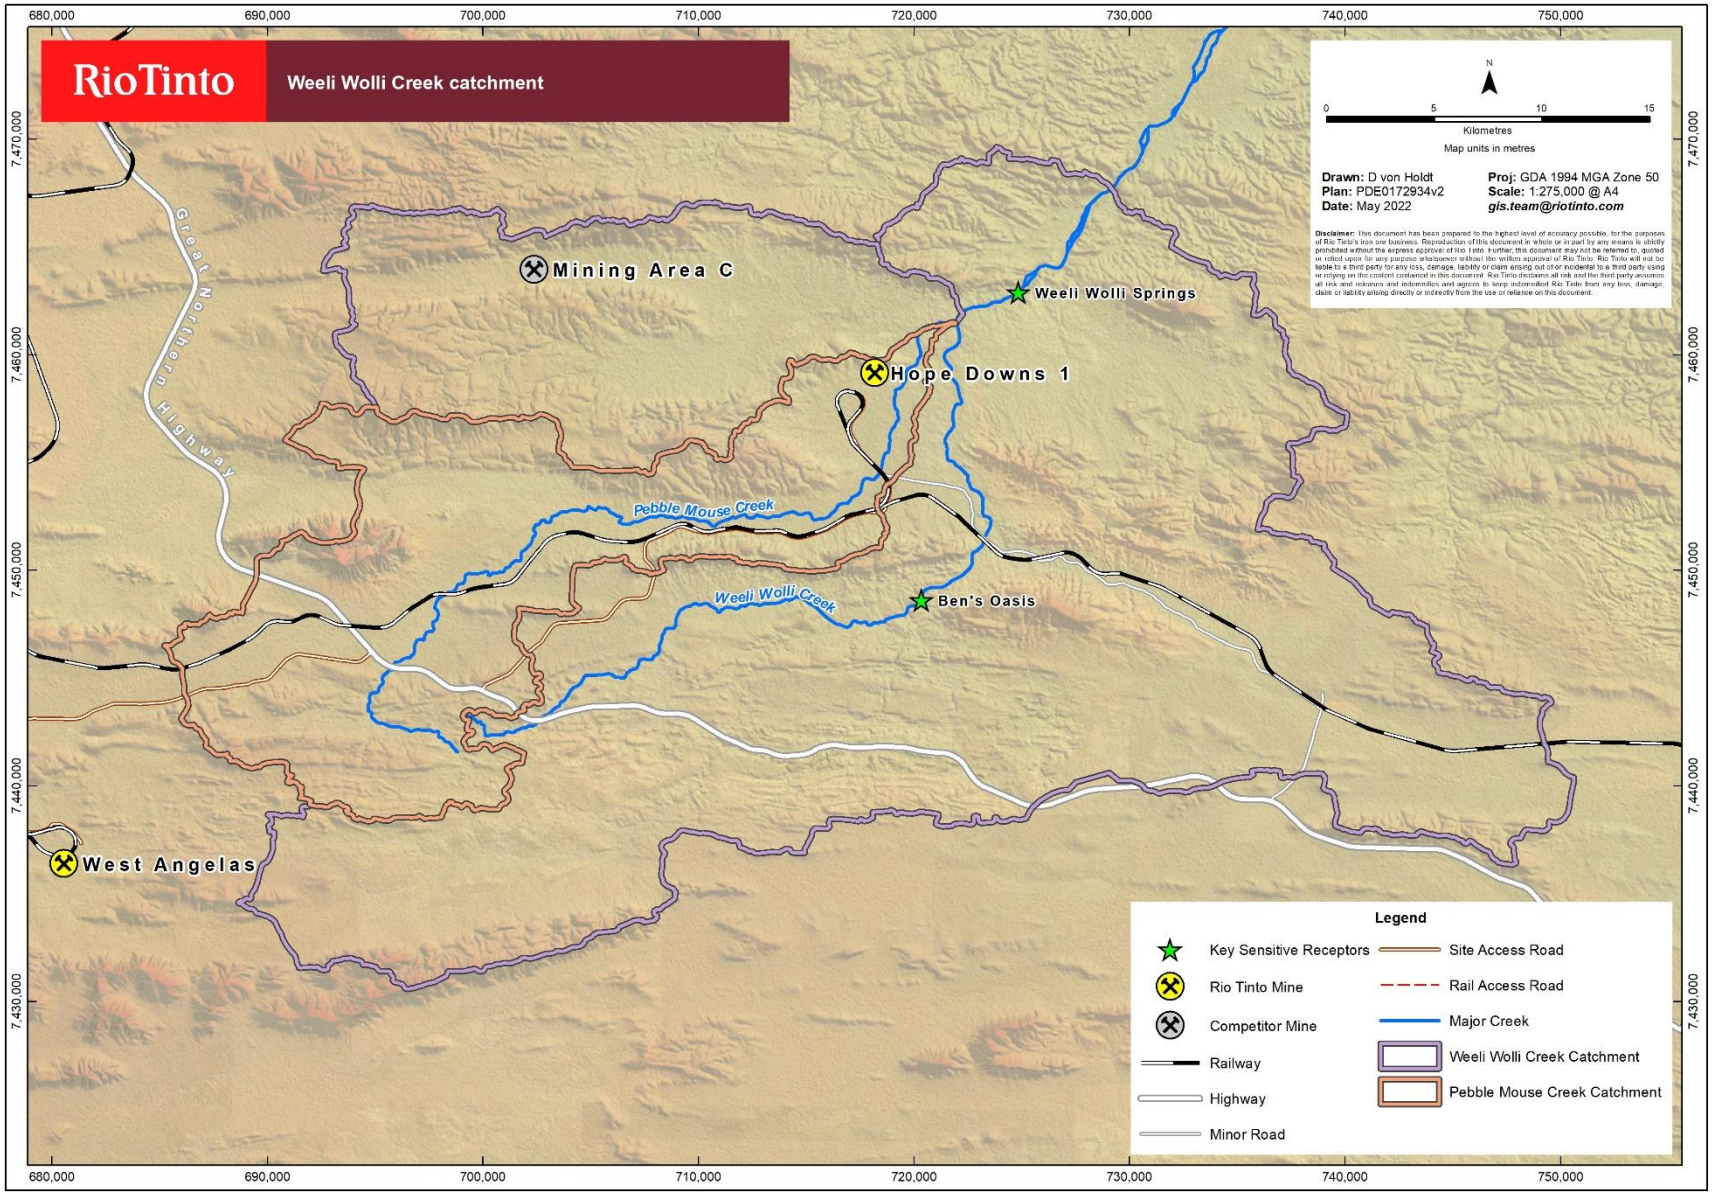

Figure 1: Weeli Wolli Creek catchment

3. MINING INFRASTRUCTURE

The proposed mine layout for HD2 and BHT is shown in Figure 2.

This report focused on the drainage infrastructure proposed to assist with surface water management at the HD2 and BHT pits, in particular the Pebble Mouse Creek Haul Road crossing, the Pebble Mouse Creek Road Train crossing and the diversion drains at HD2 as highlighted in Figure 2.

Consideration of additional waterway crossings proposed are also provided in this report. These crossings are associated with alternative transport options being explored as part of the study and include: the realignment of Great Northern Highway (GNH); an alternative mine access road; and an overland conveyor from HD2 to HD1.

Preliminary engineering designs for most of the infrastructure have been included in the hydraulic modelling undertaken for this report's analysis.

3.1. Pebble Mouse Creek Haul Road Crossing

Pebble Mouse Creek is a significant waterway separating the existing mining facilities at HD1 and the deposits of BHT and HD2. It is proposed that the haul road connecting the BHT deposit to the HD1 processing infrastructure will cross Pebble Mouse Creek. An engineered crossing will be constructed to manage flood risk and allow continuity of production. The width of Pebble Mouse Creek bed at the proposed crossing location is approximately 350 m, as shown in Figure 3**Error! Reference source not found.**.

During the development of the proposed engineered solution for the creek crossing a haul road with culverts was defined, and three different concept design options, providing varying levels of flood serviceability, were evaluated. These options along with their design criteria are summarised in Table 2.

Table 2: Pebble Mouse Creek haul road crossing design options

Option	Design AEP	Design flow rate	Crossing structure
1	1% (1:100)	827.3 m^3/s	41 x DN2700 culverts
2	5% (1:20)	257.7 m^3/s	13 x DN2700 culverts
3	Low flow (assumed 50%, 1:2)	Not specified	4 X DN900 relief culverts

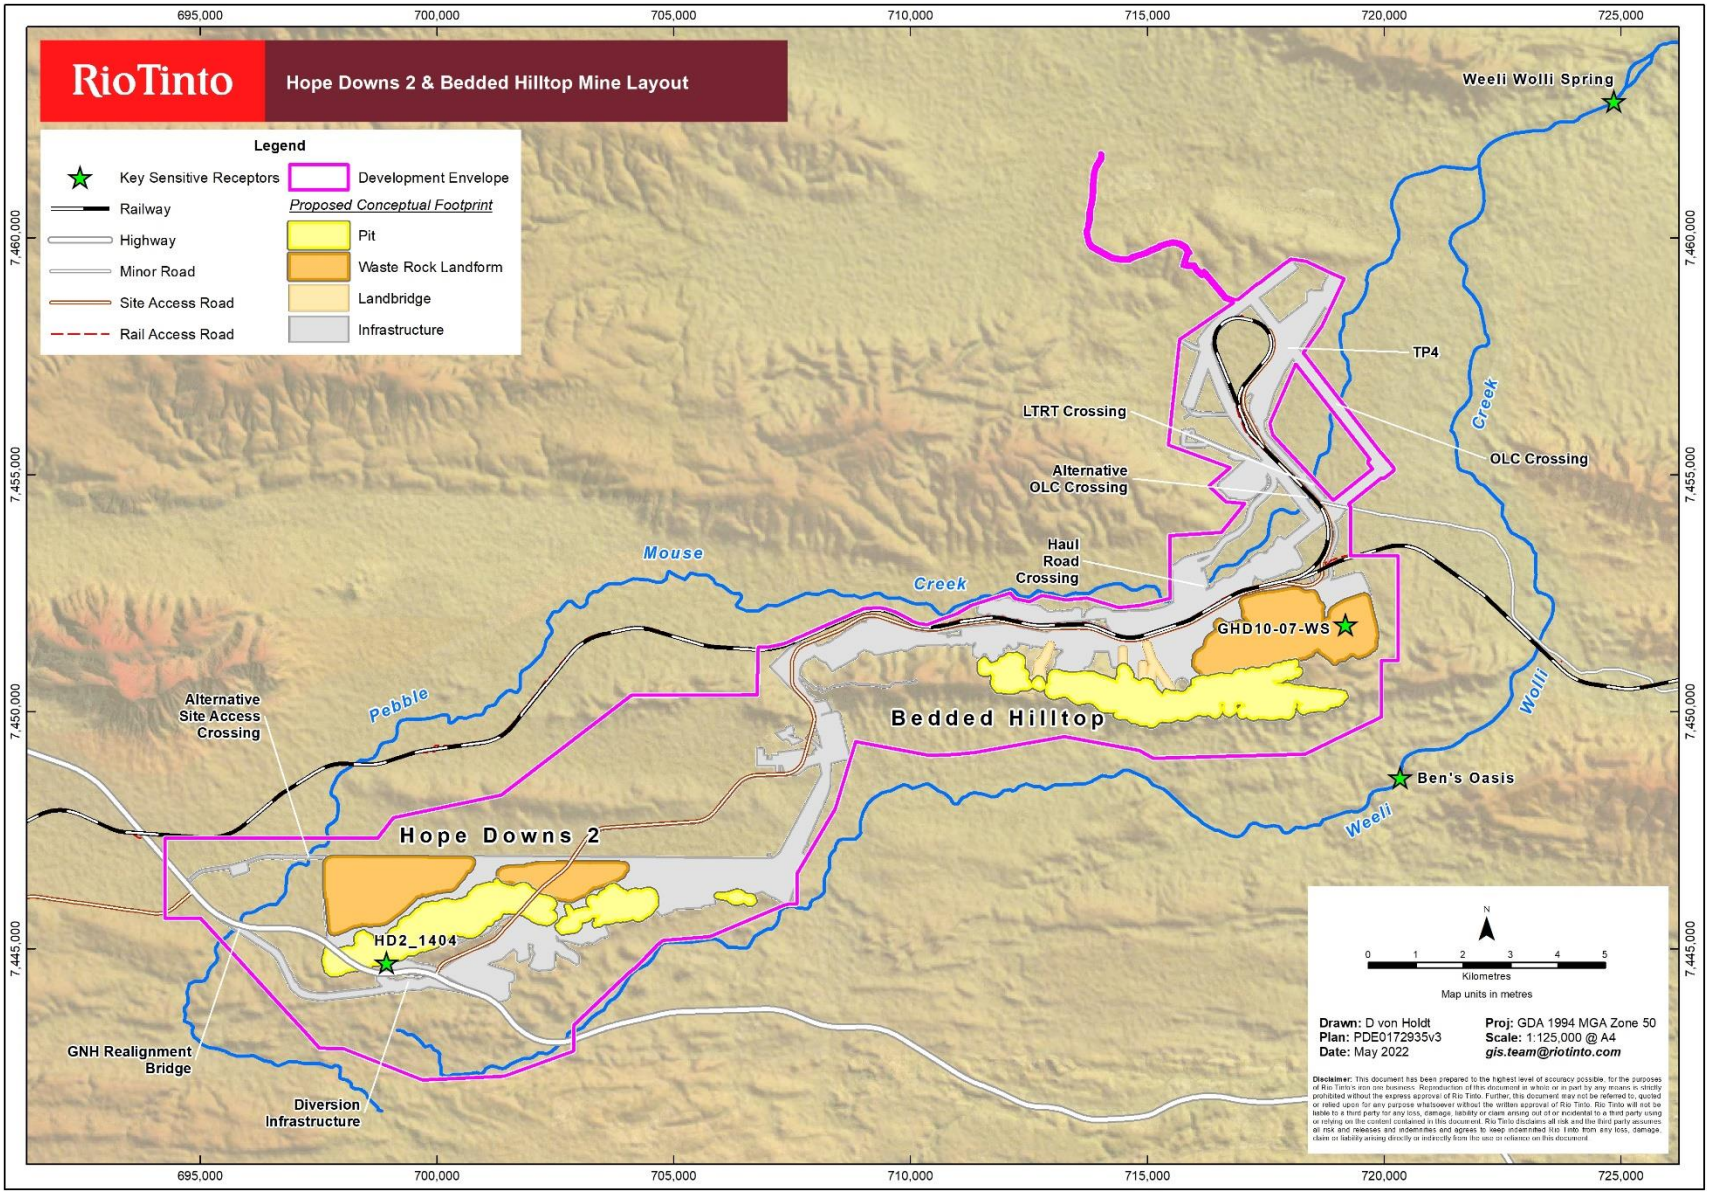

Figure 2: Hope Downs 2 & Bedded Hilltop Mine Layout

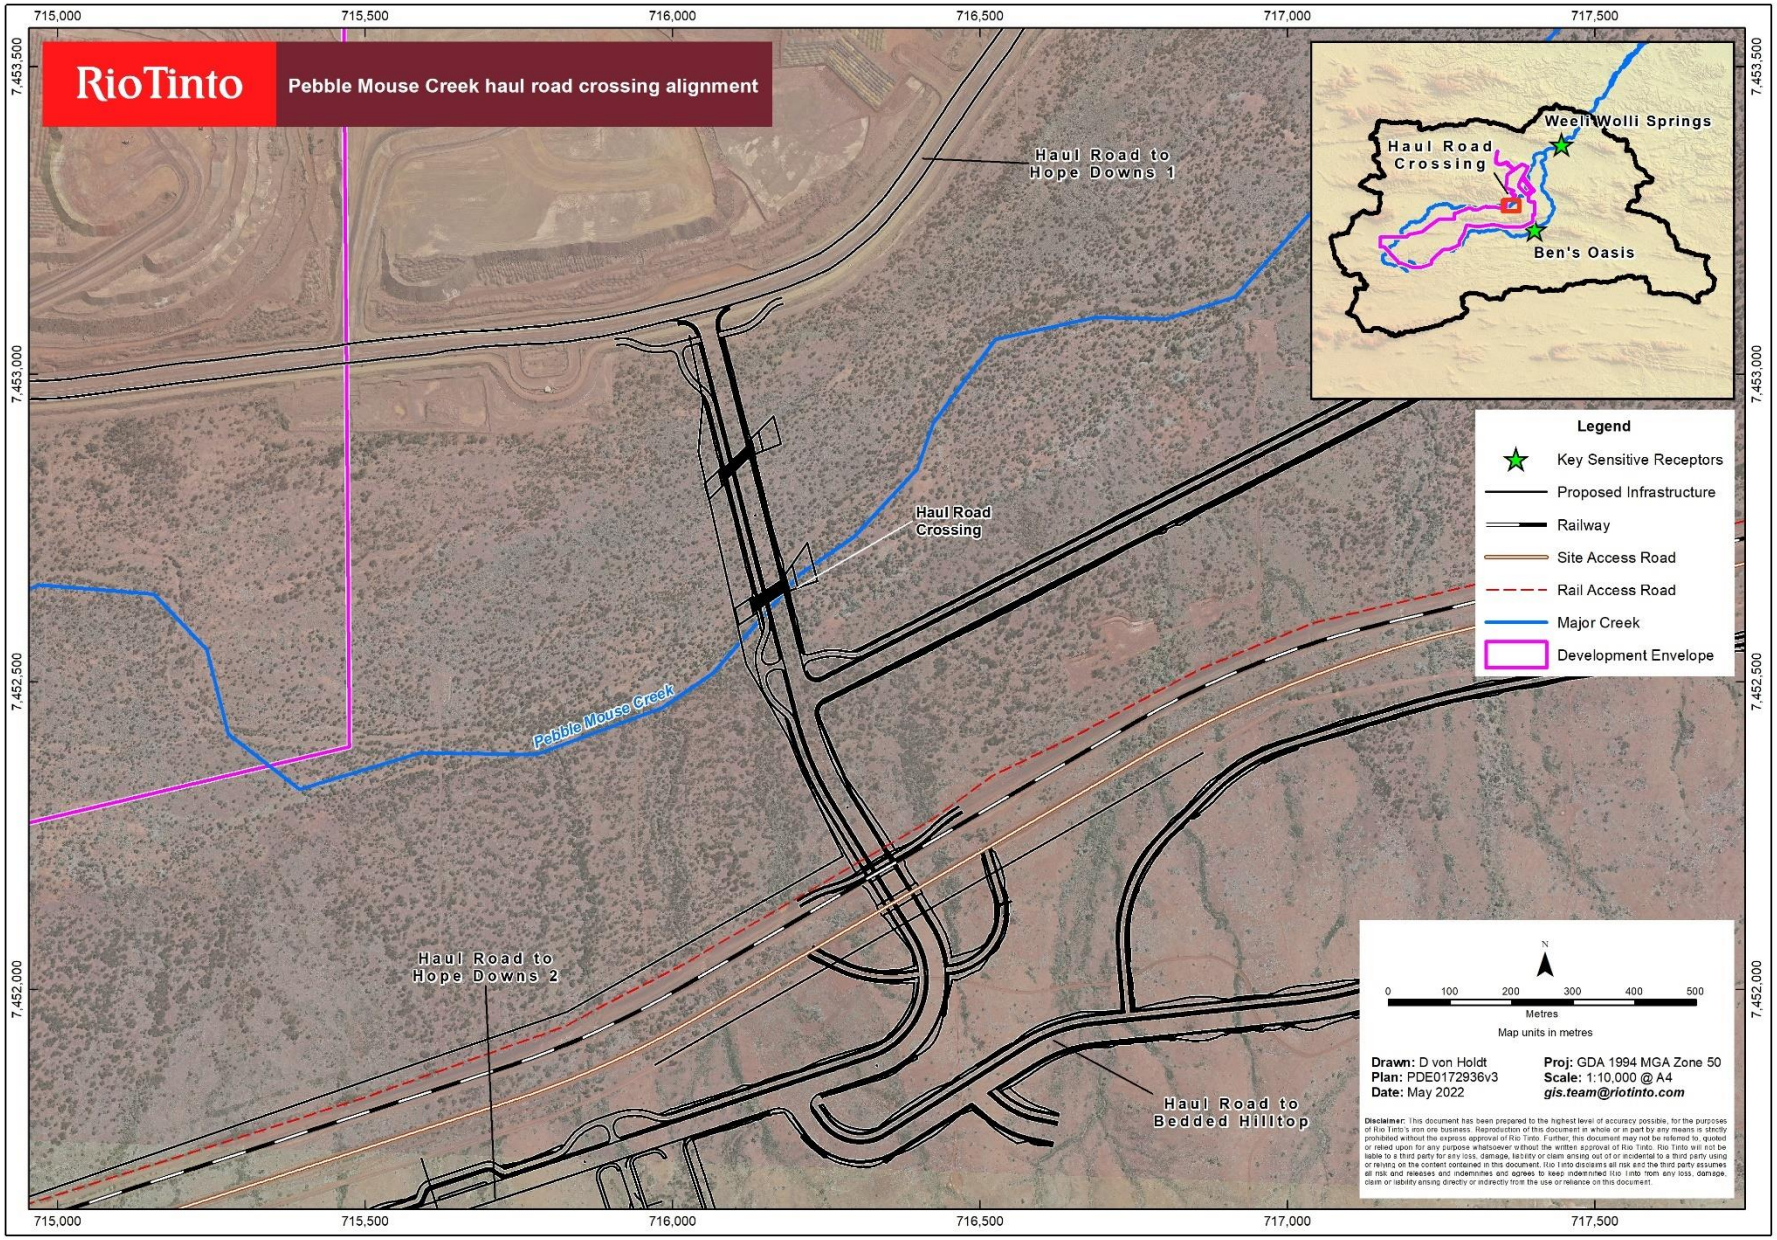

Figure 3: Pebble Mouse Creek haul road crossing alignment

3.2. HD2 Diversion Levee and Drains

Diversion infrastructure have been proposed at HD2 to manage the surface water flow around the pit. Several options were evaluated with the final design consisting of a levee (DL03) and two drains, referred to as DD01 and DD03. The drain configuration aims to divert flow from a tributary of Pebble Mouse Creek, that originally travelled north, towards Weeli Wolli Creek in the southeast. The levee and drains have been designed to convey the 1:100 AEP event. Proposed alignments of these structures are shown in Figure 4.

3.3. Pebble Mouse Creek Road Train Crossing

Long term road trains (LTRT) have been identified as the preferred ore transport option by the Prefeasibility Study (PFS). The proposed LTRT haul road will consist of a sealed road extending 27 km from HD2 to HD1 north crusher. Several options for the road alignment have been investigated and all options include a crossing over Pebble Mouse Creek, directly downstream of the existing rail line crossing.

LTRT Option 1 design includes multiple large culverts (aligned similarly to the existing railway culverts) at the creek crossing, designed to convey the 1:100 AEP flow rates. A transfer pad (TP4) will be located at the end of the haul road, close to the HD1 north crusher. Placement of TP4 has been restricted to be outside the 1% AEP flood extent of Pebble Mouse Creek.

Figure 5 includes the LTRT Option 1 road alignment and associated infrastructure (TP4).

3.4. Optional Waterway Crossings

3.4.1. Great Northern Highway Realignment

Due to the extent of the HD2 ore body, realignment of the GNH has been proposed to allow access to the ore currently situated under a section of the existing highway. Subsequently, to prevent the construction of road infrastructure that would ultimately become redundant once the GNH is realigned, an alternative mine access road has also been proposed. The GNH crossing will require a bridge structure, whereas the alternative mine access road crossing will require culverts. At this stage, preliminary designs are not available to model however the existing bridge along GNH currently crossing PMC provides the minimum design criteria expected for the new bridge on GNH. Austroads (1994) and Main Roads WA (MRWA, 2003) standard design guidelines dictate the design criteria for bridges along a main public highway, which include a serviceability design of 1% AEP and a survivability design of 1:2000 AEP.

3.4.2. Overland Conveyor (OLC)

An overland conveyor transport option was investigated, extending from HD2 to the HD1 north, as an alternative to the extensive haulage route required from HD2. The conveyor alignment requires a crossing over Pebble Mouse Creek. Several alignments were assessed including:

1. The OLC directly upstream of the existing HD1 rail line, running parallel to the rail crossing.
2. The OLC about 2 km downstream from the rail line.

The proposed design consists of an earth embankment with pipe culverts designed to convey the 1% AEP flow rates.

Figure 5 includes the OLC alignment positioned directly upstream of the rail line.

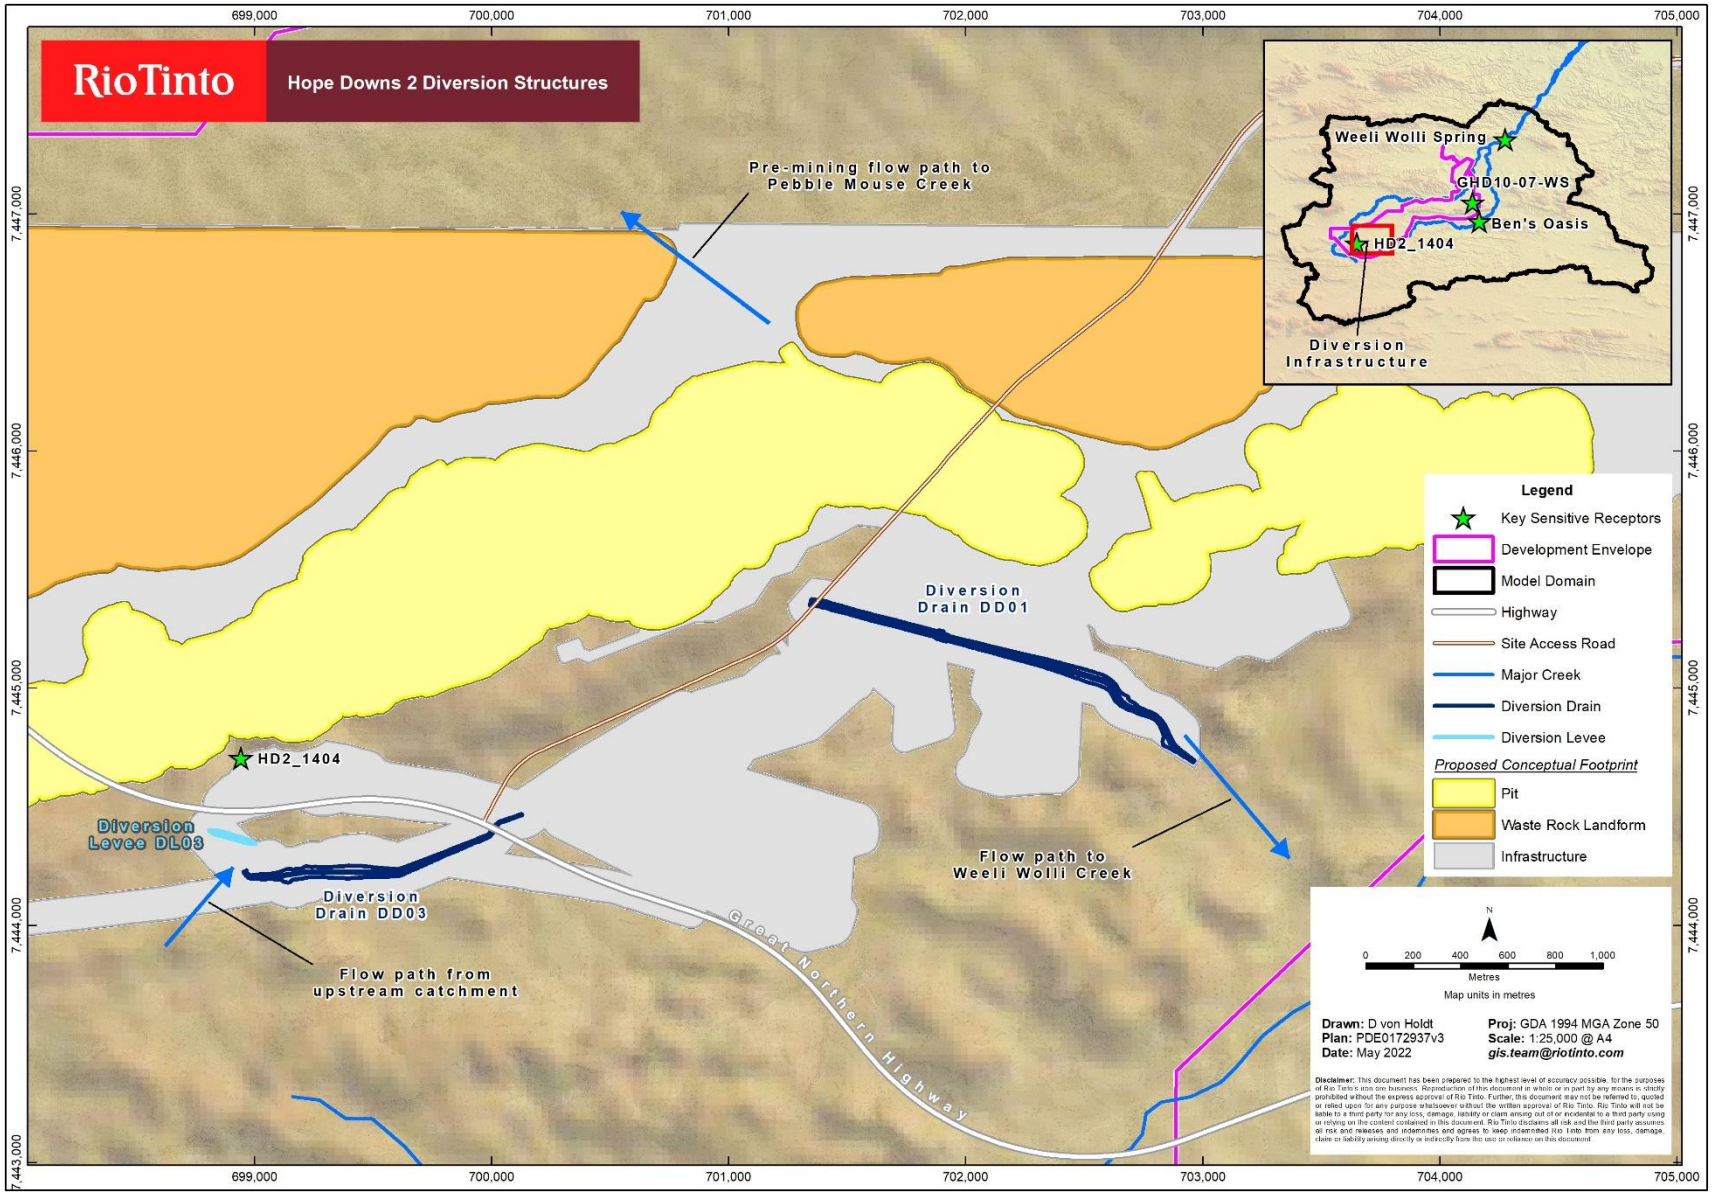

Figure 4: Hope Downs 2 diversion structures

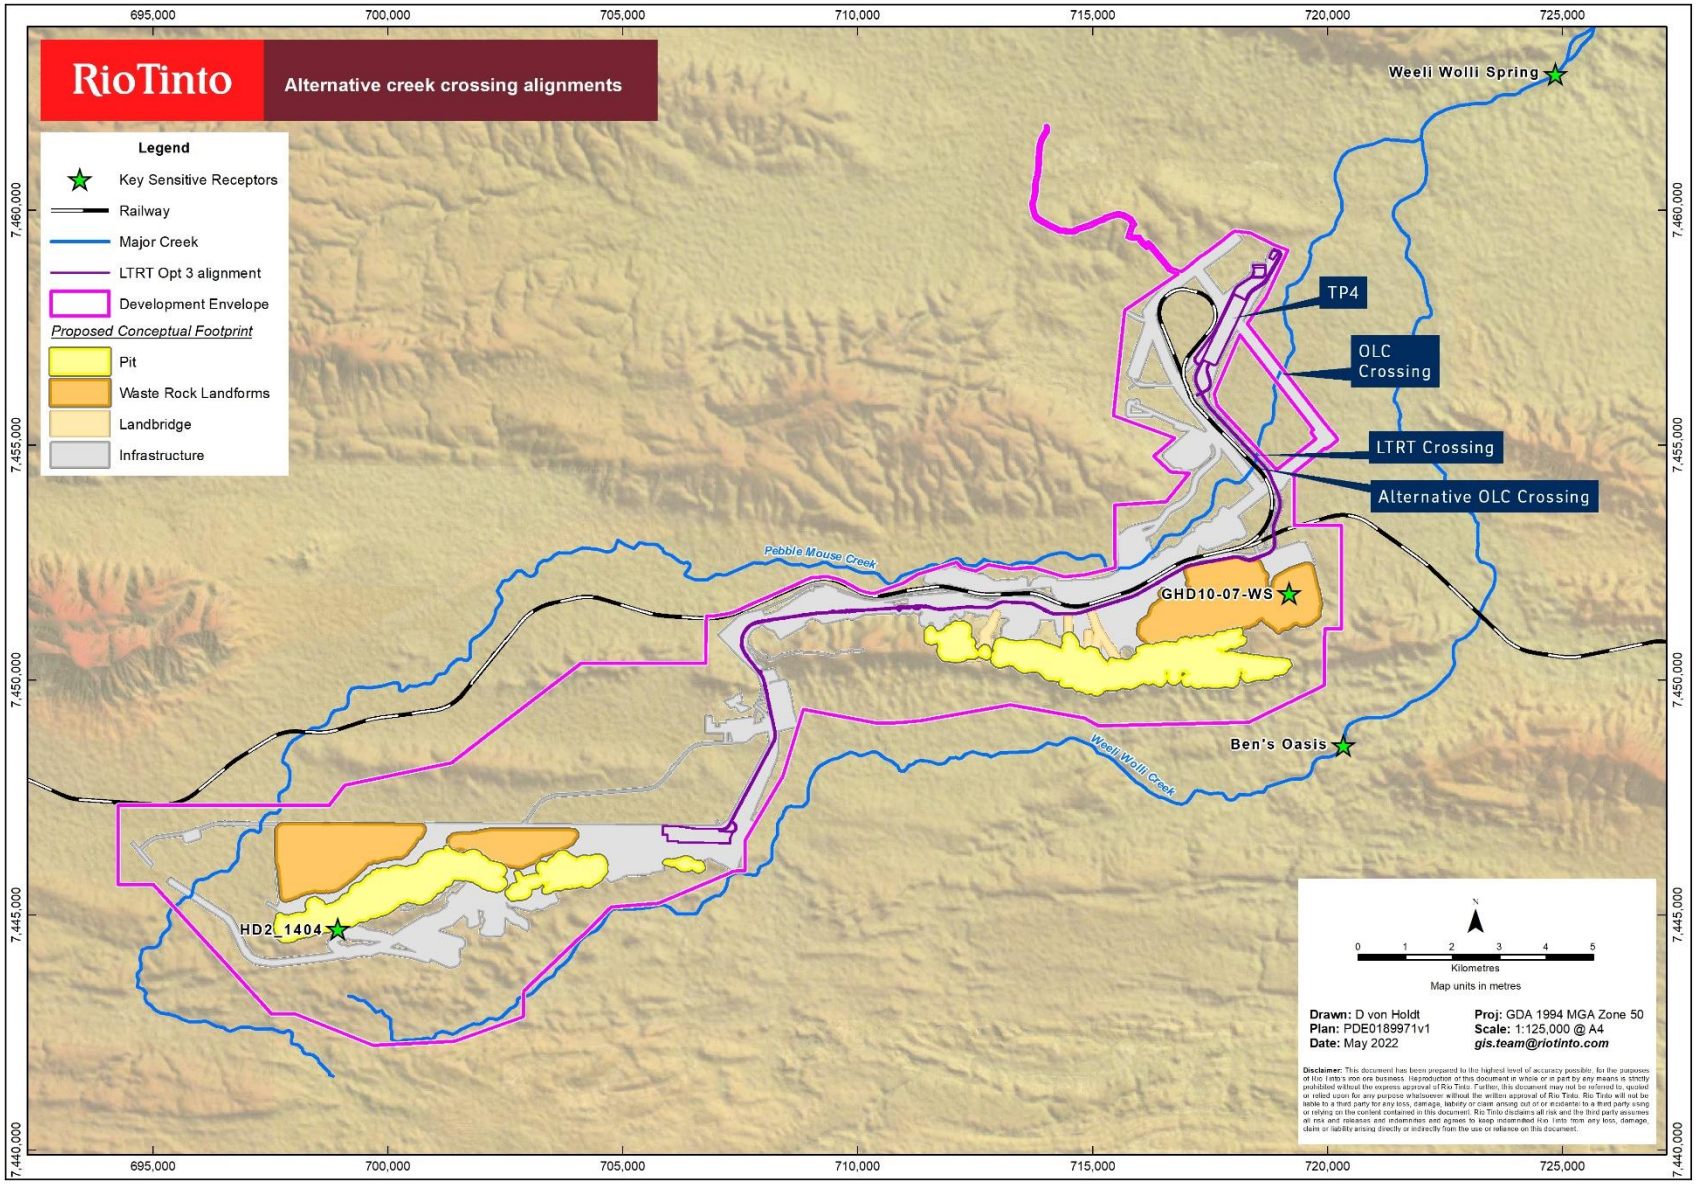

Figure 5: Alternative creek crossing alignments

4. KEY SENSITIVE RECEPTORS

Locations with heritage or environmental significance are referred to as sensitive areas or receptors. These locations require special consideration of the direct and potentially cumulative impact of all mining activities due to their high heritage or environmental value.

Regarding surface water, sensitive receptors may be impacted where modifications to the creek morphology or hydrologic regime adversely influence the heritage or environmental value of the site. The sensitive environmental receptors that have been identified as part of the HD2 Proposal are Weeli Wolli Spring and Ben's Oasis, and two waterholes situated within the Development Envelope. Locations for these sites are shown in Figure 2. The hydraulic modelling presented in this report was completed to assess the potential surface water impact on these receptors.

4.1. Weeli Wolli Spring

Weeli Wolli Spring is located approximately 7 km downstream of the confluence of Pebble Mouse Creek and Weeli Wolli Creek to the north-east of the study area. It is protected under the *Aboriginal Heritage Act 1972* and the riparian vegetation supported by the spring is categorised as a Priority 1 Ecological Community. The Spring was naturally groundwater controlled (pre-mining) and is currently maintained by discharge of surplus water from dewatering from HD1, which has occurred since 2007. Upstream of the permanent flowing portion of the Spring are several permanent and semi-permanent pools scattered over a distance of 2 km as illustrated in Figure 7.

Figure 6: Weeli Wolli Spring (photographed in October 2020)

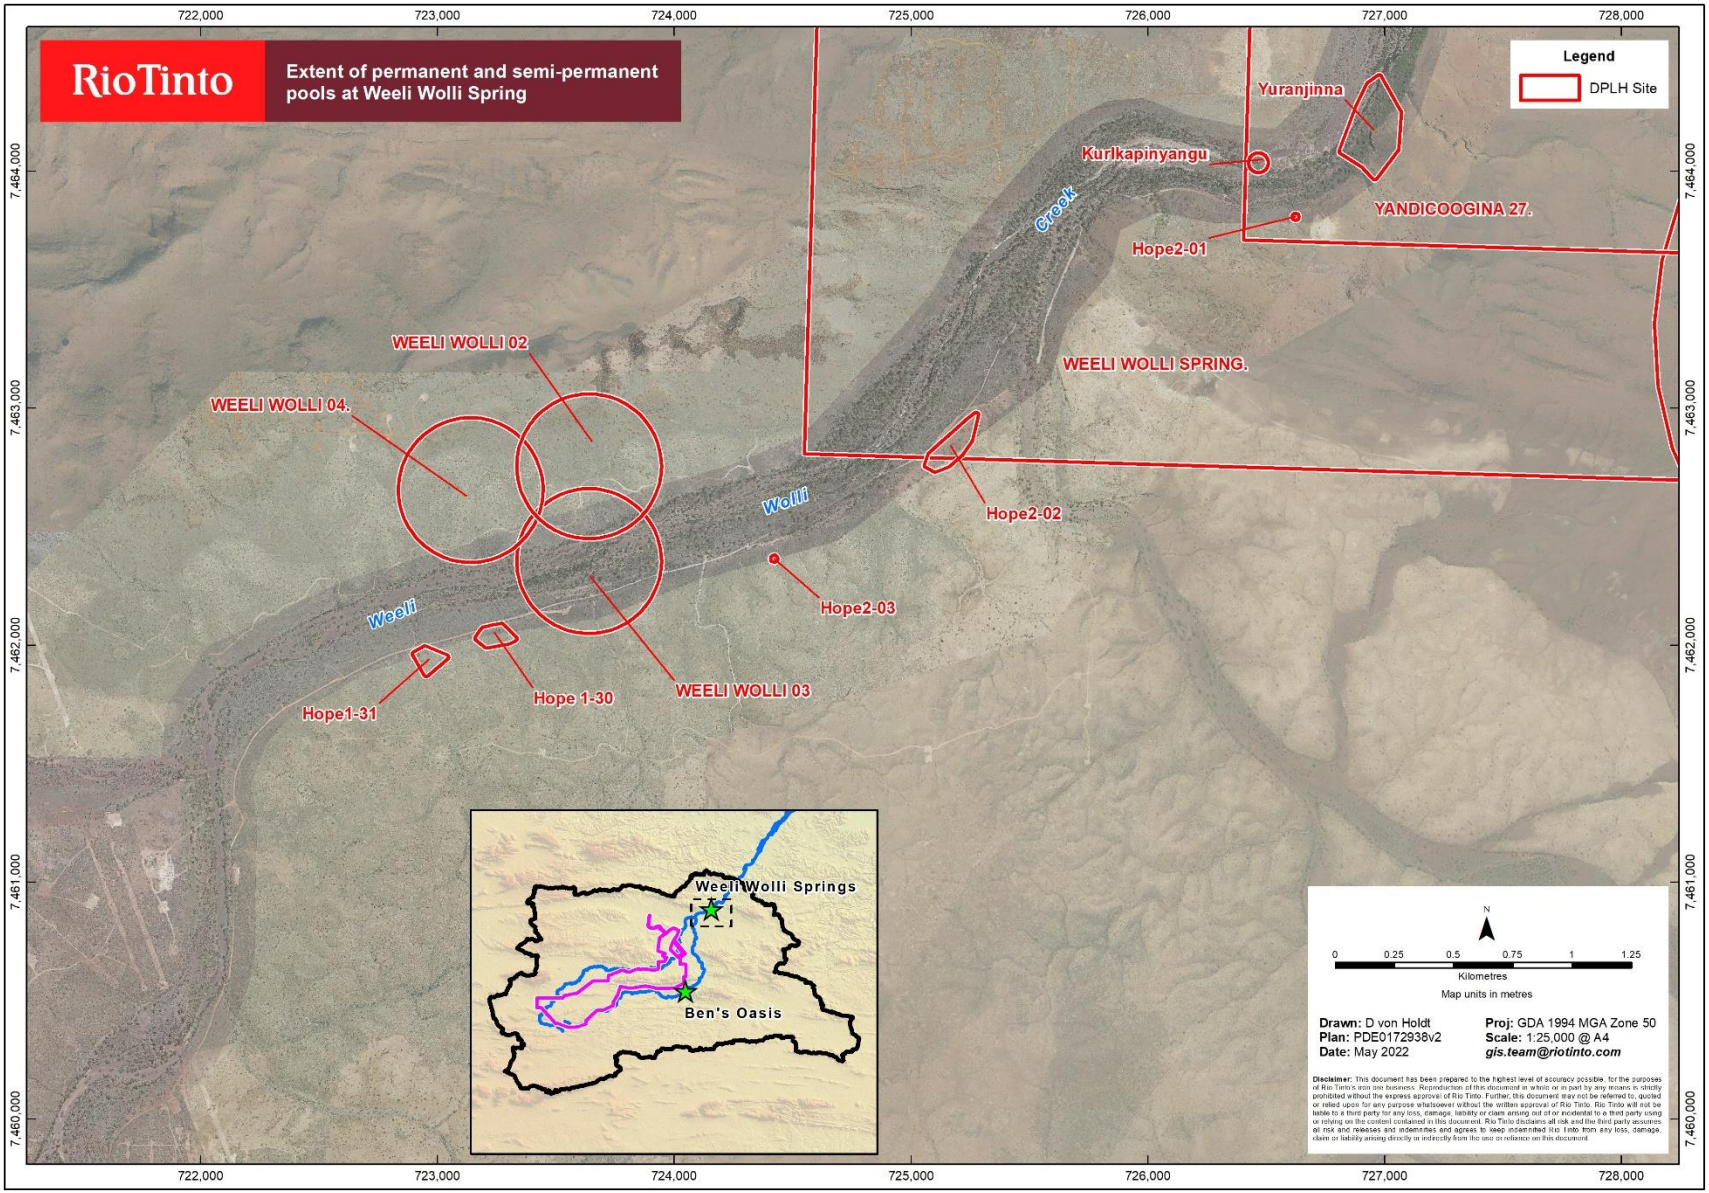

Figure 7: Extent of permanent and semi-permanent pools at Weeli Wolli Spring

Table 3 summarises the area reduction of the catchment reporting to Weeli Wolli Spring due to mining operations at both HD2 and BHT. The catchment area reduction incurred from mining the HD2 and BHT deposits will be approximately 45 km^2 based on the proposed pits and the placement of dumps provided in the current mine layouts. This area is equivalent to 3.5 % of the contributing catchment area to Weeli Wolli Spring. A catchment reduction of 3.5 % is considered relatively negligible and is therefore unlikely to impact the hydrological regime of this key sensitive receptor. Further validation of this assumption is provided in Section 6 where an impact assessment of peak flows and volumes is also discussed.

Table 3: Area reduction of catchment reporting to Weeli Wolli Spring

Mining Factor Affecting Catchment	Total Catchment Area (km^2)	Operational mining Catchment Area (km^2)	Area Reduction (km^2)	Difference (%)
HD2 & BHT pits, dumps	1,340	1,295	- 45	- 3.5

4.2. Ben's Oasis

Ben's Oasis is a significant environmental feature on Weeli Wolli Creek. Ben's Oasis is similar in function to Weeli Wolli Spring in that it is supported via groundwater expression as opposed to surface water.

Figure 8: Ben's Oasis (photographed in Jan 2019)

Table 4 summarises the area reduction of the catchment reporting to Ben's Oasis. The catchment area will be impacted by mining operations at only HD2. Proposed pits and dumps will result in approximately

6 km^2 catchment area reduction. However, this will be largely offset by the proposed HD2 diversion which would contribute an additional 5 km^2 of catchment reporting to Ben's Oasis. Therefore, the net contributing catchment area is reduced by 1 km^2, equivalent to 0.2 % of the total catchment. This is considered negligible and will have negligible impact to the flow regime at Ben's Oasis. This is discussed further in Section 6.

Table 4: Area reduction of catchment reporting to Ben's Oasis

Mining Factor Affecting Catchment	Total Catchment Area (km2)	Operational mining Catchment Area (km^2)	Area Reduction (km2)	Difference (%)
HD pits, dumps	420	414	- 6	- 1.4
HD2 diversion drains	420	425	+ 5	+1.2
	Net Changes	419	-1	- 0.2

4.3. Pebble Mouse Creek

Pebble Mouse Creek is considered to have cultural heritage significance, stemming from its use as a water source for people, plants, and animals and because it is a major tributary feeding into Weeli Wolli Creek. More consultation work is to be undertaken to completely understand the specific cultural heritage values and concerns associated with works impacting Pebble Mouse Creek.

Table 5 summarises the area reduction to Pebble Mouse Creek. About 8 % of this catchment will be reduced due to the proposed HD2 and BHT mining areas.

Table 5: Area reduction of the Pebble Mouse Creek catchment

Mining Factor Affecting Catchment	Total Catchment Area (km^2)	Operational mining Catchment Area (km^2)	Area Reduction (km^2)	Difference (%)
HD2 & BHT pits, dumps and diversion drains	340	26	314	- 7.6

4.4. Identified waterholes

Two water sources or waterholes are identified within the proposed Development Envelope: HD2_1404 and GHD19-07-WS. Their locations are shown in Figure 2.

HD2_1404 is in very close proximity to the HD2 deposit and has been described as a water source of ethnographic interest. The waterhole is 12 m by 17 m and is at least 1 m deep. The site was visited as part of the November 2021 Nyiyaparli Social Surroundings site visit. The waterhole was observed to be holding an indeterminate amount of water as shown in Figure 9.

Figure 9: Waterhole HD2_1404 (photographed in November 2021)

GHD19-17-WS is in relative proximity to the eastern end of the BHT deposit. The site is a series of five waterholes within a minor creek and measures 11 m by 17 m (covering 187 m^2). The site was also visited during the November 2021 Nyiyaparli Social Surroundings site visit. Two of the five waterholes were observed to be holding small amounts of water as shown in Figure 10.

Figure 10: Waterhole GHD19-07-WS (photographed in November 2021)

5. HYDRAULIC MODELLING

A two-dimensional hydraulic model was developed, using TUFLOW (build 2018-03-AB-iSP-w64 HPC), in order to characterise the surface water flow regime of Weeli Wolli Creek and Pebble Mouse Creek and assess potential impacts on water quantity at the sensitive receptors. The methodology and results are discussed below.

5.1. Methodology

A whole-of-catchment rain-on-grid hydraulic model was constructed for Weeli Wolli Creek, including the Pebble Mouse Creek catchment, to a downstream location of the Tarina gauge. An ensemble of simulations has been run with varying rainfall durations and temporal patterns for comparison with previous and updated rainfall-runoff model (RORB) results. However, for the purpose of this analysis, the adopted scenarios run for pre- and post-mining comparisons were the critical durations for the 1:5 and 1:100 AEP events.

The following input parameters were adopted for this assessment:

- Digital elevation model (DEM) – various LIDAR datasets mosaicked to cover the full model area
- Grid size – 20 m x 20 m, a coarse resolution was chosen to allow the full catchment to be adopted as the model domain, but limit model run times.
- Boundary conditions – height-flow (HQ) boundary downstream of Weeli Wolli Spring
- Roughness coefficient Manning's n – uniform 0.04
- Losses – initial loss of 35 mm/hr and continuing loss of 9 mm/hr (calibrated to match RORB peak flows)
- Scenarios run – pre-mining conditions and post-mining conditions including HD2 and BHT pits, haul roads, diversions and creek crossing
- Rainfall events – 1:5 AEP 12 hr TP04 and 1:100 AEP 24 hr TP02

Figure 11 illustrates the hydraulic model extent and downstream boundary location.

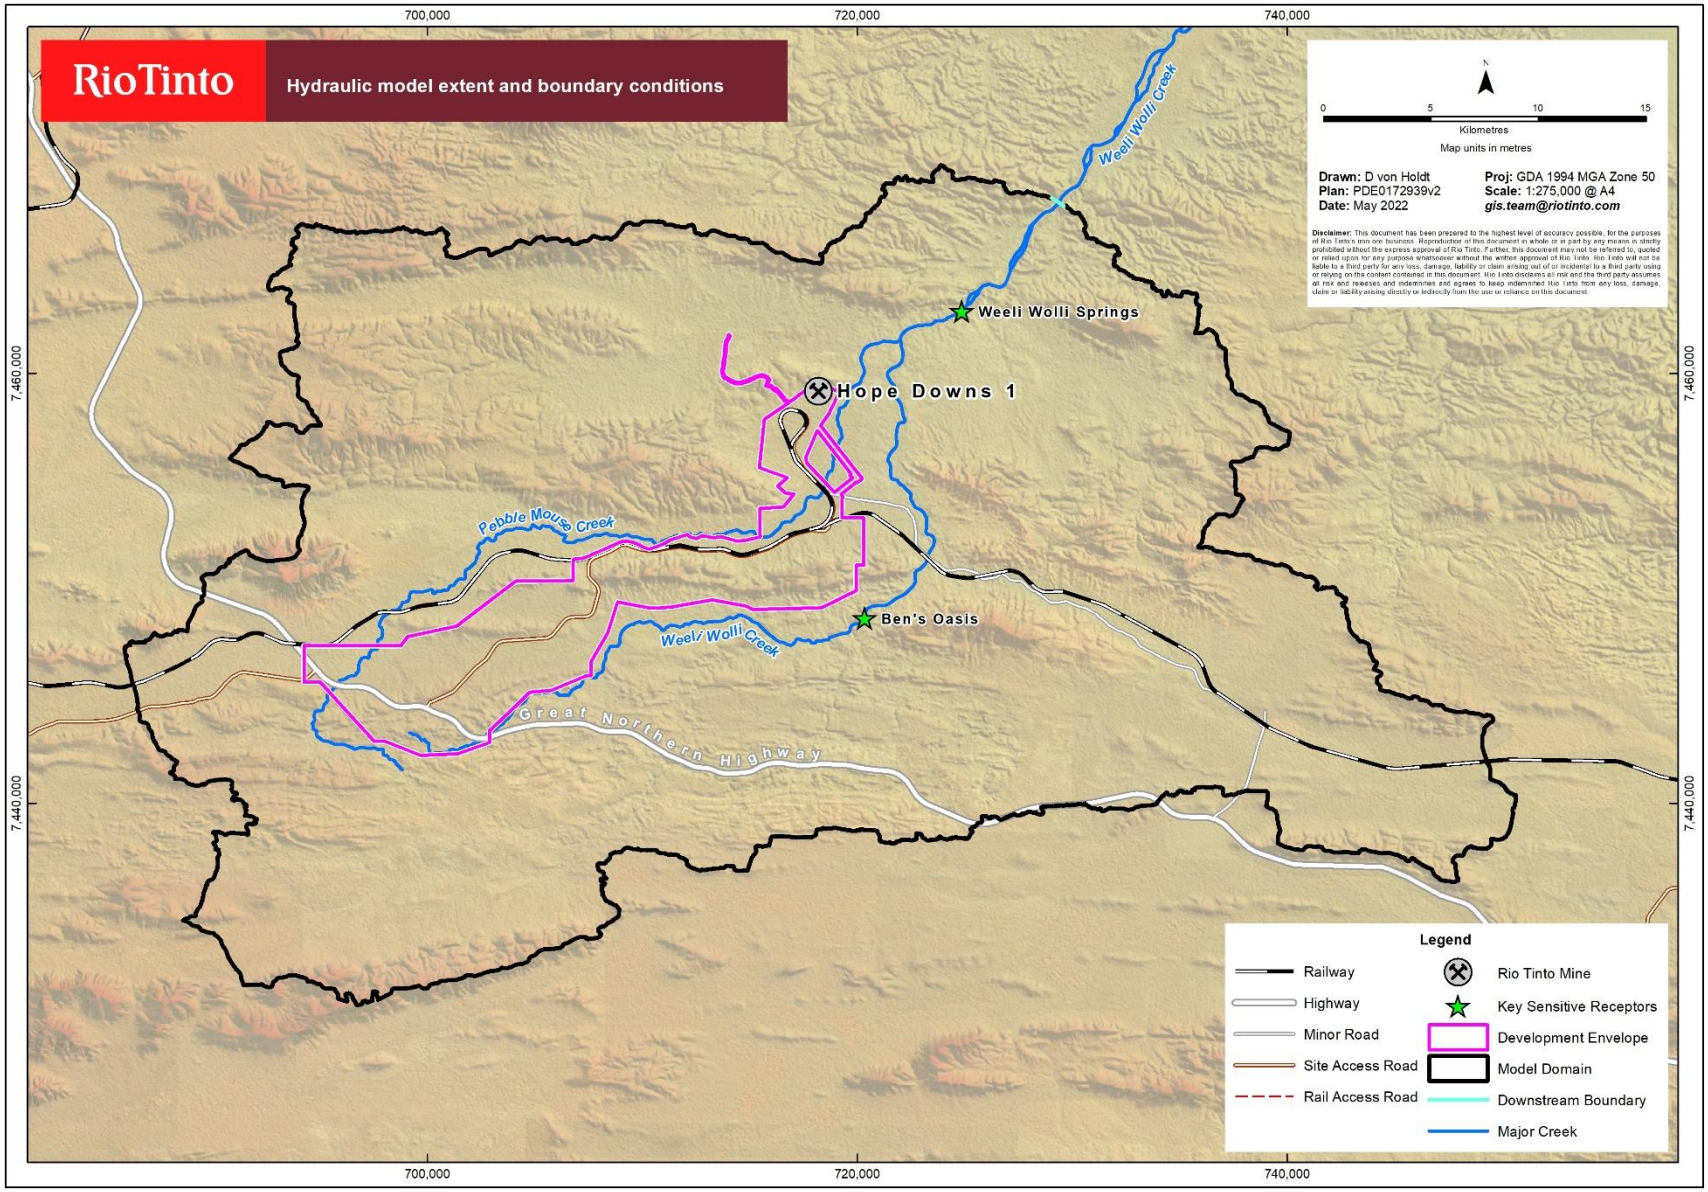

Figure 11: Hydraulic model extent and boundary conditions

5.2. Hydraulic Model Results

Results for the 1% AEP flood depths for pre mining, operational mining and a difference map are presented in Figure 12 to Figure 14. The difference map shows river reaches where modelled flood depths changed because of mining impacts.

Similar results for the 20% AEP flood depths are presented in Figure 15 to Figure 17.

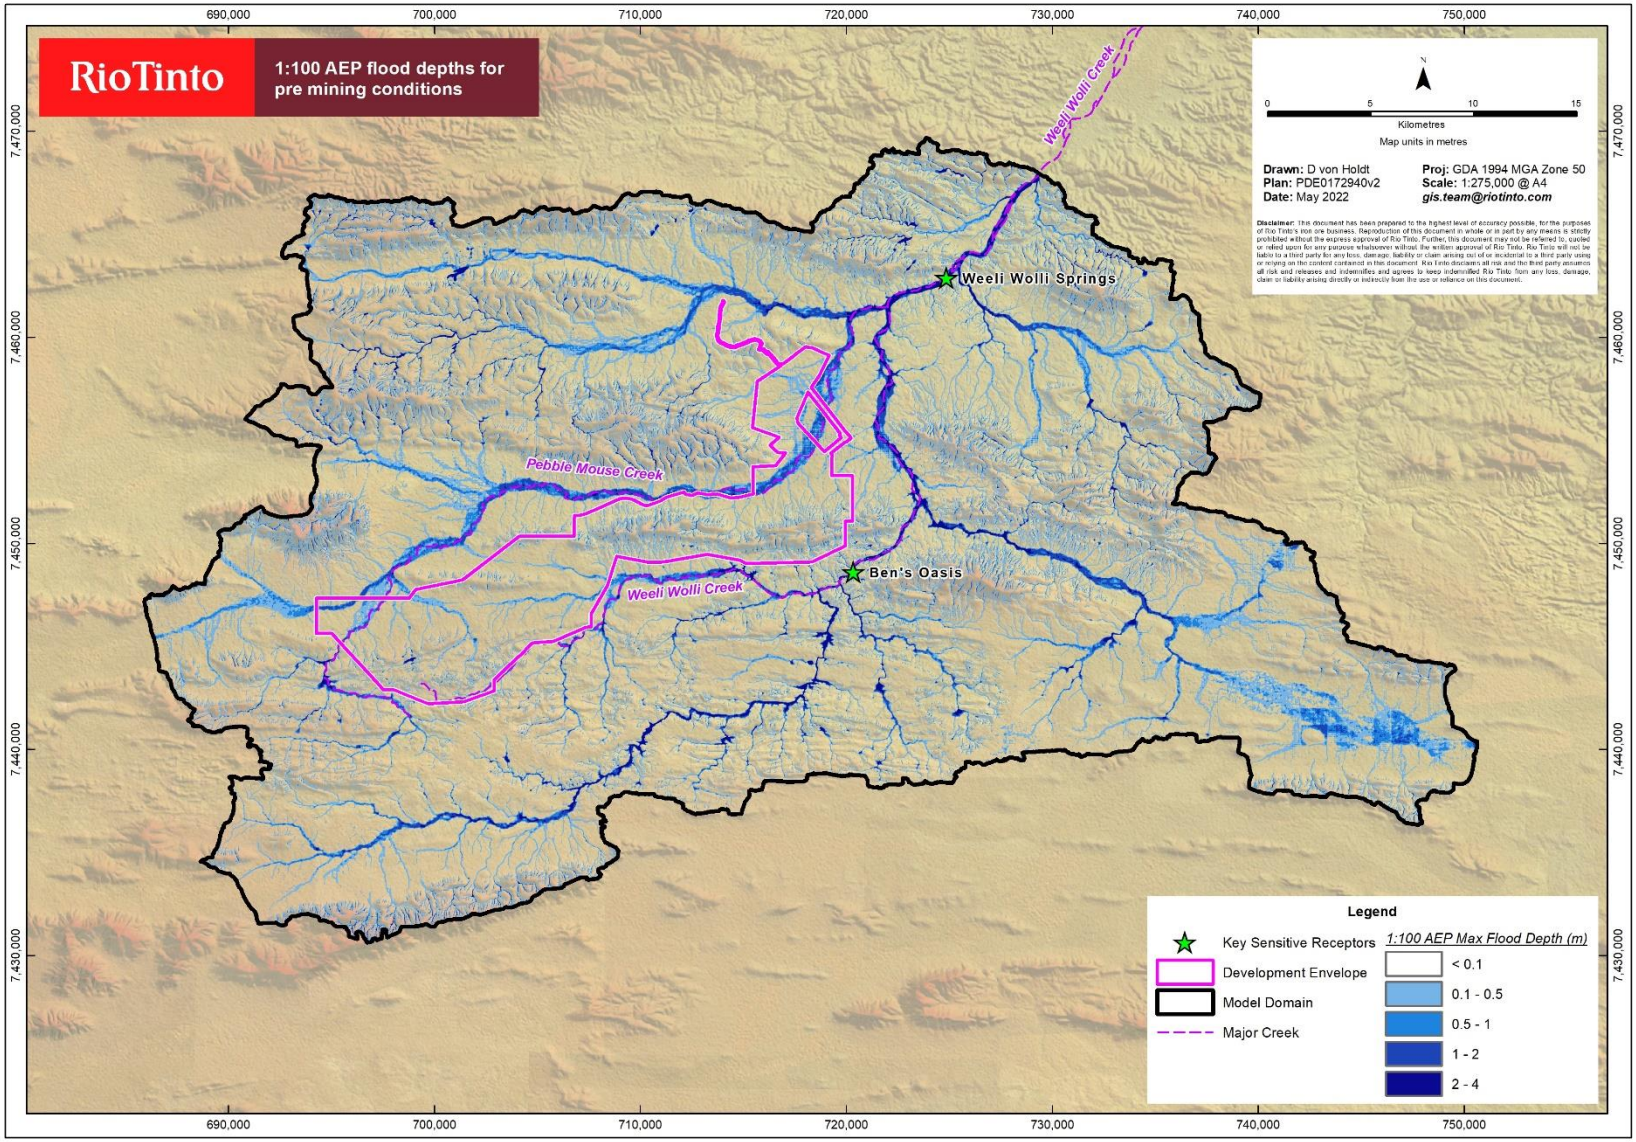

Figure 12: 1:100 AEP flood depths for pre mining conditions

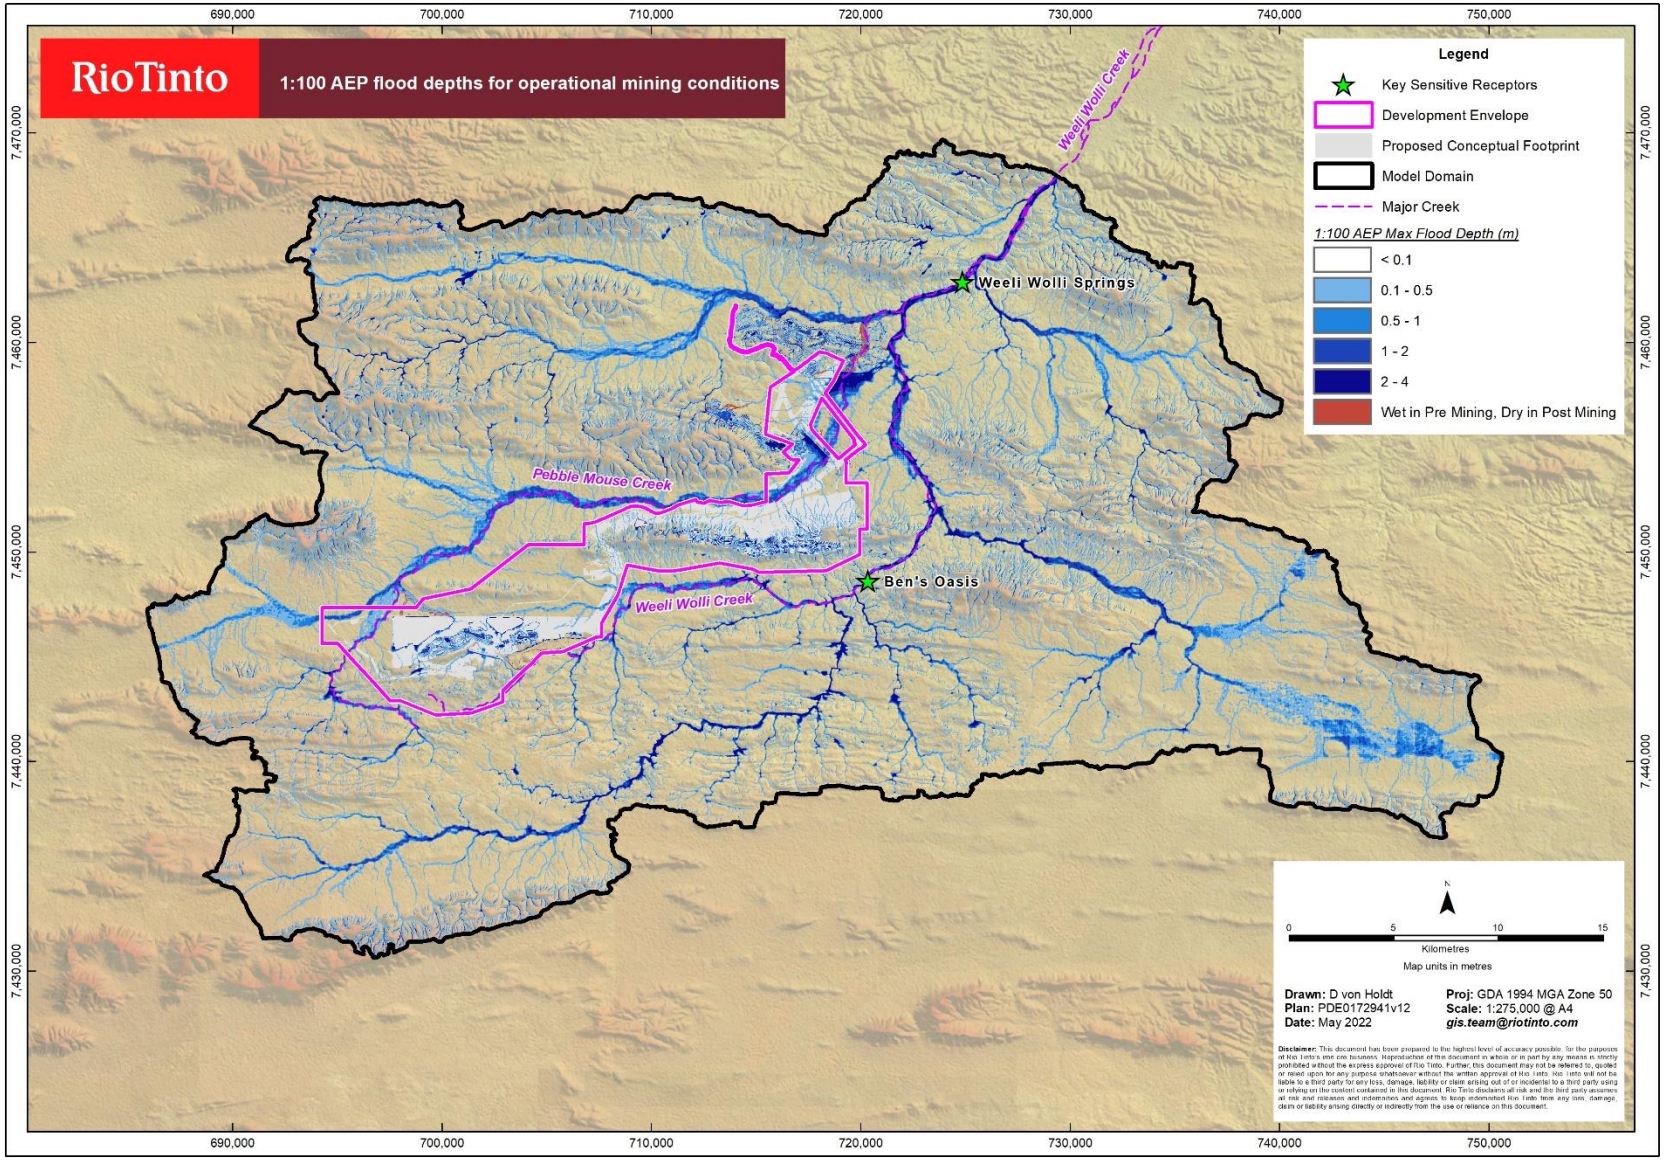

Figure 13: 1:100 AEP flood depths for operational mining conditions

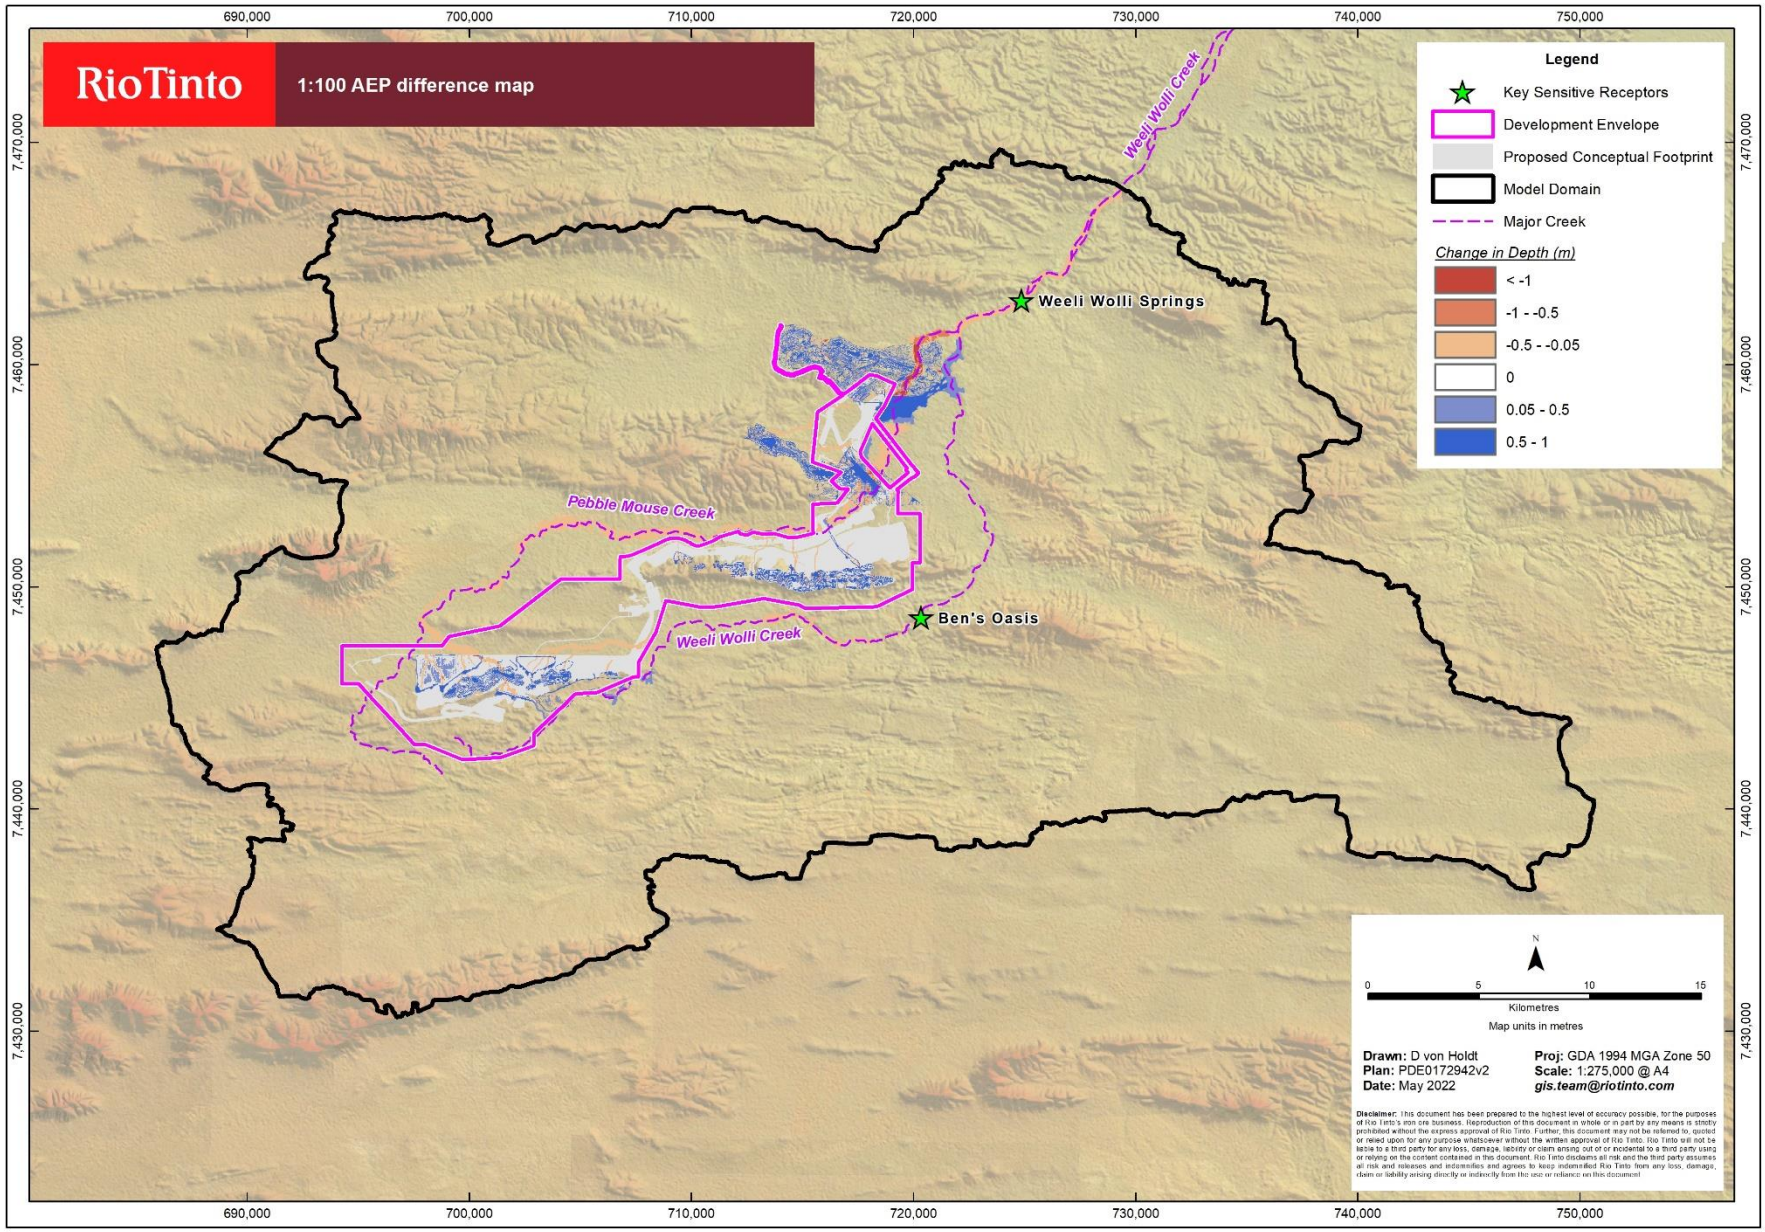

Figure 14: 1:100 AEP difference map

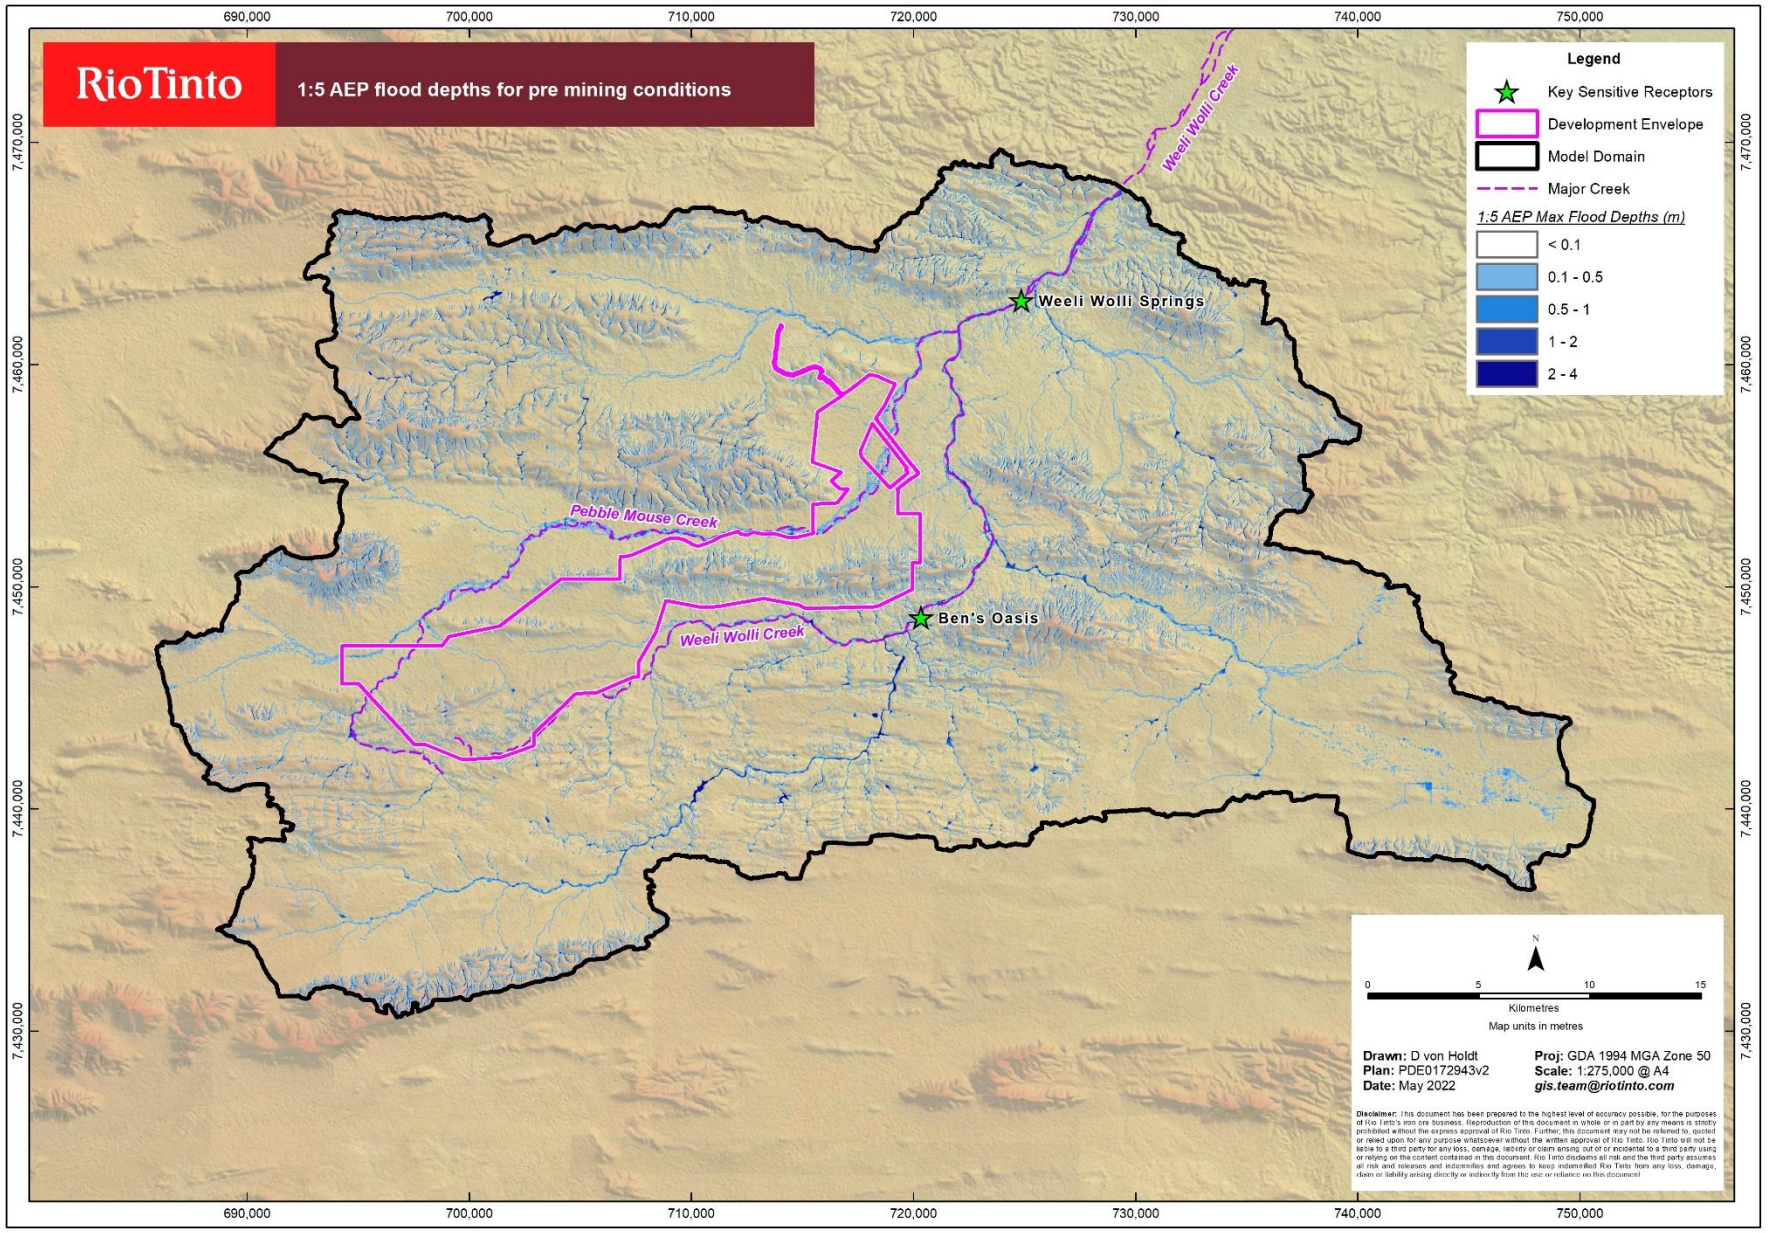

Figure 15: 1:5 AEP flood depths for pre mining conditions

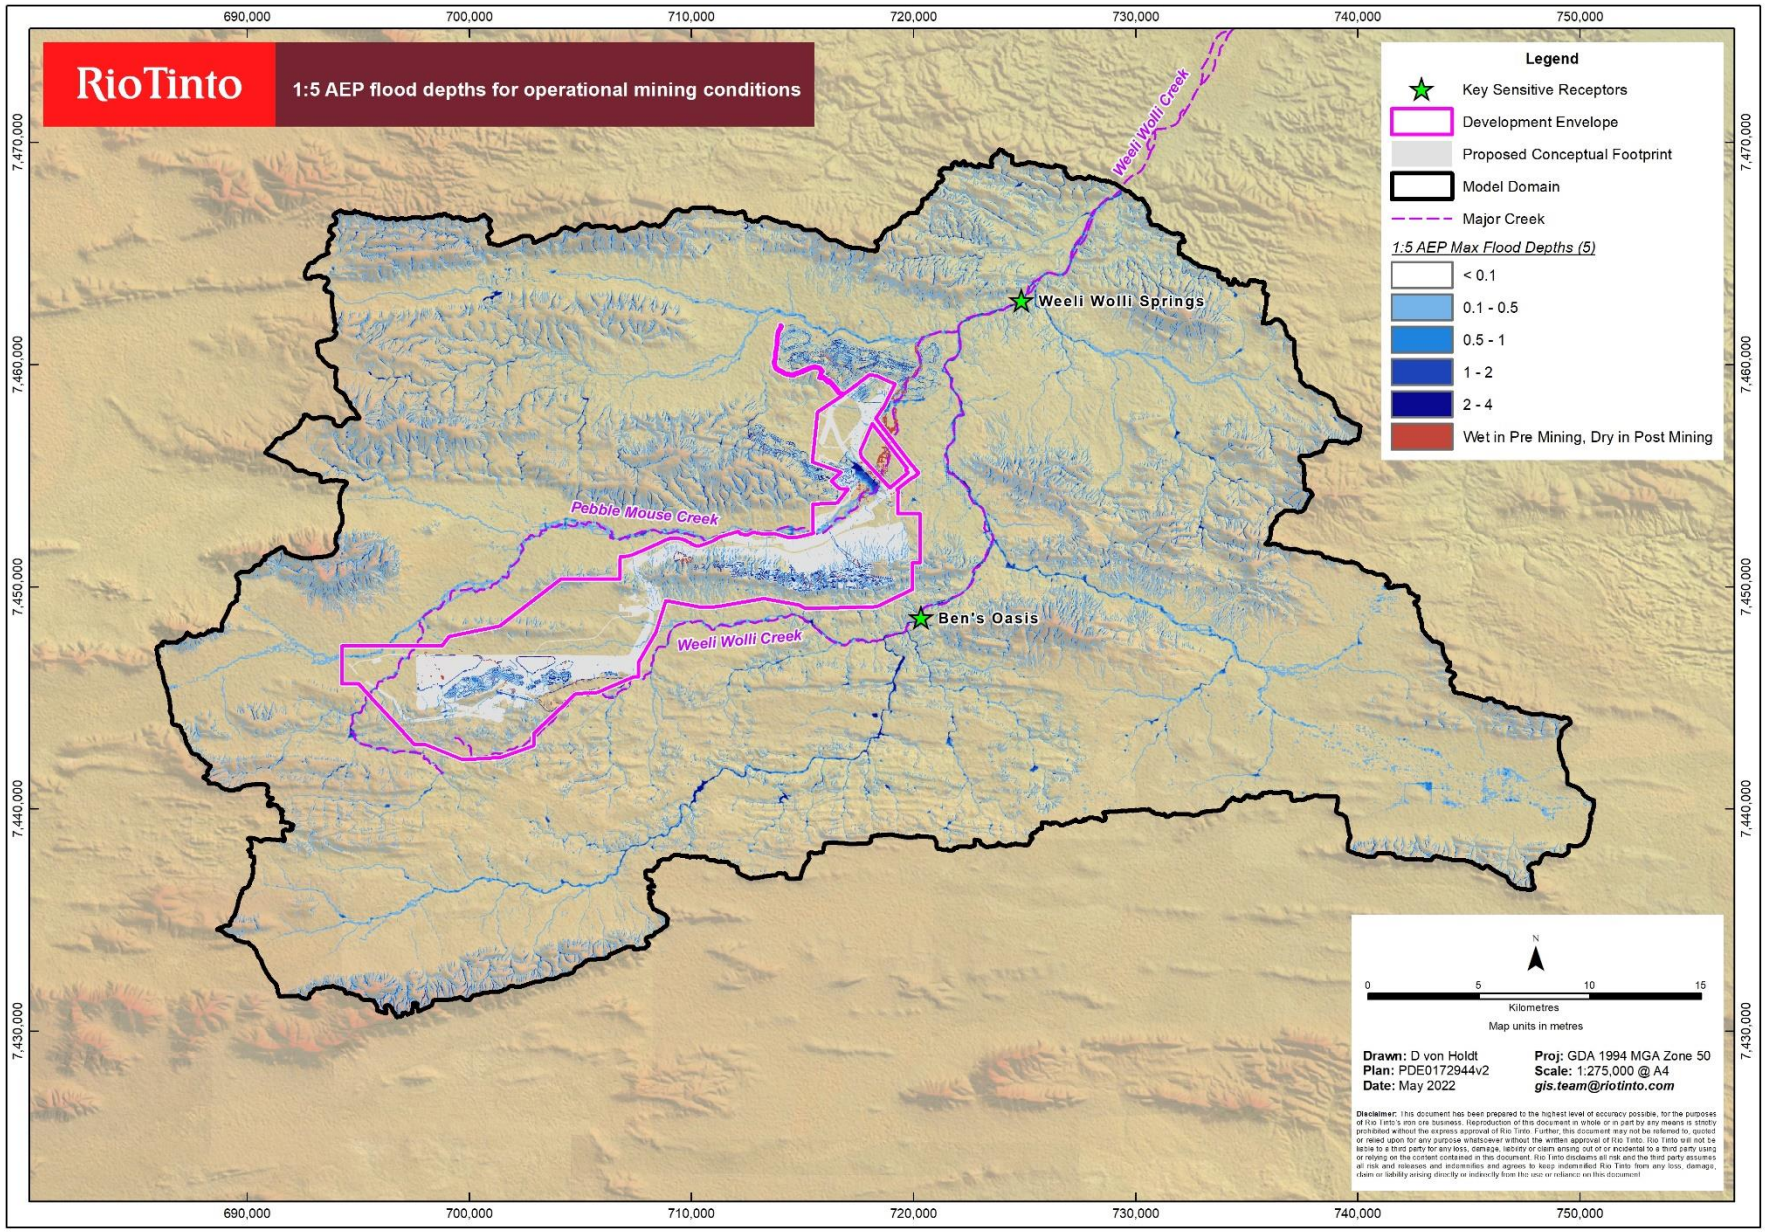

Figure 16: 1:5 AEP flood depths for operational mining conditions

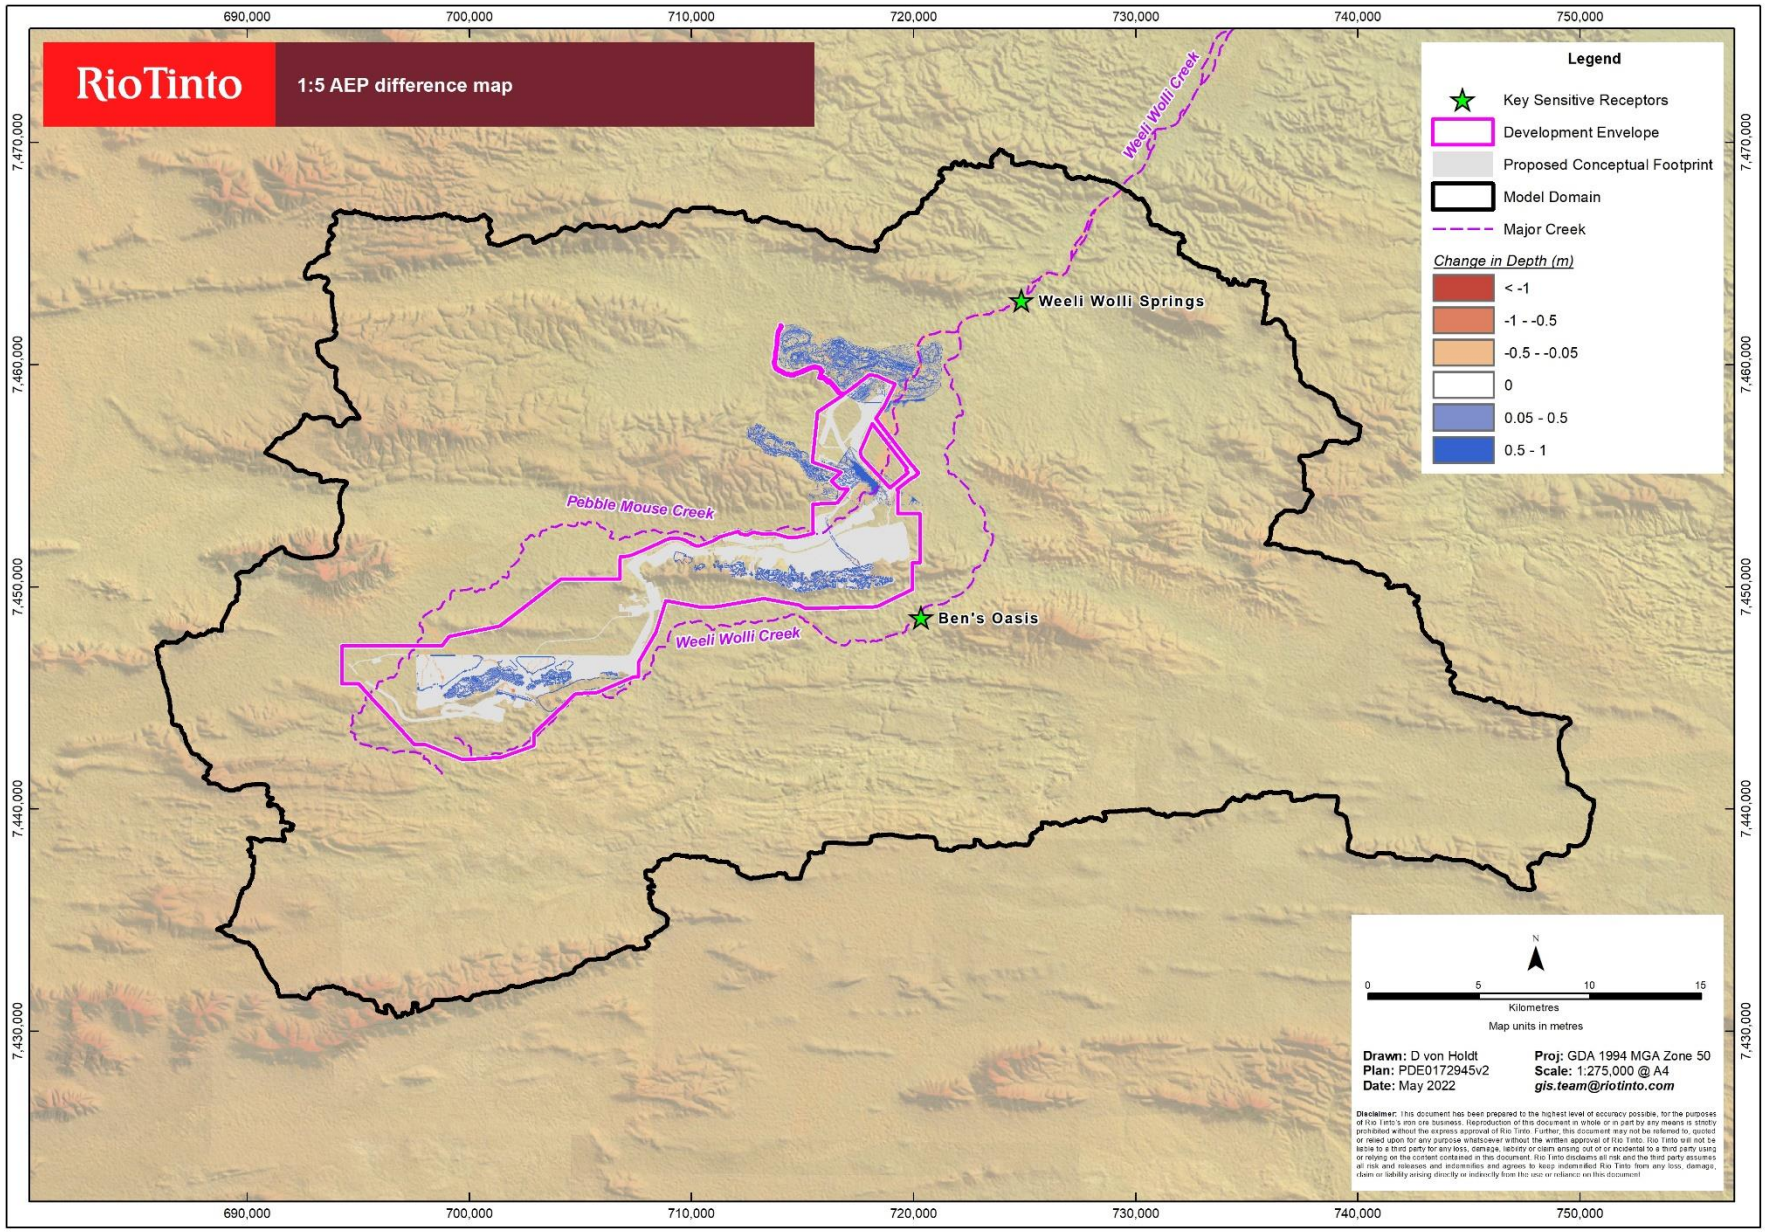

Figure 17: 1:5 AEP difference map

6. SURFACE WATER FLOW IMPACTS

6.1. Regional catchment

Difference mapping (discussed above) has highlighted the areas within Pebble Mouse Creek and Weeli Wolli Creek that are likely to experience a change in maximum surface water depths in the operational mining scenario. As expected, depths have increased at the location of HD2 diversion drains, which is predicted to result in a reduction to depths by less than 0.1 m in Pebble Mouse Creek directly north of the HD2 pits. The attenuation of surface water upstream of the Pebble Mouse Creek haul road crossing is predicted to result in an increase of depths in this area of up to 1 m. Depths downstream of the crossing appear to be impacted only slightly, with the difference map indicating a maximum decrease of 0.1 m for the 1:100 AEP.

6.2. Key sensitive receptors

A comparison of peak flows modelled, for critical duration storms at the key sensitive receptors for pre- and operational mining conditions. is provided in Table 5 and total volumes are compared in Table 6.

Table 5: Peak flows at the key sensitive receptors

Location	Event	Pre mining (m^3/s)	Operational mining (m^3/s)	Difference (m^3/s)	Difference (%)
Weeli Wolli Spring	1:100 AEP 24 hr	2,474	2,438	- 36	- 1.4
	1:5 AEP 12 hr	148	135	- 12	- 8.1
Ben's Oasis	1:100 AEP 24 hr	921	911	- 10	- 1.1
	1:5 AEP 12 hr	55	53	- 2	- 3.6

Table 6: Total modelled volumes at the key sensitive receptors

Location	Event	Pre mining (GL)	Operational mining (GL)	Difference (GL)	Difference (%)
Weeli Wolli Spring	1:100 AEP 24 hr	25.2	24.7	- 0.5	- 2
	1:5 AEP 12 hr	0.8	0.6	- 0.2	- 25
Ben's Oasis	1:100 AEP 24 hr	7.1	7.0	- 0.1	- 2
	1:5 AEP 12 hr	0.33	0.31	- 0.02	- 7

As previously discussed in Section 4.1, mining operations at HD2 and BHT (including proposed dumps) will truncate approximate 45 km^2 of the total catchment reporting to Weeli Wolli Spring. This equates to a reduction of 3.5 % in the catchment reporting to Weeli Wolli Spring. Modelling has shown that the truncation will result in the loss of approximately 2 % of the total runoff volume at the spring for the 1:100 AEP 24 hour flow event of Weeli Wolli Creek. Peak flows at the spring for this event will decrease by 36 m^3/s, equivalent to a 1.4 % reduction. Modelled flow reductions for the 1:5 AEP event is slightly higher, with an

estimated 8.1 % reduction in flow. It should be noted that this reduction is not only the result of the changes due to the proposed HD2 mining activities but a cumulative impact from both HD1 and HD2 mining activities. Water levels (and therefore volumes) at Weeli Wolli Spring are supplemented by dewatering discharge from a series of spur lines running off the main discharge pipe to Weeli Wolli Creek. There are several monitoring locations in this area used to ensure water levels at the Spring are maintained. This discharge to the creek and the spur lines will continue for the operating life of HD2 therefore the modelled reduction to flows at the Spring is unlikely to be observed and the environmental and heritage values associated with the Spring are expected to be maintained.

Regarding Ben's Oasis, the total net change to the catchment reporting to this location is a reduction of approximately 1 km^2. Modelling indicates this will result in a reduction to the peak flow at Ben's Oasis by approximately 10 m^3/s or 1.1 % during a 1:100 AEP. Flow (volume) reduction observed for the 1:5 AEP is equivalent to a 3.6 % reduction. This limited loss of runoff is not expected to impact the environmental value of Ben's Oasis as the main source of water at this location is sustained by the groundwater aquifer.

6.3. Waterholes

Although the physical location of the HD2 waterhole (HD2_1404) will remain during the operational mining period, flows to this location will be impacted. The HD2 diversion levee is directly upstream of HD2_1404 and will reduce flow rates and volumes experienced at the waterhole. Modelling results indicate that during a 1:5 AEP rainfall event, maximum flows at the waterhole are reduced by 28 %. During a 1:100 AEP event, maximum flows are reduced by 59 %.

Reductions to flow rates experienced at waterholes is not the only factor to consider when commenting on potential adverse impact. The capacity of the pool compared to the catchment yield volume is important to understand. Typically, waterholes of this size in the Pilbara will have relatively large upstream catchments contributing to the volume of water present in them. Direct rainfall onto the pool during heavy rainfall can have the ability to completely fill a small waterhole, with flow from the upstream catchment overtopping the pool and continuing to flow downstream. Analysis of multiple pools located in the Western Ranges, near Paraburdoo, using a long-term rainfall data set, demonstrated that, pending the size of catchment and capacity of waterhole, a pool can lose 80 – 85% of its upstream catchment and remain functioning in a wetting and drying cycle similar to historically cycles (undisturbed by mining activities). Therefore, similar modelling of HD2_1404 is recommended to understand the extent of impact it may experience due to the proposed HD2 mining activities. This worked is planned for the next study phase.

The BHT waterhole (GHD19-17-WS) will be directly impacted by proposed mining activities. The site is in the middle of a proposed waste dump; therefore, the waterhole will no longer exist.

Social, cultural and environmental values of both waterholes have been discussed with Traditional Owners through the Social Surroundings consultations. Significant work relating to pit and dump designs will be required if these sites are to remain unaffected by the proposed mining activities. These discussions are ongoing at the time of writing this report.

7. WATER QUALITY IMPACTS

Water quality in naturally occurring pools across the Pilbara can be highly variable due to the following factors: water supply (rainfall, creek flow, alluvial groundwater or groundwater structure); the preceding climate (drought/flood history, recent groundwater recharge); and interaction with livestock.

Furthermore, erosion is a naturally occurring process in Pilbara watercourses. This is indicated by the fact that the Pilbara ephemeral creeks typically have high sediment bed loads in their natural state and is further reflected by the range of turbidity values in water quality data collected in the region. Table 7 summarises the historic Department of Water and Regulation (DWER) water quality data collected across all Pilbara water courses. Figure 15 illustrates natural turbidity observed in Weeli Wolli Creek following rain event.

Table 7: Surface water quality values recorded across the Pilbara

	Pilbara Wide (DWER)	
	Minimum	Maximum
pH	5.2	9.4
EC (us/cm)	3	6090
Turbidity (NTU)	0.1	3200
TDS (mg/L)	22	3932

Figure 18: Examples of natural turbidity within Weeli Wolli Creek

7.1. Water quality assessment

The primary source of potential water quality impact to the key sensitive receptors is liberation of additional sediment load to the watercourse. The biggest risk is associated with the proposed haul road crossing of Pebble Mouse Creek, given waste dumps are located further away from the main creeks. Liberation of sediment could occur in the unlikely event that a haul road crossing is washed out during a heavy rainfall event. The pathway from this source to the key receptors is a significant distance of ephemeral creek line – the proposed Pebble Mouse Creek haul road crossing is 14 km upstream of the Weeli Wolli Spring; the proposed road train crossing is 11 km upstream; and the proposed transfer pad and creek diversion levee is 7 km. These distances provide significant opportunity for sediments to be captured within creek and floodplain prior to reaching Weeli Wolli Spring, therefore reducing sediment load expected to reach the Spring.

It is considered unlikely that water quality at the key sensitive receptors identified in this study will be impacted by mining development at HD2 and BHT. To assess the credibility of this potential risk, a qualitative analysis of potential sediment transport from the Pebble Mouse Creek haul road and road train crossings to Weeli Wolli Spring is presented here.

7.2. Sediment transport in ephemeral creeks

Sediment transport in ephemeral creeks generally occurs as a pulse in response to runoff generated by the short duration, high intensity rainfall events (typically rare rainfall events) (Levick et al. 2008). Due to the common presence of bed armouring in ephemeral creeks, in particular channels formed in unconsolidated alluvium comprised of sands and gravel, the bulk of sediment transported generally comprise of the channel bed material (made available for transport once the armour layer has been mobilised) and sediments stored in alluvial plains and floodplains.

Once the armour layer has been mobilised and bed flushing occurs, flows generated by high intensity rainfall events are more likely to contain heavy sediment loads with the potential to move large amounts of coarse sediment through the system. Two consequences of this occurring during such events include large transmission losses and decreasing discharge in the downstream direction, both of which promote the stepwise movement, deposition, and storage of sediment. The effect is a pulsing style of sediment movement that can be remobilised during the next flow (Levick et al. 2008).

This style of sediment movement is likely to be a characteristic of Pebble Mouse Creek in its pre mining condition. The application of this concept to the washout of an engineered crossing and mobilisation of significant loads, in addition to natural sediment loads, may be relevant due to the large amount of coarse material likely to be used in the construction of the crossing. However, it should be noted that rock armouring is likely to also feature in the construction of the crossing.

7.3. Factors affecting the Pebble Mouse Creek flow path

An important factor to consider when assessing the likelihood of sediment loading from the haul road and road train crossings impacting Weeli Wolli Spring is the flow path from the source to the receptor and existing infrastructure. The 14 km reach of Pebble Mouse Creek between the haul road crossing and Weeli Wolli Spring is intersected initially by the HD1 rail line; then the road train crossing directly downstream of the rail line; and then diverted by the HD1N levee (known as the “100 year levee”) before flowing to its confluence with Weeli Wolli Creek.

The HD1 rail line crossing is approximately 3 km downstream of the haul road crossing, consisting of 28 DN2700 culverts with projecting inlets. Experiments conducted by Faqiri (2014) found that, while projecting inlets typically provide a lower culvert capacity compared to winged wall or cut inlets, these culverts are

still capable of transporting sediment downstream. However, the inlet geometry is not the only factor affecting sediment transport through culverts. The flow condition directly upstream of the culvert (the area referred to as the expansion section) is also a determining factor. Low velocity, deeper flows were found to result in an increase of sediment deposition at the culvert expansion section compared to high velocity flows, mainly because of low velocities allowing sediments to drop out and settle. Hence, for sediment to be effectively transported through culvert barrels, flow regimes with high velocities and low depths are required. The HD1 rail line crossing is expected to reduce flow velocities, resulting in some sediment deposition upstream of and at the rail culverts, with reduced sediment loads carried downstream of the rail crossing.

The inclusion of the road train crossing (with culverts) directly downstream of the rail line presents an additional expansion section and compounds the effect of sediment deposition upstream of the culverts. Therefore, having a second set of culverts at this location would further reduce sediment loads carried downstream.

7.4. Hydraulic modelling

Hydraulic modelling has been used to assess the flow regime along Pebble Mouse Creek focussing on the characteristics of flow observed at the haul road crossing as well as the HD1 rail crossing. Using similar hydrological inputs to the regional model previously discussed, a refined model domain was adopted for this assessment as well as a higher resolution grid size (5 m). Pre and operational mining scenarios were run for the 1:5 and 1:100 AEP events.

Operational mining infrastructure included the Pebble Mouse Creek haul road crossing low flow design as this was considered the most credible scenario, compared to the other options, to release a source of increased sediment load to the creek system following a crossing failure.

A separate modelling scenario was run to assess the inclusion of the LTRT Option 3 alignment and its impact to flows in Pebble Mouse Creek.

Figure 19 illustrates the model extent and downstream boundary location of the refined model domain.

7.5. Results

Results of the maximum depths and velocities modelled at the haul road crossing and HD1 rail crossing for the 1:100 AEP and 1:5 AEP are shown in Figure 20-21 and Figure 22-23, respectively.

Results of the maximum depths and velocities modelled at the LTRT Option 3 creek crossing and transfer pad (TP4) for the 1:100 AEP are shown in Figures 24 and 25.

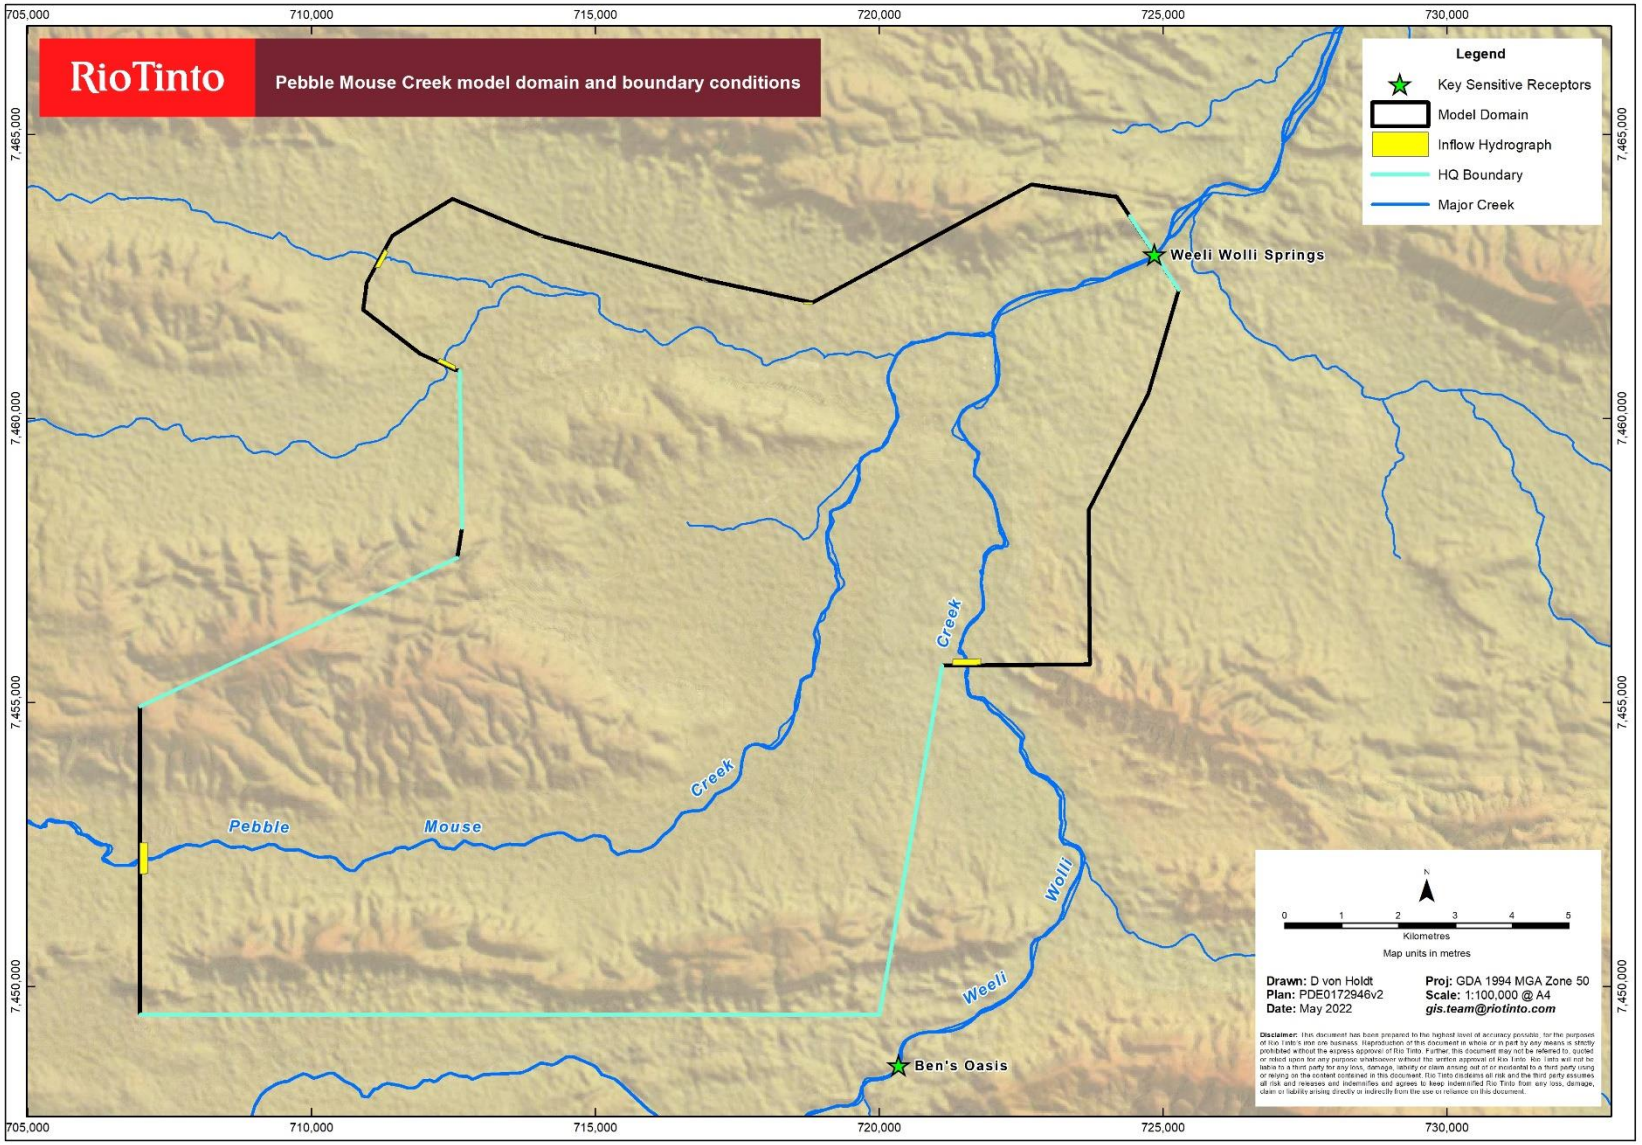

Figure 19: Pebble Mouse Creek model domain and boundary conditions

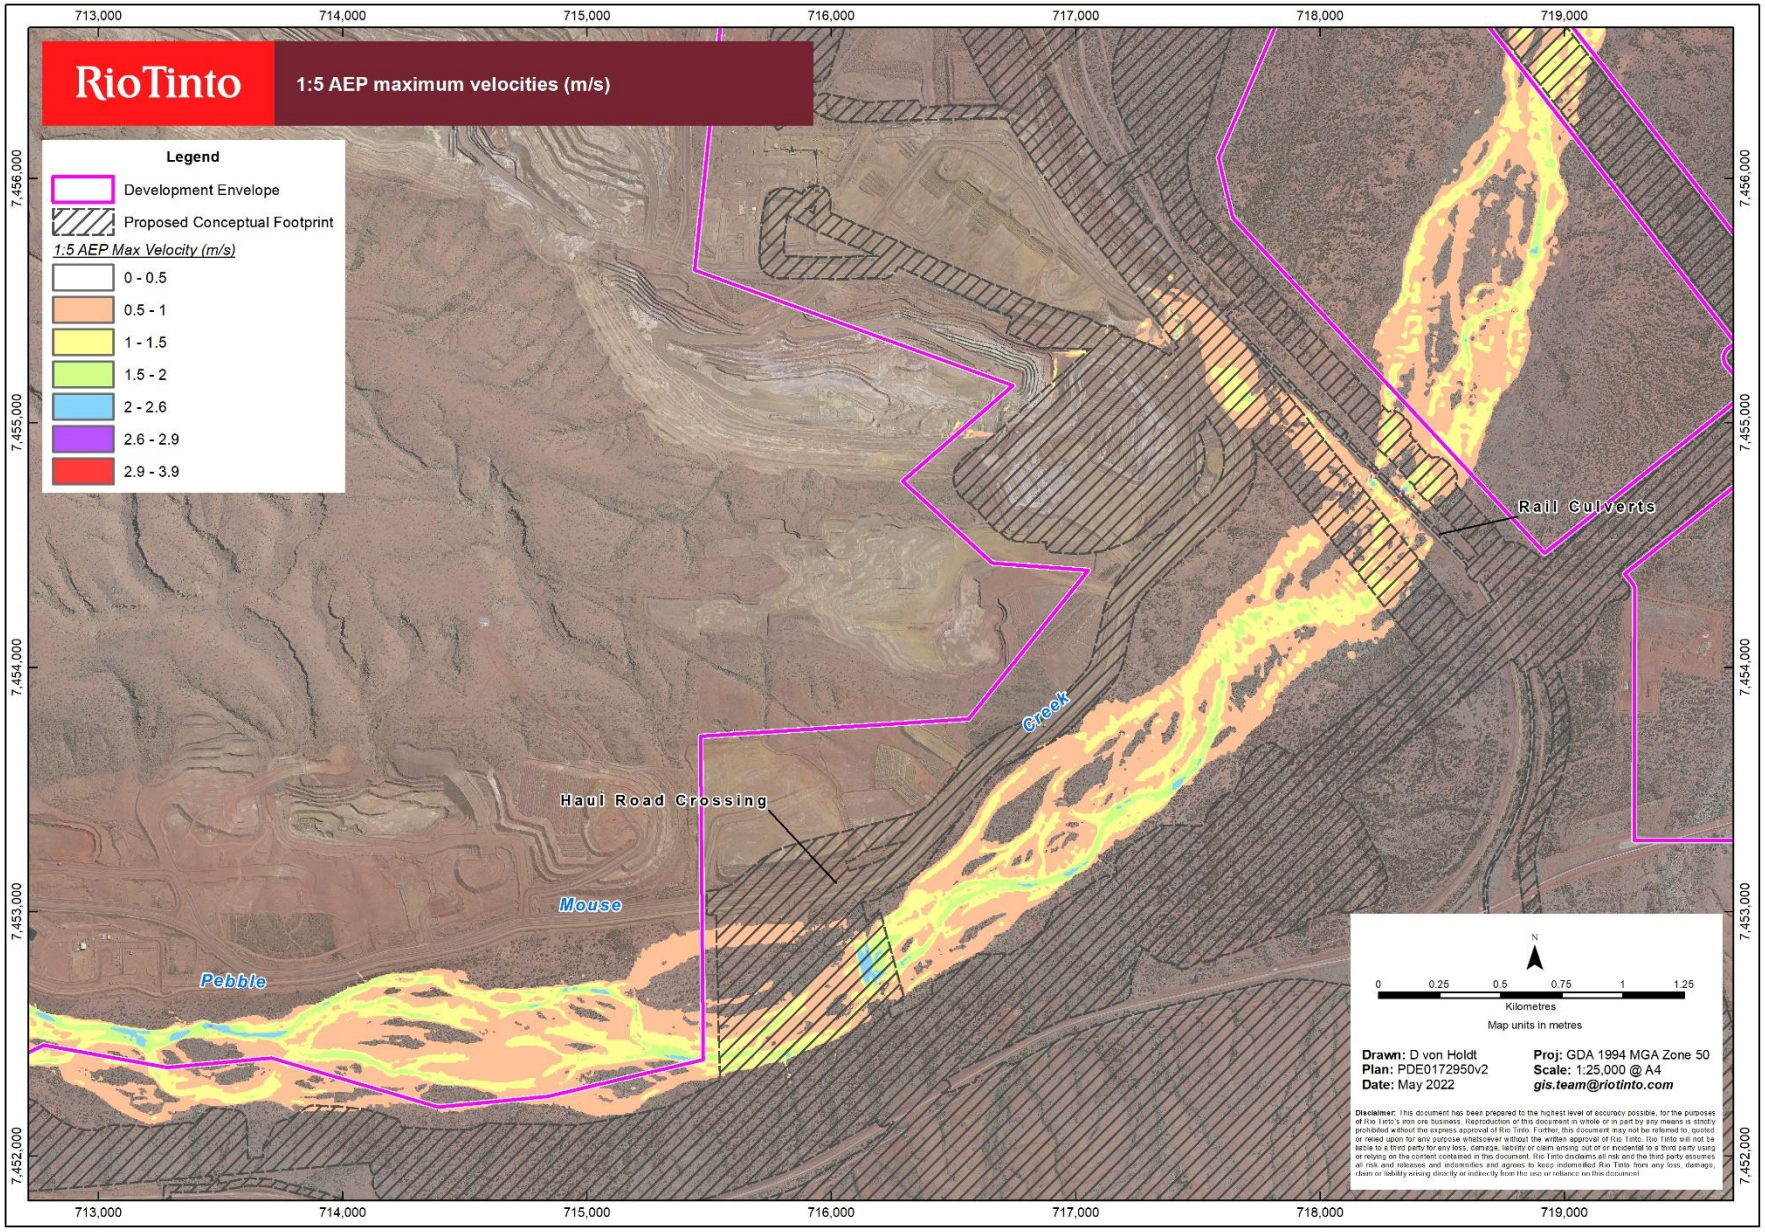

Figure 23: 1:5 AEP maximum velocities (haul road crossing)

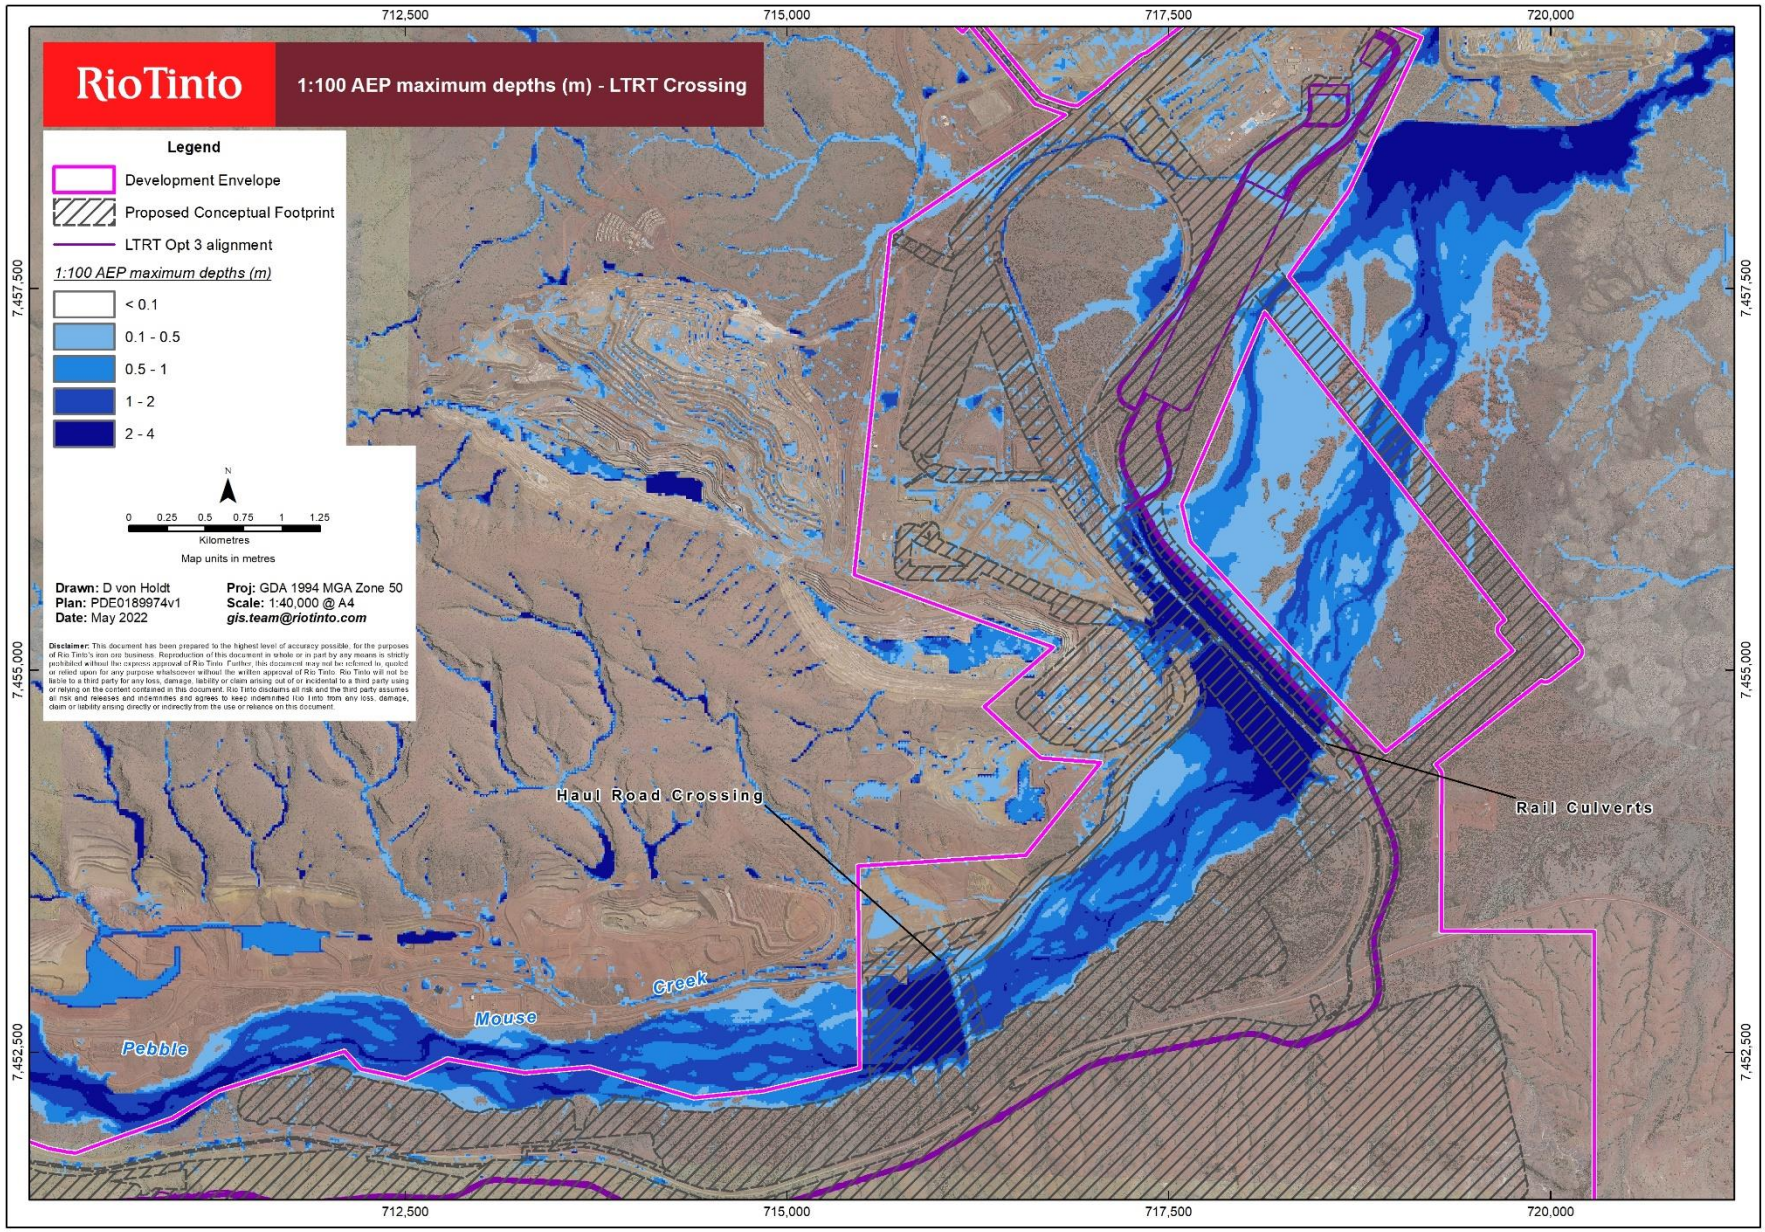

Figure 24: 1:100 AEP maximum depths (LTRT Crossing)

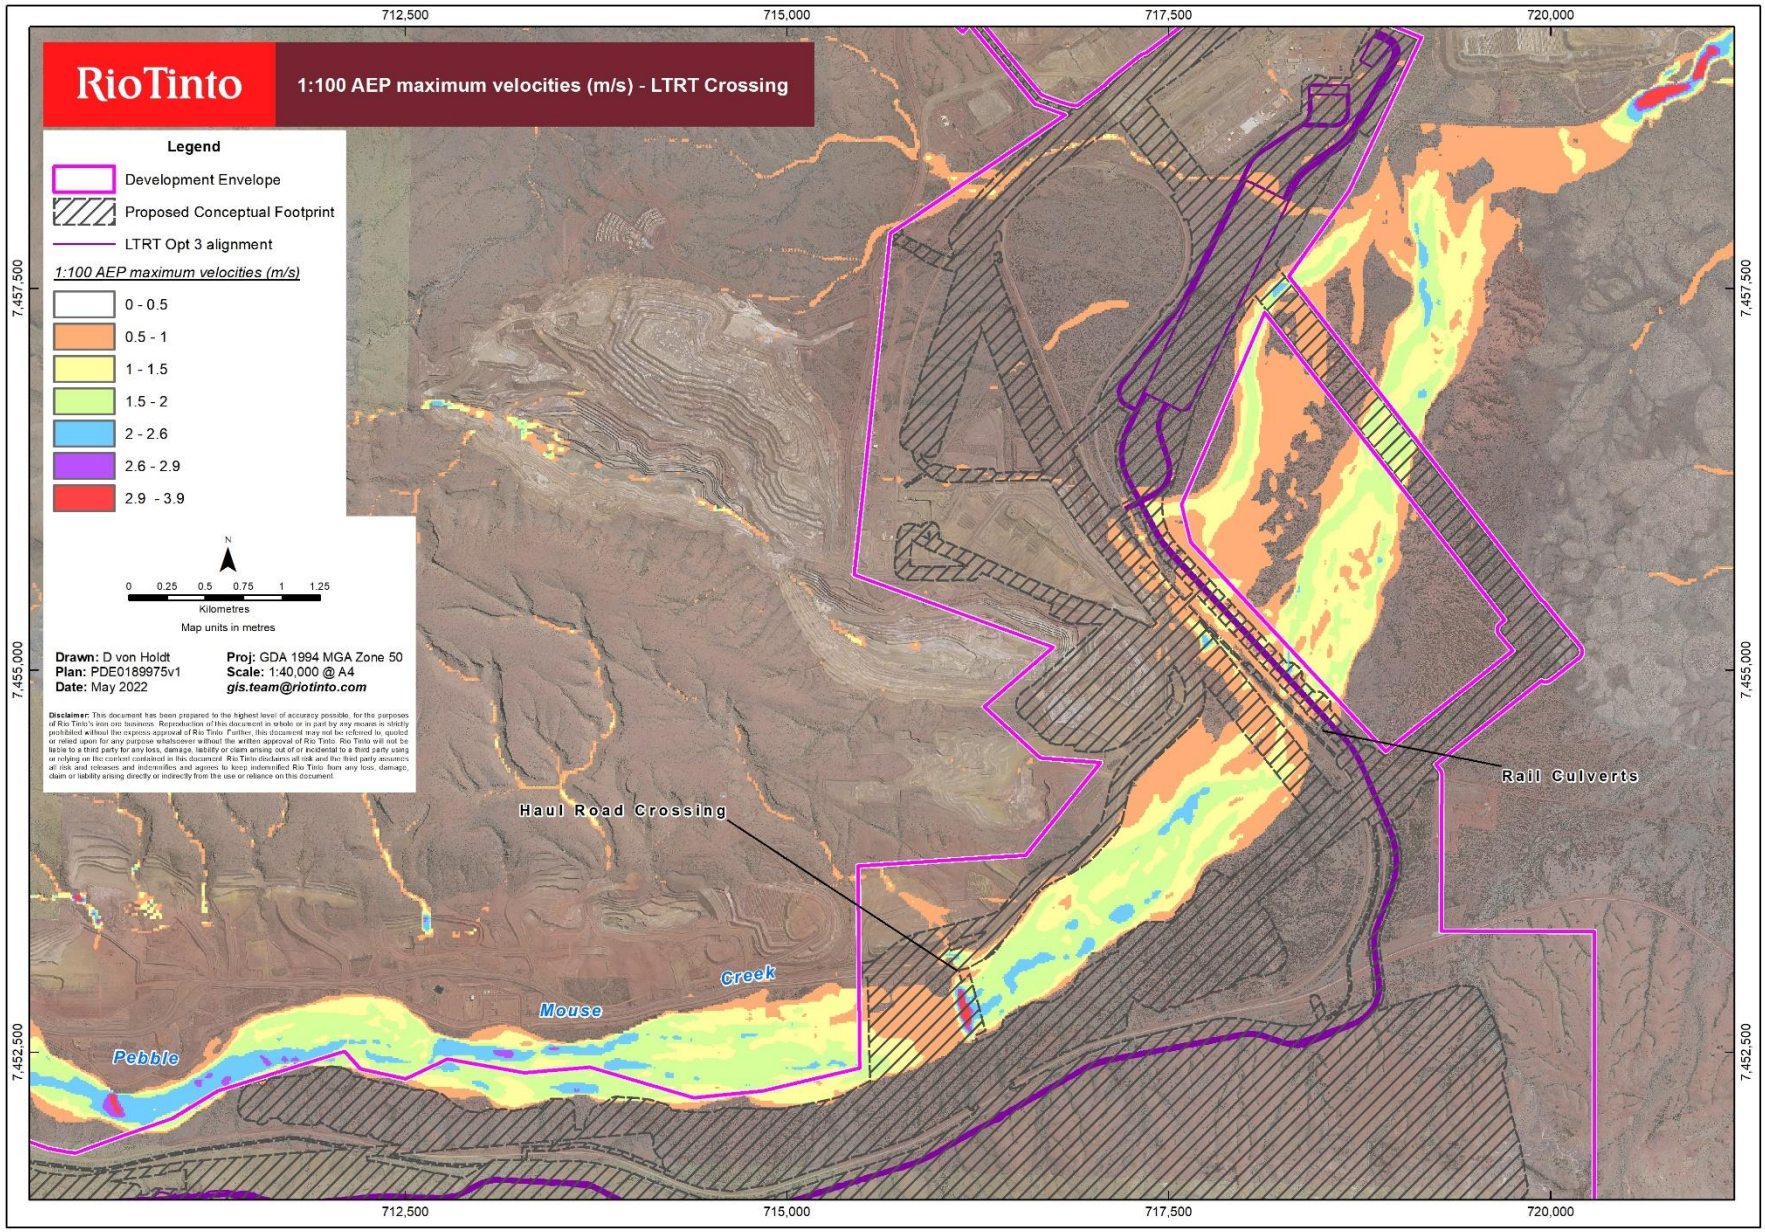

Figure 25: 1:100 AEP maximum velocities (LTRT Crossing)

7.6. Discussion

Hydraulic modelling indicates that during both frequent (1:5 AEP) and rare (1:100 AEP) events, maximum flow depths are observed upstream of the Pebble Mouse Creek haul road crossing as well as upstream of the rail line. This is expected due to the attenuation and backwater impacts of these structures. Velocity regimes at the crossing locations are typically characterised by a reduction in energy at the upstream side as flow is throttled by the crossing obstruction, with a distinct increase in the velocity at and immediately downstream of the crossing as flow is concentrated through the floodway or culvert.

Flow regimes at the crossing are likely to promote the mobilisation of sediment however it is difficult to comment on the extent of downstream sediment deposition without a detailed understanding of the crossing and bed load materials. Frequent event modelled velocities may have sufficient energy to overcome the shear stress of sediment directly at the crossing thus increasing erosion rates. Given the reduced flow velocities in the reach downstream of the crossing, the downstream flow regime is however unlikely to support the sediment loading for long distances, with sediment likely to start dropping out as flow velocities reduce. A crossing washout is more likely under a rare event, with increased velocities and higher energy potentially resulting in sediments transported over longer distances compared to frequent events.

The high flood depths and low velocities observed on the upstream side of the rail crossing supports the increased deposition of sediment at the culvert inlets and most likely poor transport of sediment through the culverts. Therefore, blockages are likely to occur at these culverts because of sediment transport from an upstream source thus reducing the culvert capacities and impacting downstream surface water flow regimes.

Based on this assessment it can be assumed that sediment transported from a potential washout of the Pebble Mouse Creek haul road crossing will most likely be because of a rare rainfall event, with sediments more likely to be deposited at / upstream of the rail crossing, causing some blockage of the culverts at this location. It is therefore considered unlikely that this sediment would have any significant impact on the water quality of Weeli Wolli Spring which is located 14 km downstream of the crossing (and 10 km downstream of the rail culverts).

A similar conclusion can be drawn regarding the LTRT Option 3 creek crossing. With the alignment running parallel to the existing rail line crossing and the culverts being identical (or bigger) than the existing culverts, the flow regime is not expected to change much downstream of the crossing.

Therefore, it is considered unlikely the LTRT Option 3 infrastructure will adversely impact the water quality of Weeli Wolli Spring, located 11 km downstream from the creek crossing and 7 km downstream of TP4.

7.7. Frequency analysis of Pebble Mouse Creek rainfall data

To qualitatively assess the likelihood of frequent and rare rainfall events occurring during the operational life of the Pebble Mouse Creek haul road crossing, a frequency analysis was undertaken. The long term flow data recorded at the DWER Tarina gauging station (located on Weeli Wolli Creek downstream of Weeli Wolli Spring) was used for the analysis. The flow rates measured at Tarina station are based on the Weeli Wolli Creek catchment (1,530 km^2) however the rainfall patterns and streamflow responses observed within this catchment are considered like that observed within the Pebble Mouse Creek catchment. Therefore, the Tarina gauge dataset was scaled to apply to Pebble Mouse Creek using a scaling factor of

0.46. The scaling factor was calculated using the ratio of the two catchment areas to the power of 0.7 (Grayson et al, 2004).

Using peak design flow rates for various AEP events, previously calculated as part of the RORB hydrological modelling, the dataset was interrogated to identify periods of flow at Pebble Mouse Creek responding to frequent to rare rainfall events.

The frequency analysis identified 18 rainfall events characterised as equal to or greater than the 1:5 AEP event occurring over the 30-year period of the dataset. Majority of events were in the 1:5 to 1:10 AEP range, with two 1:20 AEP events and one event greater than the 1:100 AEP.

If mainly rare events have the potential to mobilise significant bed load in a creek and demonstrating that Pebble Mouse Creek has only experienced five rare events over 30 years, the risk of the haul road crossing impacting a key sensitive receptor 14 km downstream of the washout site is considered unlikely to occur.

7.8. Consideration of optional waterway crossings

Based on the alignment of the overland conveyor crossing, environmental flow volumes (lower magnitude than a 1:5 AEP event) in Pebble Mouse Creek will not be impeded. There is potential for flow regimes during the rare events (1:100 AEP event and above) to be altered at the crossing location. However, engineering design of the conveyor crossing will ensure full conveyance of design flows and provide the appropriate level of scour protection downstream. Typical design solutions under consideration, as described in Section 3.4, are expected to result in negligible change from the baseline depth and velocity values and any changes should be confined to those areas a short distance up and downstream of the crossings. Overall flow volume and flow rates are typically unchanged for at-grade crossings and culvert installations. Therefore, given that appropriate scour protection will be provided it is considered unlikely that any sediment movement associated with this crossing would have any significant impact on the water quality of Weeli Wolli Spring, which is located 14 km downstream.

The bridges proposed at GNH and the alternative mine access road are approximately 34 km upstream of Weeli Wolli Springs. Modelling results presented in Section 7.5 indicated that a crossing 14 km upstream from the sensitive receptor would not significantly impact its water quality. Therefore, the addition of both these bridges will have no additional impact on Weeli Wolli Springs over and above those previously stated for the Pebble Mouse Creek haul road crossing.

8. CONCLUSIONS

Hydraulic modelling has shown that mining infrastructure related to the HD2 and BHT deposits will result in minor reductions to peak flows at the key sensitive receptors. The slight loss of runoff is expected to have little effect on the flow regime at Weeli Wolli Spring or Ben's Oasis and therefore is not expected to impact the environmental and heritage values of these areas.

A qualitative assessment of the potential for sediment transport from the Pebble Mouse Creek haul road crossing was undertaken to highlight the potential impacts on water quality at Weeli Wolli Spring. Hydraulic modelling demonstrated that velocities required to mobilise sediment load from the haul road crossing were more likely to be experienced during rare rainfall events. During the frequent events, sediment loading is unlikely to move far downstream due to the low energy estimated downstream of the haul road crossing. The significant distance between the sediment source and key sensitive receptor suggested it was unlikely that water quality would be impacted. This was further supported by the positioning of the HD1 rail line culvert crossing downstream of the haul road crossing through which sediment transport would be poor.

II ..... WATER LEVEL AND WATER CHEMISTRY DATA

EXECUTIVE SUMMARY

Rio Tinto is proposing above water table (AWT) mining of the Hope Downs 2 (HD2) and Bedded Hilltop (BHT) iron ore deposits (the Proposal). The project area is located in the Pilbara region of Western Australia, approximately 80 km northwest of Newman in the Shire of East Pilbara on the traditional lands of the Nyiyaparli people, with smaller portions located on land held by the Banjima and Ngarlawangga people. The project is an unincorporated joint venture (50:50) between Hope Downs Iron Ore Pty Ltd (a member of Hancock Prospecting Group) and Hamersley WA Pty Ltd (a member of the Rio Tinto Group). The Hope Downs JV (HDJV) is managed by Hamersley HMS Pty Ltd (HHMS), a Rio Tinto Group company.

Water for the project will be required to support the construction and operational mining phases for each deposit. Subject to approval, ore from the HD2 and BHT deposits will mined using open-cut, load and haul methods, processed on-site and then transported to the Hope Downs 1 (HD1) mine for mineral processing and transportation by rail to port. The Proposal's construction phase is expected to be carried out over an approximate 2-to 3-year period and mining operations are expected to extend over a 7-to10-year period. Annual water demand has been calculated based on construction, dust management, ore processing and potable water requirements and is expected to be approximately 3 GL per year.

This report describes the hydrogeology of the project area, summarises the proposed water supply options, and presents predicted groundwater drawdown that may occur due to the project's proposed groundwater consumption. Dewatering of the ore body for the purpose of dry-mining is not considered herein as the Proposal is to mine only AWT ore bodies.

Rio Tinto has undertaken work to assess water sources that are in-line with the company's water strategy and are:

Source 1: Use the water currently abstracted at HD1 for mine dewatering which will minimise water volumes released to the environment and minimise use of additional groundwater resources; and

Source 2: Establish a borefield local to HD2 to meet any shortfalls of Source 1 (noting that HD1 mine dewatering diminishes towards the end of mining at HD1 and a local supply will likely be required).

Source 3: Establish a borefield local to BHT to meet small local demands (i.e. office/crib room potable supply and/or small construction supply).

The assessments show that:

Use of HD1 Mine dewatering (Source 1) - will be sufficient for initial periods of mining at HD2/BHT however an additional source of water may be required both during commissioning and when water availability at HD1 is limited post 2033. Drawdowns from abstraction at HD1, due to this proposal, are in line with previously reported assessments (PER, 2002).

A borefield at HD2 (Source 2) - is expected to provide a sustainable supply sufficient to meet demand for the combined HD2/BHT mine life. Drawdowns from abstraction at HD2 are not expected to propagate towards any existing users or environmental receptors (namely, Ben's Oasis or Weeli Wolli Spring).

The supply potential of BHT (Source 3) - is limited due to the small aquifer extent; only minor supplies are likely to be obtained.

1 Introduction

1.1 Project Summary

Mining of the Hope Downs 2 (HD2) and Bedded Hilltop (BHT) iron ore deposits has been proposed and, subject to approval, is expected to include the following:

- AWT mining and movement of iron ore;
- Construction and operation of a transport route, including landbridges, creek crossings and ore transfer pads;
- Construction and operation of crib rooms, administration and ancillary facilities;
- Ore processing at existing facilities;
- Ore transport along existing rail lines; and
- Construction and operation of a power and water supply.

HD2 is located southwest of the Hope Downs 1 (HD1) mining village and is ~30 km from the nearest crusher at HD1. The deposit has a northeast-southwest strike extending up to 9 km. BHT is a hilly, high terrain deposit located about 7 km south of the Hope Downs 1 Southwest (HD1SW) pit and is relatively close to the current processing infrastructure located at the HD1 minesite. BHT has an east-west strike extending up to 9 km. Mining operations are expected to extend over a 7-to10-year period.

A location map is provided in Figure 1.

1.2 Ownership & Tenure

The Proposal (which includes both the HD2 and BHT deposits) is an unincorporated joint venture (50:50) between Hope Downs Iron Ore Pty Ltd (a member of Hancock Prospecting Group) and Hamersley WA Pty Ltd (a member of the Rio Tinto Group). The Hope Downs JV (HDJV) is managed by Hamersley HMS Pty Ltd (HHMS), a Rio Tinto Group company. The tenure associated with the project has been issued on Unallocated Crown Land (UCL). There is no pastoral activity in the immediate vicinity of the mine, with Marillana Station (N050368) the nearest pastoral station lease. Marillana Station lease is owned and operated by BHP.

1.3 Existing Licensed Groundwater Users

The HD2 deposit is situated in DWER's Pilbara groundwater licensing area; sub-area East Pilbara. There is available allocation from the licensed Hamersley - Fractured Rock aquifer; with the Wittenoom - Wittenoom aquifer reported as fully allocated. A groundwater licence search on DWER's Water Register, within a 10 km radius of the HD2 deposit, reports 13 licences are held in the fully allocated Wittenoom aquifer (including HD1's groundwater licence) and 119 licences held in the Hamersley - Fractured Rock aquifer; however it should be noted that while licences are held in this vicinity abstraction does not necessarily occur within the 10 km radius as licensees are able to attach multiple and geographically distant tenements on a single licence. The main, proximal licensees are:

- Rio Tinto, who hold GWL (groundwater licence) 161141 which permits 40.15 GL per annum of abstraction for the dewatering of the HD1 deposit (Wittenoom aquifer), GWL 161143 which permits 0.5 GL per annum

of abstraction from the HD1 Village for potable supply, GWL 98740 which permits abstraction of 14 GL per annum from Rio Tinto's West Angelas (WANG) Mine, inclusive of Deposit B, GWL 172872 which permits 23 GL of abstraction from Rio Tinto's Hope Downs 4 operation and numerous small volume 5C licences held for ad hoc abstraction along the Rio Tinto' rail corridor; and

- BHP Iron Ore Pty Ltd holds a total of 27 licences; the largest and most proximal to the HD2 project area are GWL 166389, which permits the abstraction of 21.9 GL per annum (Wittenoom aquifer), and GWL 110044, which permits the abstraction of 36.5 GL per annum. It is understood that these licences are attached to BHP's Mining Area C and are used for mine dewatering.
- Additional licensees, holding licences with allocations of less than 0.5 GL, include the Main Roads, Ascot Resources Ltd, Wonmunna Iron Ore Pty Ltd and Fortescue Metals Group Limited.

1.4 Regional Setting

The project is located in the Pilbara region of Western Australia, approximately 80 km northwest of Newman, within the Shire of East Pilbara (Fig. 1).

and lies predominantly on the traditional land of the Nyiyaparli people, with smaller portions located on land held by the Banjima and Ngarlawangga people (Figure 2).

The Great Northern Highway intersects the southern end of the project area, providing public access between the towns of Newman and Port Hedland and tourist access to Karijini National Park, approximately 30 km to the west of the HD2 deposit (Fig. 1).

Large groundwater users in the vicinity of the project (Figure 3) are current mining projects:

- Rio Tinto – HD1 Iron Ore Mine (including Baby Hope/HD1SW), immediately north;
- Rio Tinto – West Angelas (WANG) Iron Ore Mine, approximately 10 km southwest;
- BHP – Area C and South Flank Iron Ore Mine, approximately 12 km north-northwest; and
- Rio Tinto – Hope Downs 4 (HD4) Iron Ore Mine, approximately 42 km southeast.

1.5 Previous Work

The HD1 region has been the subject to numerous hydrogeological investigations dating back to the mid 1990's. Early hydrogeological conceptualisation assumed an extensive lateral extent of the groundwater system across the HD1 area. Subsequent investigations based on long-term pumping of the HD1 aquifer for mine dewatering and aquifer injection at neighbouring operations (i.e. BHP's Mining Area C) have allowed the HD1 aquifer boundaries to become well defined. It is now understood that the HD1 aquifer is notably much smaller than initially thought, and the HD1 aquifer is hydraulically disconnected from the groundwater system at both HD2 and BHT (see Section 2.5).

More recently, the HD2 and BHT areas have been investigated for the purpose of mining and water supply.

1.5.1 Field Investigations

Hydrogeological field investigations (drilling and test pumping of bores) have been undertaken in and around the location of each deposit in the Proposal since 2013. The information obtained from field investigation, along with local hydrogeological knowledge, and subsequent groundwater modelling has been used herein to assess available groundwater volumes.

At HD2 field investigations were undertaken between 2015 and 2022 and in the surrounding areas as early as 2006. Work has included the installation of 29 monitoring bores, 4 test production bores and several supply bores used for rail construction and maintenance (LHRP series).

At BHT, field investigations were undertaken between 2013 and 2018 and in the surrounding areas as early as 2006. Hydrogeological drilling carried out at the BHT deposit included the installation of 9 monitoring bores and 2 test production bores.

Bore construction data are provided in Appendix I.

1.6 Sensitive Receptors

Locations with heritage or environmental significance are referred to as sensitive areas or receptors. These locations require special consideration of the direct, indirect and potential cumulative impact of all mining activities due to their high heritage or environmental value.

Surface water sensitive receptors are not specifically considered in this report unless there is a known or perceived groundwater contribution to the surface water receptor and are herein referred to as sensitive groundwater receptors. Sensitive groundwater receptors may support fauna (including sub-surface fauna) and vegetation and/or provide cultural and/or social value through direct use (i.e. swimming, fishing, camping) or cultural connection.

The sensitive groundwater receptors that have been identified as part of the Proposal are Weeli Wolli Spring PEC (inclusive of Ben's Oasis), with locations shown in Figure 3. Although Pebble Mouse Creek is also considered to hold cultural, social and heritage significance, it has not been considered a key sensitive receptor as there are no known permanent water bodies along the creek, indicating that groundwater contributions to the creek are negligible to non-existent.

Further detail on sensitive groundwater receptors is given in Section 3.1.

2 Hydrogeological Setting

2.1 Climate & Rainfall

The Hope Downs area is a semi-arid to arid environment (Koppen-Geiger classification), characterised by hot summers and warm winters. The region experiences climate extremes, where severe droughts and major floods can follow in close succession.

The long-term annual rainfall for the region is approximately 324 mm and at HD1 the average annual rainfall received since 2008 is 313 mm (Table 1). Rainfall is highly variant, falling mainly in the summer months from January to March. This is generally a result of scattered thunderstorms producing heavy localised falls and/or tropical lows originating off the Pilbara coast bringing widespread rain to the area.

Rainfall events of more than 60 mm in 24 hours are estimated to occur on average once each year. Analysis of gridded rainfall and streamflow data from the Tarina streamflow gauge located on Weeli Wolli Creek and operated by the Department of Water and Regulation (DWER) indicates the study area experiences on average two rainfall events 35 mm per day or greater per year. This analysis suggests that the minimum amount of rainfall required to generate flow in the catchment is approximately 35 mm per day. The average annual evaporation rate for the region is 1900 mm (sheltered free water surface) and the average annual pan evaporation is approximately 3400 mm, an order of magnitude larger than mean annual rainfall.

Table 1: Rainfall – HD1 Weather Station and Newman Averages (mm)

	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Total
Hope Downs 1 Weather Station Average (2008 to 2021)	106	45	44	14	19	49	14	6	6	4	47	27	313
Newman* Average (1971 to 2021)	68	72	41	22	18	16	14	6	4	6	12	35	324

*Newman Aero Station 007176

2.2 Hydrology

The HD2 and BHT deposits are located within the upper reaches of the Weeli Wolli Creek catchment that forms part of the Fortescue River Region. Weeli Wolli Creek has a total catchment area of approximately 4,770 km^2 to Waterloo Bore gauging station and drains north into the Fortescue Marsh.

The upper reaches of the Weeli Wolli Creek catchment include Pebble Mouse Creek, a major tributary of Weeli Wolli Creek, which has a catchment area of 340 km^2. The HD2 and BHT deposits are bisected by the Pebble Mouse Creek and Weeli Wolli Creek catchment divide and do not interact with the flood plains of either creek. Locations of these catchments are shown in Figure 3.

2.3 Geology

The Hope Downs area is situated at the south-eastern corner of the Pilbara Craton, in the Ophthalmia region, within the eastern area of the Hamersley Basin. The cratonic basement comprises Archean granite-greenstone and is overlain by the Archean-Proterozoic rocks of the Hamersley Basin. These rocks can be divided into three stratigraphic groups: the Fortescue, Hamersley and Turee Creek groups, with the Hamersley Group forming the outcrop in the area. The Hamersley Group is a thick sedimentary sequence comprising banded iron formations (BIF), shales and dolomites, with minor felsic volcanic and extensive dolerite dykes and sills. The group contains the Brockman Iron Formation and the Marra Mamba Iron Formation which together, host most of the known major iron ore deposits in the Pilbara.

The lower-most formations of the Hamersley Group occur within the project area and include (youngest to oldest):

- Brockman Formation
- Mount McRae Shale
- Mount Sylvia Formation
- Wittenoom Formation:
    - Bee Gorge Member (calcareous shale and dolomite)
    - Paraburdoo Member (dolomite)
    - West Angela Member (magnesium-rich shale with minor BIF and chert bands)
- Marra Mamba Iron Formation:
    - Mount Newman Member (BIF with thin shale bands – includes the HD1N and HD1S orebodies)
    - MacLeod Member (BIF with extensive interbedded shales and “podded” BIF horizons)
    - Nammuldi Member (cherty BIF with occasional shale bands)

The HD2 deposit lies on the Northern limb of the Wonmunna Anticline. The Wonmunna Anticline is a W-E trending, shallowly plunging antiform. HD2 is a Marra Mamba Iron Formation and detrital deposit, with high grade bedded mineralisation mostly located in the Mt Newman Member, and with low grade mineralisation found at the base of the West Angela, MacLeod and Nammuldi Members. The deposit lies predominantly under detrital cover, typically unmineralised clay and immature detritals with some zones of mature detritals, limonites and red ochre detritals. Mineralisation in the deposit is predominantly martite-goethite.

The BHT is a Brockman Iron Formation derived deposit which lies as a major syncline between the Weeli Wolli Anticline and the Wonmunna Anticline. The deposit is located on an E-W striking Brockman ridge. The geology is typically flat throughout the hilltop with some gentle folding. Mineralisation in the deposit is predominantly martite-goethite mineralogy and occurs primarily within the Dales Gorge Member of the high phosphorous Brockman Iron Formation.

2.4 Regional Hydrogeology

The dominant aquifer within the regional groundwater system is the Paraburdoo Member of the Wittenoom Formation which occurs in the strike orientated valley floors between ridges of the Brockman and Marra Mamba Iron formations. The dolomite of the Paraburdoo Member can show extensive karstification. Secondary permeability is commonly formed within ore bodies as a part of the mineralisation process leading to areas of higher

permeability. These zones are often hydraulically connected to the overlying Tertiary detritals and the underlying, upper Marra Mamba Iron Formation (that being the Mt Newman Member where mineralised).

Overlying the regional aquifer are Mt Sylvia and Mt McRae Shale formations which comprise low permeability shale and can be usually be considered as aquitards. The lower, low permeability members of the Marra Mamba Formation (the MacLeod and Nammuldi members) form the base of the aquifer. Local and/or regional dolerite intrusive and faulting act to bound, or compartmentalise, the groundwater system.

2.5 Local Hydrogeology

There are 3 distinct local aquifers relevant to the Proposal: the HD1, HD2 and BHT aquifers. The HD1 aquifer is considered to be more extensive aquifer but hydraulically disconnected from HD2 and BHT. At HD2 groundwater availability is primarily limited by the vertical extent (thickness) of the aquifer and low permeability units that bound or compartmentalise the aquifer. At BHT the aquifer is bounded, and 'bathtub-like' at BHT. Figure 4 maps the lateral extents of the 3 aquifers.

There are 2 main units that comprise the aquifers:

1. Wittenoom Formation, occurring at HD1 and HD2, comprising the often karstic dolomite within the Bee Gorge and Paraburdoo Members of the Wittenoom Formation and the mineralised and/or fractured zones of the underlying Mt Newman Member of the Marra Mamba Iron Formation.
2. Brockman Iron Formation, occurring at BHT, and comprising the mineralised zones of the Dales Gorge Member and Joffre Member where fractures are encountered.

Surficial sediments (Tertiary age detritals and chemical sediments including calcrete) occur locally and may be saturated and are often in hydraulic connection with underlying units.

Valleys and associated surface drainage features overlie regional aquifers and groundwater generally flows in a similar direction to surface water. Aquifer recharge may occur following large rainfall and subsequent stream flow events causing infiltration through surface drainage features such are major creeks, minor tributaries and bedrock runoff at valley margins. Actual recharge volumes are unknown, however they are expected to be localised and a relatively small component of rainfall volumes with evaporation significantly exceeding rainfall throughout the year; except during the short periods of intense rainfall.

2.5.1 HD1

Groundwater occurrence

The iron ore mineralisation at HD1 occurs within the Marra Mamba Iron Formation. Groundwater occurs at HD1 within Surficial sediments (comprising Tertiary age detritals including surface calcrete), the Wittenoom Formation (comprising weathered dolomite, mainly within the Paraburdoo and the West Angela member), and the underlying Mount Newman Member (of the Marra Mamba Iron Formation).

The aquifer extends over an area of around 206 km^2 (Figure 4). Vertically, the aquifer is in the order of 160 m thick in the vicinity of the north pit, reducing to 120 m in the south pit, and thinner again (~80 m) between the north pit and south pits. Towards Weeli Wolli Creek, the aquifer thins substantially to just 7 m in thickness along the creek.

Regionally, groundwater over the HD1 area is fresh with total dissolved solids less than 700 mg/L. Major ion concentrations show no dominant species type, although all samples are hard to very hard which is attributed to mineral dissolution within dolomite aquifer units. As expected, surface water samples collected along Weeli Wolli Creek contain a very similar major ion composition to regional groundwater.
Groundwater recharge occurs directly from incident rainfall and indirectly from infiltration of streamflow.

Aquifer boundaries

The lower units of the Marra Mamba Iron Formation (the MacLeod and Nammuldi members) are significantly less permeable than the above Newman Member and Wittenoom Formation and therefore effectively form the hydraulic basement of the aquifer system. Due to the northerly dip of the geological structures in this region, the contact with these low permeability units is immediately to the south of both the HD1N and HD1S ore deposits. Additionally, geological structures and dykes form effective groundwater barriers between HD1S and the HD1SW (Baby Hope) deposit and bound the HD1 aquifer northwest of HD1N, effectively separating HD1 from neighbouring mining operations. Boundaries can be confirmed by field observations (i.e. diminished drawdown responses across barriers) and groundwater levels across the sites.

Groundwater Discharge -Weeli Wolli Spring

Pre-mining groundwater levels in the area ranged from 620 mAHD (metres above Australian Height Datum) in the upper catchment areas to around 547 m AHD at Weeli Wolli Spring, where, pre-mining, groundwater discharged at the surface of the Weeli Wolli Creek at Weeli Wolli Spring. Weeli Wolli Spring (detailed in Section 3.1.1), is located 7.5 km down-gradient of the HD1 actively mined and dewatered pits. It is a groundwater dependent ecosystem comprising stygofauna habitat, a riparian vegetation area of phreatophytes and was a perennial (pre-mining) spring. Dewatering of the HD1N and HD1S ore bodies has altered the natural spring flow at Weeli Wolli Spring, and as such, spring flow has been artificially maintained since December 2006 via surface irrigation via a series of off-take spurs lines.

The groundwater system underlying Weeli Wolli Creek essentially consists of a single aquifer unit: detritals/alluvium and weathered Paraburdoo Member of the Wittenoom Formation which are in hydraulic connection, forming an unconfined aquifer. Where the aquifer underlies Weeli Wolli Creek it is thin. The bottom of the aquifer is bound primarily by fresh Wittenoom Formation but also the unmineralised Brockman Iron Formation (low permeability), and groundwater expression at the Spring pools occurs as groundwater is forced to the surface where the aquifer pinches out above these lower permeability units.

At the conclusion of mining Rio Tinto is required to re-instate the HD1 aquifer so that the Weeli Wolli Spring pools return to self-sustaining (permanent) water features.

Groundwater Chemisity

Regionally groundwater over the HD1 area is fresh with TDS (total dissolved solids) less than 700 mg/L. Major ion concentrations show no dominant species type, although all samples are hard to very hard, attributed to mineral

dissolution within the dolomite aquifer. As expected, surface water samples collected along Weeli Wolli Creek reflect regional groundwater, very similar major ion composition.

2.5.2 HD2

The assumed extent of the HD2 aquifer is shown in Figure 4 and in Figure 5 with current water levels, as recorded in 2020, which at the HD2 deposit approximate 626 mAHD. A hydrogeological cross-section across the HD2 deposit is shown in Figure 6, bore locations are shown in Figure 7. Water level data are shown in Figure 8 and included in Appendix II.

Hydrogeological properties are summarised in Table 2.

Groundwater occurrence

The HD2 orebody is located within both the Marra Mamba Iron Formation and the overlying detrital deposits. In the HD2 area, the Marra Mamba Iron Formation abuts the regionally extensive Wittenoom Formation and is underlain by the Fortescue Group (Figs. 5 and 6).

The groundwater table in the HD2 area is located within both the Marra Mamba Iron Formation and Wittenoom Formation and is generally below the base of the detrital deposits. The water is hosted by secondary permeability structures associated with mineralisation and fractures within the Mt Newman Member of the Marra Mamba Iron Formation and overlying West Angela Member of the Wittenoom Formation, and by secondary porosity within the weathered Bee Gorge and Paraburdoo Member (Wittenoom Formation). The lower members of the Marra Mamba Iron Formation (the MacLeod and Nammuldi members) are significantly less permeable than the Mt Newman Member and are most likely the basal unit of the aquifer system, yielding only negligible volumes of groundwater. Groundwater in the upper Marra Mamba Iron Formation is in hydraulic connection with the overlying Wittenoom Formation, effectively forming a single aquifer unit. It is a fractured rock aquifer, channel like in geometry at the HD2 deposit extending east-west along strike for approximately 40 km (Fig. 6). Although the Wittenoom Formation is a known regional and extensive aquifer, at HD2 it is bounded in the east making it a local, somewhat compartmentalised aquifer.
Water yielded during drilling in the upper Marra Mamba Iron Formation (Mt Newman Member) and/or Wittenoom Formation at HD2 is typically low (under 5 L/s) with some higher yields of about 15 L/s encountered. The groundwater is fresh; with a salinity of generally less than 1000 µS/cm Electrical Conductivity (EC)

Table 2: Hydro-stratigraphic Units and Aquifer Characteristics – HD2

Deposit	Aquifer	Hydro-stratigraphic unit	Lithology	Typical characteristics	Distribution, local characteristics
HD2	HD2 Wittenoom aquifer	Wittenoom Formation	Weathered/altered dolomite, shale with minor BIF and chert bands.	Often associated with drainage valleys and saturated Tertiary cover. Major yields where dolomite is karstic (Paraburdoo Member) and from mineralised Mount Newman Member (yields from 40 to 100 L/s), high hydraulic conductivity.	Main aquifer at HD2; average thickness of 85m. Compartmentalised by cross-cutting dykes and abutting low permeability lithologies (ie fresh/massive dolomite) , channel like geometry. Yields of 5 to 15 L/s. EC ~1000 uS/cm. Saturated detritals present along drainage lines. Known connection to the aquifer at Deposit B at West Angelas (evident from abstraction at Deposit B drawing down water levels at HD2).
		Marra Mamba Iron Formation – upper member	BIF with thin shale bands.		
	aquitard	Marra Mamba Iron Formation – lower members	BIF, chert with extensive interbedded and/or extensive bands of shales with 'podded' BIF horizons.	Comprises low permeability, lower members of the Marra Mamba Iron Formation (MacLeod and Nammuldi) and the upper Fortescue Group. Generally poor yielding and forms no flow boundaries to Marra Mamba ore bodies (unless mineralised). Yields of ~10L/s can be encountered if fractured or weathered.	Underlies or abuts Wittenoom aquifer at HD2. Low to negligible yields. EC ~3000 uS/cm.
		Jeerinah Formation	Shale, sandstone, siltstone, mudstone, dolomite, local micro banded chert, jaspilite, thin basalt/dolerite and andesitic basalt flows.		

Aquifer boundaries

The lateral extent of the Wittenoom aquifer is shown in Figure 4 and Figure 5; the boundaries are:

- Outcropping unmineralised Marra Mamba Iron Formation to the north,
- The Fortescue Group to the south,
- A regionally extensive south-west to north-east trending dyke to the west, and
- Two separate eastern boundaries of the aquifer;
    - A folded zone of low permeability silica which forms the north-eastern boundary and separates HD2 from HD1SW
    - A change in lithology resulting in reduced permeability in the south-eastern area to the east and south of the HD1 Village;
    - It is noted that an additional potential barrier may also exist in the vicinity of the HD1 Village that aligns with a fault that extends from west of the HD1 Village and extends south-east to south of Ben's Oasis.

Evidence of these boundaries are as follows, and when realised by water levels, are shown in the hydrographs (Fig. 8):

- There is a discontinuity of groundwater flow to the north where unmineralised Marra Mamba Iron Formation outcrops;
- The north-eastern boundary of the aquifer is indicated by a 24 m head difference which occurs across a low permeability high silica zone (MB15H1SW0001 – 596 mAHD, MB17H1SW0025 – 621 mAHD);
- The south-eastern boundary of the aquifer is formed by the outcrop of fresh dolomite with absence of secondary permeability. Evidence of an inactive aquifer zone is provided by absence of any water strikes during drilling and the extended periods of water level recovery post-water sampling. Within this inactive aquifer zone there is evidence of faulting in the vicinity of the HD1 Village, where some anomalous water levels have been recorded, and a barrier (possible dyke) to the east. Water levels indicate that there is likely local compartmentalisation within the broader inactive aquifer zone.
- There is a 65 m head difference across the southern boundary between the Wittenoom aquifer and the Fortescue Group. Groundwater levels in the Fortescue Group range between 735 and 691 mAHD (MB18HD20012 – 691 mAHD). Monitoring bore MB18HD20012 is located approximately 500 m from the HD2 deposit. Additionally, the groundwater salinity at MB18HD20012 is much higher than at HD2 (EC is approximately 3000 µS/cm at MB18HD20012 compared to around 1000 µS/cm at HD2), and
- The regional dyke which forms the western boundary of the aquifer is located west of Deposit B WANG. Deposit B is therefore interpreted to be located within the same aquifer as the HD2 deposit. A 38 m difference in pre mining groundwater levels was identified either side of this dyke indicating that the dyke forms an impermeable barrier to groundwater flow in the area (LHRP11 – 667 mAHD to the west and LHRP2, LHRP9 and LHRP12 – 627 mAHD to the east). This dyke forms the western boundary of the aquifer across a distance of approximately 38 km and possibly extends as far north as BHP's Mining Area C. Groundwater level data at the northern extent of this dyke are not available and therefore it is not known whether a similar head difference exists ubiquitously along the dyke (as indicated in the WANG area).

The vertical extent of the aquifer averages about 85 m in thickness. The base of the aquifer corresponds to the low permeability members of the Marra Mamba Iron Formation. South of HD2 and underlying the Marra Mamba Iron Formation is the Fortescue Group, which is composed of mafic volcanics – basaltic, andesitic lavas and siliciclastic sedimentary rocks; it is hydraulically disconnected to the overlying and abutting Wittenoom aquifer, and is interpreted to be effectively impermeable to groundwater flow.

Groundwater Levels

Bore locations and hydrographs are shown in Figure 7 and Figure 8, respectively.

Pre-mining groundwater levels fall from around 630 mAHD near Deposit B (WANG) to 621 mAHD in the north-east and to 623 mAHD in the east. The depth to water below ground surface ranges between approximately 90 and 40 m respectively. The shallowest depth to groundwater is along Weeli Wolli Creek and Pebble Mouse Creek where the creeks cross the eastern boundaries of the aquifer.

Hydrographs show a water level decline in the eastern part of HD2 that is attributed to groundwater abstraction at Deposit B; this confirms aquifer continuity between the HD2 and Deposit B (Fig. 8).

Groundwater Inflow and Outflow

The general direction of groundwater flow is from south-west to north-east, generally following the surface water drainage system. Groundwater abstraction from bores near the HD1 Village has increased the hydraulic gradient between HD2 and the Village and reversed the flow direction from Wonmunna north to the Village.

Groundwater inflow and outflow is expected to be limited given the shallow gradient (0.0001 to 0.0003). Recharge may occur through streambed leakage following episodic large rainfall and stream flow events and/or direct rainfall recharge, however it is likely to be rare and/or small in volume.

Groundwater Chemisity

In general groundwater at HD2 is fresh; with a salinity of generally less than 1000 µS/cm, recorded as Electrical Conductivity (EC), and is near neutral. Data obtained from the 2016, 2018/2019 and 2021 hydrostratigraphic drilling programs are included in Appendix II and shown in Figure 9 and show:

- Salinity (as EC) ranges from approximately 650 to 1,250 µS/cm, excluding higher salinity bore MB18HD20012;
- pH ranges from 6.6 to 7.6; a pH of 8.8 has been recorded in bore WB18HD20002 on 3 occasions, and a low pH (<6) has been recorded in MB18HD20012 on 4 occasions;
- Total nitrogen was only recorded in 2 bores, concentration ranged from 0.8 to 3.8 mg/L;
- Iron concertation ranges from <0.05 to 1.5 mg/L (and as high as 20 mg/L in bore MB18HD20012); and
- Water from MB18HD20012 notably varies in composition, including elevated salinity, upwards of 2,500 µS/cm, low pH and elevated metals (iron, manganese, nickel and zinc). This bore is constructed into the Fortescue Formation, and located to the south of the HD2 deposit, outside of the assumed HD2 groundwater system.

2.5.3 BHT

Aquifer boundaries and water levels (2020) are shown in Figure 10. A hydrogeological cross-section for BHT is shown in Figure 11, bore locations are shown in Figure 12, and water level data are shown in Figure 13 and included in Appendix II.

Hydrogeological properties are summarised in Table 3.

Groundwater occurrence

The BHT orebody is located within the mineralised Dales Gorge Member of the Brockman Iron Formation. A localised aquifer is present within the Brockman Iron Formation where the orebody mineralisation extends below the local groundwater table.

The BHT aquifer is interpreted as being predominantly isolated from the surrounding regional Wittenoom aquifer due to the presence of the underlying Mt McRae Shale (Fig. 10 and 11). The Mt McRae Shale generally outcrops at surface (or subcrops above the elevation of the groundwater table) and surrounds the orebody. Due to the low permeability of the shale bands, the Mount McRae Shale almost completely encapsulates the aquifer with the exception of a small area in the central portion of the deposit (Fig. 10). In this area, the BHT aquifer is interpreted as being in connection to the Wittenoom aquifer. Moderate groundwater yields of between 10 and 20 L/s have been obtained during drilling at BHT and the groundwater is fresh (EC <1500 µS/cm).

To the north of the BHT deposit groundwater is within both the Marra Mamba Iron Formation and Wittenoom Formation (Wittenoom aquifer). This aquifer is analogous to, and a geological continuation of, the Wittenoom aquifer in which the HD2 deposit sits. However, up gradient of BHT groundwater flow from the HD2 aquifer is interrupted by the zone of low permeability silica referred to above.

A sequence of detritals (comprised of alluvium/colluvium, clay, pisolite and calcrete) overlies the Brockman Iron Formation at BHT and extends north across Pebble Mouse Creek to HD1SW where it is underlain by the Wittenoom Formation. The detritals are typically partially saturated over intervals that range in thickness from <10 m up to 90 m and extend along the length of Pebble Mouse Creek (Fig. 11).

Table 3: Hydro-stratigraphic Units and Aquifer Characteristics – BHT

Deposit	Aquifer	Hydro-stratigraphic unit	Lithology	Typical characteristics	Distribution, local characteristics
BHT	BHT Brockman aquifer	surficial sediments (detritals)	surficial sediments (gravelly clays, thick clays, chemical sediments-calcrete/silcrete, high Fe detritals).	Heterogeneous and varying in thickness, can be perched or in hydraulic connection with underlying units. Variable permeability, high storage, recharged by rainfall and surface flows.	Associated with topographic lows and drainage lines. Extends from water table and ranges from <10 up to 90m in thickness. Negligible to no water yield is often encountered during drilling; bore yields vary up to ~30 L/s .EC <1000 uS/cm.
		Brockman Iron Formation	BIF with shale and chert.	Where BIF is mineralised forms a significant, moderate to high yielding aquifer, high conductivity and storage. Where BIF is unmineralised permeability, storage (and yields) are low.	Main aquifer at BHT (not present at HD2). Bounded aquifer. Typical yield 10 to 20 L/s. EC <1500 uS/cm.
		Wittenoom Formation	Weathered/altered dolomite, shale with minor BIF and chert bands.	Major yields where dolomite is karstic (Paraburdoo Member) and from mineralised Mount Newman Member (yields from 40 to 100 L/s), high hydraulic conductivity.	Hydraulically connected with Brockman Iron Formation over a small area; evident from the equal groundwater level elevations within both the Brockman deposit and adjacent Wittenoom Fm.
	aquitard	Mount McRae Shale / Mount Sylvia Formation	thin bedded shale and chert with some dolomite and BIF.	Minor groundwater resource, permeability is typically low and the unit acts as a barrier to flow and confines underlying aquifer. Individual beds may be permeable and yield low to moderate flows and fracturing can produce hydraulic connections.	Underlies and bounds the Brockman aquifer at BHT.

The interpreted, lateral extent of the BHT aquifer (BHT Brockman aquifer and Wittenoom aquifer) is shown in Figure 4 and Figure 10, boundaries to the aquifer are formed by:

- Outcropping unmineralised Marra Mamba Iron Formation to the north (MacLeod and Nammuldi members);
- Outcropping Mount McRae Shale to the south;
- A folded zone of low permeability silica which forms the western boundary and separates the BHT aquifer from the HD2 aquifer, and
- A north west – south east trending dyke located to the east separating the BHT aquifer from the HD1 aquifer.

Evidence of these boundaries are as follow:

- The eastern boundary of the aquifer is indicated by a 45 m head difference which occurs across a pair of dykes located to the east of the HD1SW (MB17HD1S0002 – 594 mAHD, MB18HD1S0002 – 549 mAHD). The groundwater level on the eastern side of these dykes has been influenced by dewatering of the HD1 deposits, with water levels having decreased about 20 m (from 570 mAHD to 550 mAHD), whilst groundwater levels on the BHT side of the dyke have remained unchanged since monitoring commenced (Fig. 13).

Groundwater Levels

Bore locations are shown in Figure 12 water level data are shown in Figure 13 and data tabulated in Appendix II.

Groundwater levels across both the BHT Brockman and Wittenoom aquifers are consistently around 594 mAHD. The lack of a distinct groundwater gradient across these aquifers indicates there is very little to no groundwater flow. Depth to groundwater ranges from around 25 to 100 m bgl. The large range in depths to groundwater is a reflection of the large variation in surface elevations and not the local groundwater gradient. The shallowest groundwater levels occur along Pebble Mouse Creek and range between 30 m bgl in the west to 25 m bgl in the east. The water level at RC18BHT0221 (552 mAHD) suggests this bore is within the HD1 aquifer and impacted by the dewatering of the HD1 mine.

Given groundwater levels recorded within both the BHT deposit and adjacent Wittenoom aquifer are the same (~594 mAHD) and the Mount McRae Shale does not extend above the groundwater table, the BHT Brockman ore body and Wittenoom formation are interpreted to be hydraulically connected, albeit over a small area.

Groundwater Inflow and Outflow

The interpreted aquifer boundaries surrounding the BHT aquifer suggests that there is very little to no groundwater inflow or outflow. If any outflow from this groundwater system occurs, it is likely to be negligible and occur by either groundwater overtopping or flowing through the very low permeability dykes present along the eastern boundary.

The aquifers present in the BHT area are considered to be compartmentalised from the surrounding regional aquifers and as such behave as a predominantly isolated system.

Groundwater Chemisity

The groundwater is fresh; with salinity ~~is~~ typically about 1000 µS/cm EC, and slightly alkaline. Water quality data obtained from groundwater sampling and laboratory analyses are included in Appendix II and show:

- Salinity (as EC) ranges from approximately 650 to 1,250 µS/cm,

- pH ranges from 7.4 to 8.2;
- Total nitrogen was recorded at concentrations of less than 0.4 mg/L;
- Iron concentration ranges from 0.4 to 4.2 mg/L; and
- Arsenic concentrations of 0.011 and 0.017 mg/L, slightly exceeding Australian Drinking Water Guideline value for arsenic of 0.01mg/L (NHMRC, NRMMC, 2011), have been recorded, and
- Manganese concentrations of up to 0.7 mg/L have been recorded, also slightly exceeding Australian Drinking Water Guideline value for arsenic manganese of 0.5 mg/L (NHMRC, NRMMC, 2011).

3 Groundwater Supply Assessment

The Proposal is seeking to have 2 approved major water supply sources - that being the existing groundwater abstraction from HD1 and a proposed groundwater abstraction from HD2. Either of these sources are sufficient to provide the full water demand for the Proposal; however a combination of the 2 sources is likely to provide the most practicable solution due to location and timing of works. For example:

- abstraction of water at HD2 to provide the supply during early construction at HD2 whilst pipelines from HD1 are established,
- provision of water from HD1 to provide the supply for construction at BHT (potentially supplemented by a minor, short-term draw of groundwater at BHT),
- provision of water from HD1 to provide the supply during final construction at HD2 and during mining operations, and
- abstraction of water at HD2 at the conclusion, or reduction of, abstraction of water at HD1.

Potential groundwater availability from HD2 and BHT has been assessed via field investigations, groundwater modelling and assessment of sensitive receptors. Initial results showed that only a small volume of water (less than 3 ML/d) is likely to be available from BHT and that groundwater abstraction solely from BHT would likely be insufficient to meet the Proposal's total water demand. As such, the option of groundwater abstraction from BHT is not considered further and abstraction from BHT is not recommended except for in small volumes for a potable water supply or short-term construction supply.

3.1 Sensitive Receptors

3.1.1 Weeli Wolli Spring

Weeli Wolli Spring is located approximately 7 km downstream of the confluence of Pebble Mouse Creek and Weeli Wolli Creek to the north east of the HD1 mining area. It is protected under the *Aboriginal Heritage Act 1972* and the riparian vegetation supported by the spring is categorised as a Priority 1 Ecological Community (PEC). The Spring was naturally groundwater fed (pre-mining) and is currently maintained by discharge of water from the dewatering of the HD1 mine, which has occurred since 2007. Water is discharged to Weeli Wolli Creek at both the gabion structure located just downstream of the Spring, and into the pool area via dedicated off-shoot lines (referred to as the spurs). The total discharge generates a permanent flowing section of the creek downstream. The wetting front (that being the area of creek-line under permanent inundation) in 2021 approximated 16 km, extending as far as Rio Tinto's Yandicoogina mine site. Upstream of the permanent flowing portion of the Spring, Weeli Wolli Creek remains ephemeral. The Spring, under irrigation, is shown in Figure 14.

Pre-mining, the recharge to the Weeli Wolli Spring was via direct infiltration and concentrated stream-bed leakage (during episodic stream flow events) within the confines of the currently known aquifer extents.

3.1.2 Ben's Oasis

Ben's Oasis is a system of designated PEC surface water pools located along a 200 m reach of Weeli Wolli Creek situated approximately 5 km southeast of BHT and 15 km east of the HD2 deposit. The pools persist throughout the dry season and it is expected that Ben's Oasis is similar in function to Weeli Wolli Spring in that it is supported via groundwater expression in addition to surface water.

The current conceptualisation is that groundwater is expressed at surface at Ben's Oasis due to a flow constraint, currently understood to be the tight, impermeable dolomite of the Wittenoom Formation. At the location of Ben's Oasis and surrounds the dolomite outcrop is massive (Fig. 15) and shows no properties of a typical aquifer (i.e. the rock does not hold or allow flow through of water). The direction of groundwater flow to Ben's Oasis is inferred to be from the south where, about 2 km south of the creek, water level responses to rainfall events provide evidence of direct rainfall recharge. It is assumed that here, the dolomite is locally fractured with recharge occurring along drainage lines during flood events (Fig. 16). In addition to the groundwater flow from the south, a small contribution to the flow sustaining the pools may result from release of bank storage (where surface water is temporarily held locally along the creek line following flood events) and natural throughflow in the streambed alluvials.

Ben's Oasis is located to the west of a known set of dykes that bound the HD1 aquifer (Fig. 4) so that the main pools of Weeli Wolli Spring and Ben's Oasis are effectively hydrogeologically separated and the dewatering operations undertaken at HD1 do not impact upon Ben's Oasis.

Separation of Ben's Oasis from the HD2 aquifer is also evident by groundwater levels and groundwater recovery signatures recorded in the area to the west of Ben's Oasis that indicate a low permeability area (equivalent to a 'non-active aquifer'). This low permeability area, as mentioned above, located to the south and east of the HD1 Village and between the HD2 deposit and Ben's Oasis, is an effective hydraulic divide that would prohibit groundwater flow from HD2 towards Ben's Oasis, so that groundwater contributions from the HD2 aquifer to Ben's Oasis are considered to have a low to non-existent potential. In addition to this lithological barrier to flow, there is evidence of compartmentalisation within the non-active aquifer. Water levels lower than those recorded at Ben's Oasis have been recorded between the HD2 eastern boundary and the Oasis indicating existence of an effective hydraulic barrier (possible dyke) and the impossibility of eastward groundwater flow from the HD2 aquifer.

The dolomite exposure at Ben's Oasis is shown in Figure 15. A hydrograph and bore location map of the area to the south of Ben's Oasis is presented in Figure 16 (showing the potential for rainfall recharge to drive the persistence of the pools) and the location of Ben's Oasis in respect to the groundwater systems across HD1, HD2 and BHT is shown in Figure 4.

Water level data available for Ben's Oasis and surrounds are included in Appendix II.

3.2 Aquifer Parameters

Test pumping of 3 test production bores at HD2 has been undertaken to determine suitable abstraction rates from the bore and to calculate the aquifer's hydraulic parameters. Expected yields are as follow:

- WB16HD20001 –1.4 ML/day = (0.5 GL/a)
- WB18HD20001 –1.7 ML/day (0.6 GL/a)
- WB18HD20002 –0.7 ML/day (0.3 GL/a)
- WB18HD20003 –1.6 ML/day (0.6 GL/a)
- **Total yield 4.7 ML/day (2.0 GL/a)**

Test details and results for HD2 are summarised in Table 4 and included in Appendix I.

Table 4: Test Pumping Summary – HD2

Pumping Bore	Test Duration (days)	Pumping rate (L/s)	Total drawdown in pumping bore (m)	Aquifer Thickness (m)	Adopted T (m2/day)	K range (m/day)	Specific Storage (1/m)
WB16HD20001	7	22	29	90	65	0.7 to 1.7	0.003
WB18HD20001	7	25	43	85	105	0.9 to 1.2	0.001
WB18HD20001	7	25	43	85	105	0.9 to 1.2	0.001
WB18HD20003	6	18	41	120	119	1.1 to 2.1	0.019

3.3 Groundwater Modelling

To assess the impacts of groundwater abstraction at HD2, an analytical groundwater model was developed using AnAqSim, an aquifer simulator software package. The model was run under steady state and then transient conditions to replicate abstraction and predict groundwater drawdown as a consequence of abstraction.

The model domain, boundaries and hydrogeological inputs were generated from the current conceptual understanding which has been developed from geological information, hydrogeological field investigations, groundwater level data and neighbouring operating mine site data and information.

Based on the results of the analytical modelling, further work was undertaken by consultants IGS (IGS, 2022). Work included the construction of a numerical model and scrutiny of model sensitivities in respect to varied hydraulic parameters.

3.3.1 Model Boundaries

The IGS HD2 model consisted of a single domain layer (180m in thickness) with grid cells ranging from 40 to 320 m in size.

Aquifer extent and model boundaries were determined using the hydrogeological barriers described in Section 2.5.2. All boundaries were assigned as normal flux (no flow) with the exception of the south west boundary represented by West Angelas Deposit B and the north east boundary. A specified head was applied to mimic the West Angelas Deposit B boundary, set inwards of the conceptual aquifer boundary to limit the spatial extent of the model, and a head-dependent normal flux was assigned to the north eastern boundary (the area separating HD2 and HD1SW).

3.3.2 Model Parameters

The Wittenoom, BIF and mineralisation represents the single layer aquifer which have their respective hydraulic parameters assigned as per Table 5. The fresh dolomite and outcrops represent the low permeability zones which are not considered a productive aquifer. These zones were incorporated to best simulate the conceptual hydrogeological system and were assigned with very low hydraulic parameters resulting in poor hydraulic connection to the aquifer system (for example the area between the HD2 mineral deposit and the HD1 Village).

Table 5: Adopted model parameters (after IGS, 2022)

Unit	Upper bound	Lower bound
Regional hydraulic conductivity (m/day)	10	0.01
Orebody hydraulic conductivity (m/day)	15	0.1
Regional specific yield	0.12	0.005
Orebody specific yield	0.15	0.05

3.3.3 Model Results

Groundwater abstraction was simulated over a period of 13 years (representing 3 years of construction and 10 years of mining). A total, combined volume of 38 GL was abstracted (i.e. 3 GL per year), with combined daily abstraction ranging from 3.7 to 9.5 ML/d which allows demand to be met with contingency for larger demands (see Section 3.4); plus an additional 4.9 ML/d was abstracted from the HD1 Village, each year, to simulate meeting Village's potable water demand (Table 6).

Results of the modelled abstraction (based on the lowest SRMS-case, IGS 2022) at the end of 13 years show a predicted drawdown of 29 m in the immediate areas of the proposed HD2 borefield. The extent of groundwater drawdown is expected to be relatively localised and mostly remain within the proposed borefield area. Drawdowns of about 2 m were produced at a distance of 10 km to the west of the centre of the HD2 deposit and borefield area, and drawdowns of about 18 m were produced at a distance of 6 km to the east. Drawdown did not extend beyond aquifer boundaries, most notably, there is no drawdown propagation into the Fortescue Group, nor at Ben's Oasis. Groundwater drawdown is therefore not expected to have any influence on surrounding GDE's or extend beyond the extent of the aquifer.

Groundwater level drawdown contours, after 13 of pumping, are shown in Figure 17.

in addition 4.8 ML/d is abstracted from the HD1 Village

3.4 Water Demand

Water will be required during construction and operation. Water volumes presented that are required for construction (Table 7) are based on a 21-month construction period for HD2 and a 14-month, possibly concurrent, construction period for BHT. Operational water demand volumes presented are based on a 10-year mining period (Table 8); demand also includes the expected 10-year water demand for the HD1 operation; relevant to show that water is available from HD1 to supply the Proposal (see section 3.5.1). Demands have been calculated based on construction inputs (product additive volumes and dust suppression) and operational inputs (process plant and ore movement based on expected ore and waste rock tonnages and dust suppression requirements based on transport routes and methods). Based on these estimates the total expected water demand is 24.4 GL.

Table 7: Estimated Construction Water Demand (over 2 to 3-year period)

Deposit	Est. construction period	Unit	Volume
HD2	21 months	ML/d	2.3
		GL	1.36
BHT	14 months	ML/d	1.6
		GL	0.62

3.4.1 Potable Demand

A potable supply of 400 L per day per person will be required (equivalent to 0.1 GL per annum), and could be sourced locally from either HD2 or BHT and/or from the existing HD1 Mine Village.

Currently, the potable water for the HD1 Village is abstracted under GWL 161143, utilising 2 production bores (HDVP1 and HDVP2; Figure 7) that are located approximately 2.5 km north of the closest part of the HD2 deposit and target the same aquifer. Abstraction from the village bores commenced in late 2006, the total annual abstraction is generally close to the annual licence allocation of 500,000 kL. This equates to an average combined abstraction rate of around 16 L/s (Fig. 18).

3.4.2 Dewatering Demand

Dewatering is not required to access AWT ore and therefore no work has been carried out on determining dewatering rates.

It is noted that groundwater abstracted for supply produces a modelled drawdown across the HD2 aquifer which is equivalent to (partial) orebody dewatering (i.e. water levels are predicted to drawdown almost 30 m below the AWT pit floor in some locations at HD2).

3.5 Water Supply Forecast

Water balance forecasts have been compiled for 2 supply sources (HD1 and HD2) using the Proposal's water demands during construction and operations (Tables 7 and 8, respectively), the expected future discharge volumes from HD1 and the modelled pumping rates for a borefield local to HD2, noting that the modelled abstraction rates for HD2 are on average 25% higher than demand estimates so to assess the impacts of increased demands.

Supply sources are:

Supply Source 1: uses HD1 discharge water.

Supply Source 2: uses the HD2 local aquifer for supply.

3.5.1 HD1 Supply Forecast

Groundwater is currently abstracted for potable supply at the HD1 mine village (under GWL 161143) and significant volumes (up to 40.15 GL/yr) are licensed at HD1 (under GWL 161141) which could be made available to service the Proposal's potable demand, dust suppression demands and/or processing requirements, given approval.

The existing HD1 Village potable supply network currently includes 2 abstraction bores and the aquifer is expected to be able to support increased abstraction, if required, and subject to approval of an increase in allocation for GWL 161143 or a receipt of a new GWL for potable supply. Groundwater level drawdown at the HD1 mine village, recorded since abstraction commenced, is shown in Figure 18 and indicate that a licensed allocation is available to support the HD2 Proposal's potable demand.

The HD1 dewatering network comprises 3 borefields; the HD1N, HD1S and HD1SW. The maximum allowable annual abstraction is 40.15 GL, noting that to-date that no abstraction has occurred from the HD1SW borefield. Abstraction volumes are expected to reduce at a rate of ~10% per year as mining and dewatering of the HD1 deposit moves towards mine closure and aquifer volumes deplete (i.e. as dewatering reduces the thickness and storage of the aquifer and the pit void area reduces in lateral extent resulting in the volume of required dewatering diminishing over time).

At HD1 abstracted groundwater is used primarily to fill local demands (i.e. dust suppression and processing) with a dedicated component used to maintain permanent pools at Weeli Wolli Spring via irrigation. Water not used on site or discharged via irrigation is discharged to Weeli Wolli Spring down-stream of the Spring at 'the gabion', HD1's licensed discharge point. Pipelines are currently configured to send dewatering volumes to a collector dam north of HD1N pit with discharge directed away from that location. To make this supply source available, reconfiguration of the pipe network and ongoing assessment of the availability of volumes over time would need to be undertaken.

Reduction in the flow from the gabion discharge point would occur if HD1 supplies water to the Proposal. Based on predicted, future dewatering volumes, water usage at HD1 (inclusive of continued supplementation of the Weeli Wolli Spring pools) and subsequent future discharge volumes the percentage of reduction would reduce by 5% at the commencement of the Proposal (i.e. during construction) and then increasing to almost 50% after 10 years of supplying the Proposal. Figure 19 shows the predicted discharge volumes from HD1 into the creek from 2024 to 2035, and compares discharge volumes with and without HD1 supplying water to the Proposal. Accounting for the water requirements of HD1 (i.e. maintaining all HD1 expected water demands) the HD2 Proposal's water demand can be met until 2033 (Fig. 19).

While it is noted that if HD1 supplies the Proposal with water the discharge volume into Weeli Wolli Creek at the gabion outlet will reduce, the reduction in volume is small when compared to seasonal surface water flow in the creek, and as the gabion discharge point is located down-stream from the Weeli Wooli Creek pools flow at the pools will not be impacted upon by reducing discharge at the gabion. Down-stream of the gabion, surface water flow, recorded at the DWER's Tarina gauging station located approximately 5 km downstream of the HD1 discharge point, has been collected since 1985. Data are presented in Figure 20 and summarised in Table 9 and show that flow, pre-2007, occurred seasonally. Post 2007 (i.e. since HD1 has been discharging water into the creek) flow at Tarina has been continual with a minimum flow of 0.6 cubic metres per second and typical continual flow that fluctuates between 0.8 and 1.4 cubic metres per second (Fig. 20). In comparison, seasonal peak flows range from about 50 up to over 500 cubic metres per second; equating to a median total volume of 33 GL per year (Table 9). A reduction in continual flow of 0.1 cubic metres per second (equalling 3 GL per annum) can be expected if the HD1 operation provides supplies the Proposal's water requirement.

Table 9: Tarina Gauging Station Flow Data

Gauging station	Tarina
Period	1985 -2019
Number of years of no flow	6 (all pre-1996)
Median flow volume (GL/annum)	36
Maximum flow volume (GL/annum)	311
Volume required for HD2 Proposal (GL/annum)	3

3.5.2 HD2 Local Supply Forecast

It is proposed that a borefield is established at the HD2 deposit. Investigative drilling has included the drilling and construction of 4 test production bores (details provided in Table 10 and Appendix I) that produce an expected yield of approximately 4.7 ML/day; just over half the required water demand. An additional 4 to 5 bores can be constructed, and the test bores converted to production bores to meet the full water demand Section 3.3 details the simulated results of abstracting the total supply (which includes an allowance for a contingency volume – i.e. the peak demand volume is 6.9 ML/d and the peak modelled abstraction volume is 9.5 ML/d), and shows that the water demand can be met by groundwater abstraction at HD2.

Table 10: Existing Production Bores – HD2

Deposit	Bore ID	mE	mN	Top of casing (mAHD)	Bore depth (m)	Construction date	Screened interval	Casing diameter (ND) (mm)	Screened across (FM / lithology)	Initial yield (est.) (ML/d)	Combined Final yield (est.) ML/d

3.6 Risk to Sensitive Receptors and Contingent Supply

The HD2 aquifer intended as a supply source for the proposal is well isolated from the Bens Oasis Spring groundwater system as has been described above.

A large data set of groundwater level response from abstraction at HD1 shows that HD2 is separated from the HD1 aquifer (Figs. 4 and 8), and as such it is considered that abstraction from HD2 poses no risk to the Weeli Wolli Spring pools, located downstream from the HD1 mine and outside of the HD2 groundwater system.

In the event of insufficient supply to meet demand, several opportunities exist that will need to be employed. Those being:

1. Partnership with nearby operations to source and convey water from existing dewatering (BHP South Flank/ Mining Area C, West Angelas);
2. A focus upon water efficiency in the ongoing proposed operations to reduce the demand for water, or
3. An increased network (spread) of bores within the HD2 aquifer.

4 Summary and Conclusion

A groundwater assessment has been undertaken with the intent to support the HD2 Proposal in securing a water supply for a period of about 13 years. The assessment has been based on hydrogeological investigations, regional hydrogeological knowledge, water demand forecasts and availability of water outside of the Proposal. The largest, local, water source available to meet the Proposal is the groundwater currently abstracted from the HD1 operation under GWL 161141. Alternatively a suitable local groundwater supply is available at HD2. At BHT the long-term supply is likely to be small and most suited to provision of a small potable supply or short-term construction water supply.

Findings of the water supply assessment for the Proposal are:

1. Water demand for the Proposal has been calculated to be between 2 to 3 GL per annum.
2. The Proposal considers AWT mining only and investigation into ore dewatering has not been undertaken in this assessment.
3. The pre-mining water table approximates 626 mAHD at HD2 and 594 mAHD at BHT.
4. Groundwater at both HD2 and BHT is fresh and is held within compartmentalised or isolated aquifers which are typically bounded by low permeability units or structures.
5. Regional and local groundwater flow mimic surface drainage, and flow is predominantly south-west to north-east.
6. The groundwater systems at HD1, HD2 and BHT are isolated from one another.
7. Modelled abstraction from HD2 at rates of up to 9.5 ML/day (or 3 GL/yr) over a 13-year period (totalling 38 GL) resulted in a reduction in water levels of 29 m in the vicinity of the borefield and a 2 m water level drawdown propagated 10 km to the west of the borefield, and a 18 m water level drawdown propagated 6 km to the east.
8. It is noted that the simulated abstraction volumes from HD2 are higher than the estimated water demand and, if water is sourced from HD1 for all, or a portion of the project, abstraction volumes would in reality be much less, consequently modelled drawdown is likely to be over estimated
9. The depth to groundwater across the HD2 and BHT aquifers is greater than would typically support groundwater dependent vegetation (i.e. >15 m below ground level). The 2 known sensitive groundwater (Ben's Oasis and Weeli Wolli Spring, located on Weeli Wolli Creek) receptors are not within the aquifers where the proposed abstraction for the Proposal would occur.
10. Ben's Oasis has been interpreted as a groundwater dependent surface water feature sustained largely by groundwater flow from the south. The Oasis is isolated from HD2 with eastward groundwater flow from HD2 impeded and/or precluded by a combination of lithological hydraulic barriers and groundwater compartmentalisation.
11. Weeli Wolli Spring is currently supplemented by dewatering discharge from the HD1 operations. A south east trending dyke, located to the east of BHT, effectively bounds the HD1 aquifer and abstraction from outside of the HD1 aquifer (i.e. the proposed abstraction at HD2) is not expected to impact Weeli Wolli Spring.
12. Supplementation of the Weeli Wolli Spring pools will continue under the proposed supply option which sees HD1 dewatering supplying water to the Proposal. The volume of water required to

maintain pool water levels are excluded from any future available water forecasts (i.e. water cannot be provided to the Proposal at the detriment of Weeli Wolli Spring supplementation).

13. Discharge into the creek, downstream of the Weeli Wolli Spring pools, would reduce by ~3 GL per year if the HD1 operation supplied water to the Proposal. The reduced discharge is in-line with Rio Tinto's water efficiency strategy to reduce environmental discharge; it is noted that the volume of reduction is small in comparison to seasonal flow volumes (about 10% of the median flow volume as recorded from 1985 to 2019).

E.3: Baby Hope Hydrology & Hydraulic Assessment

Water Resource Evaluation / Projects & Development

Baby Hope Hydrology & Hydraulic Assessment

28 February 2014

Executive summary

This report presents the results of a flood study to determine the expected annual exceedance probability (AEP) design flood quantiles for Pebble Mouse Creek at the Baby Hope ore deposit and the Hope Downs 1 South East pit. Additionally, the results of 2D hydraulic modelling have been used to determine the 1% AEP flood depths and extent under existing and post pit development conditions for the Baby Hope deposit.

A RORB rainfall-runoff routing model was calibrated to the Tarina gauging station on Weeli Wolli Creek (708014) and used to estimate design flood quantiles at Baby Hope and the HD1 SE pit. The expected 1% AEP design flows for Pebble Mouse Creek at the Baby Hope deposit and HD1 SE pit are 970 m^3/s and 890 m^3/s respectively.

The spatial variability of rainfall and streamflow exhibited in the region introduces a large degree of uncertainty in design flood estimates, as there are no streamflow gauges or rainfall gauges within the Pebble Mouse Creek catchment. To reduce uncertainty in estimates it is recommended that pressure transducers are installed in Pebble Mouse Creek to record the surface water response to rainfall events. This data can then be used to validate the design flood estimates for Baby Hope.

1. Introduction

1.1 Terminology

Probability concepts are fundamental to design flood estimation. The terminology used in the communication of these concepts is paramount if it is to be effective for all stakeholders. The term 'average recurrence interval' or 'ARI' has generally been used within Rio Tinto and by industry professionals to describe the probability of a particular magnitude of flood occurring ie. '100 yr ARI' or '1 in 100 year flood'.

Average Recurrence Interval (ARI) - the average period between occurrences equalling or exceeding a given value.

This description of flood events has often been misinterpreted by professionals, community members impacted by floods and other stakeholders as the probability of the chosen event is not explicitly defined. To ensure effective communication of event probabilities alternative terminology has been adopted by the Bureau of Meteorology (BoM) and other industry bodies. Australian Rainfall and Runoff (ARR) has outlined the proposed terminology to be adopted (Ball, 2013), and this follows;

Annual Exceedance Probability (AEP) - the probability of an event occurring or being exceeded within a year. For example a 1% AEP event has a 1% probability of being equalled or exceeded in any year.

The annual exceedance probability (AEP) expressed as a percentage, will be used to describe flood event probabilities for this study. Additionally, where appropriate, peak flows described as Q_y for the year ARI, will now be described as $Q_{n\%}$ AEP (including the percentage sign). Table 1-1 gives the AEP equivalent for ARI's commonly in used in flood studies.

Table 1-1: ARI and equivalent AEP

ARI	AEP (1 in x)	AEP %
1.44	2	50
4.48	5	20
9.49	10	10
20	20	5.0
50	50	2.0
100	100	1.0
200	200	0.50
500	500	0.20
1000	1000	0.10

1.2 Previous reports

Surface water investigations of the local catchment area have been previously undertaken for the development of Hope Downs 1. Regional catchment hydrology has been investigated for the development of Yandicoogina. Studies relevant to the Baby Hope deposit hydrology include:

- "Hope Downs Iron Ore Project: Preliminary Investigation into Surface Water Hydrology" – unpublished technical report prepared for Hope Downs Management Services, Halpern Glick Maunsell 1999.

- "Hope Downs Project Stage 1: Report for review of hydrology" – technical report prepared for Rio Tinto Iron Ore Expansion Projects, KBR March 2006.

- "Hope Downs Project Stage 1: Surface water management plan" – technical report prepared for Rio Tinto Iron Ore Expansion Projects, KBR March 2007.

- "Weeli Wolli hydrology and hydraulics" – unpublished internal technical report 2013 RTIO-PDE-0117748.

Other relevant regional studies include:

- "Surface Hydrology of the Pilbara Region" – technical report by the Water and Rivers Commission (Ruprecht, J. & Ivanescu, S., 2000).

- "Pilbara Surface Water Management Strategy" unpublished internal report RTIO-PDE-0053914.

2. Catchment characteristics

The Baby Hope study area is located in the Pebble Mouse Creek catchment within the Weeli Wolli Creek catchment that forms part of the Fortescue River Region (BoM, 2012a). Pebble Mouse Creek has a total catchment area of approximately 340 km² to the confluence with Weeli Wolli Creek, 258 km² of which is upstream of the study area, Figure 2-1. The targeted ore deposit lies on the lower northern slopes of a 2 km wide valley, approximately 10 km south west of Hope Downs 1 mine site and 78 km north west of the Newman township. A railway line and road, both containing culverts, are located south of the deposit on the opposite side of the Pebble Mouse Creek valley.

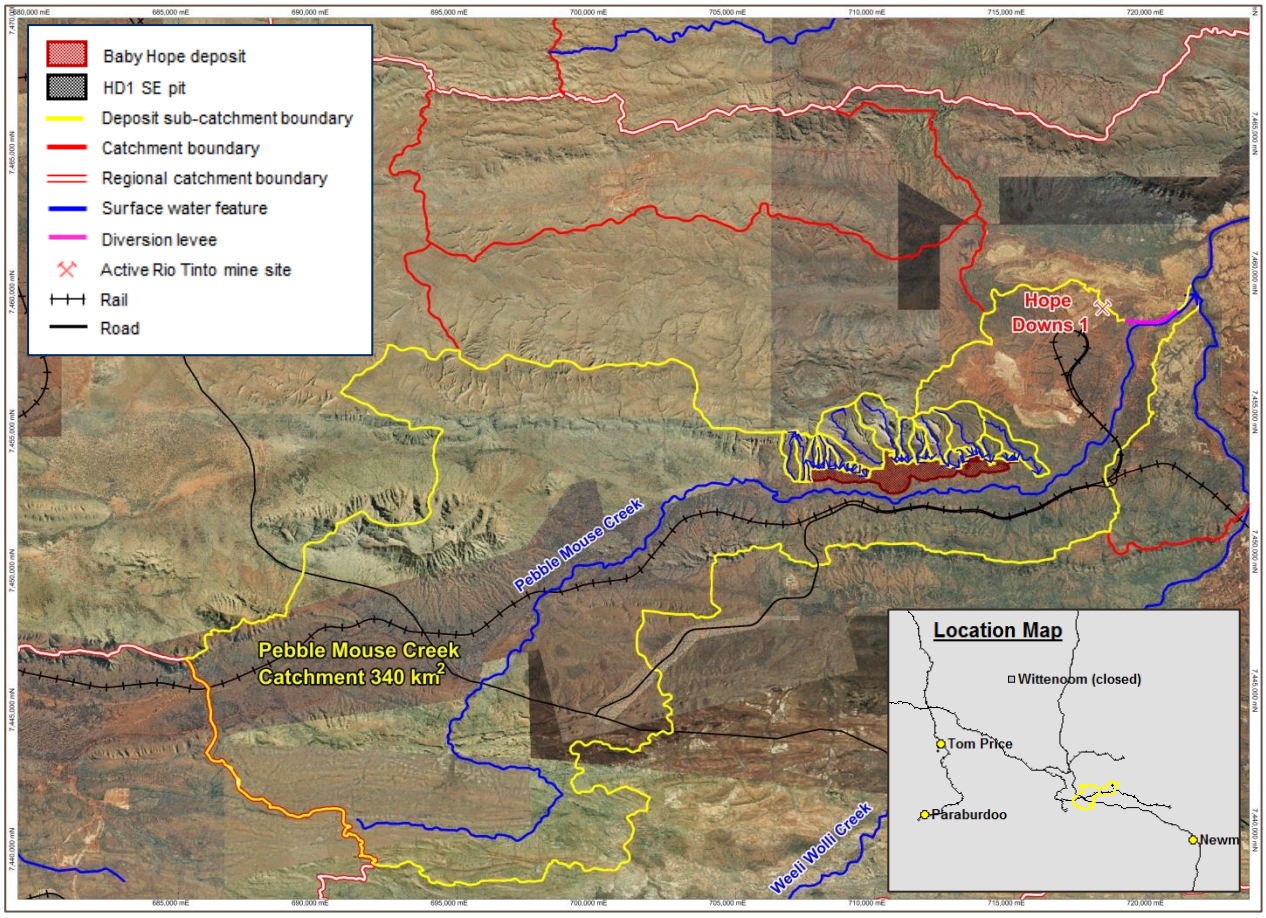

Figure 2-1: Catchments reporting to the Baby Hope ore deposit

The upper reaches of Pebble Mouse Creek tributaries are dominated by the Newman land system and lower reaches by the Boolgeeda and Platform land systems (van Vreeswyk et al. 2004). The Newman land system is characterised by rugged jaspilite plateaux, ridges and mountains supporting hard spinifex grasslands. The Boolgeeda and Platform land systems are characterised by stony slopes and plains below hill systems supporting hard and soft spinifex grasslands and mulga shrub lands.

Pebble Mouse Creek is generally well defined with little braiding and has an equal area slope of 3.4 m/km. The lower section of the catchment, approaching the deposit becomes confined in a 2 km wide valley that runs west to east with average low flow channel width of 10 m and depth of 1.5 m. A diversion levee was constructed to divert a section of the Pebble Mouse Creek low flow channel around Hope Downs 1 mine site as shown in Figure 2-1.

Runoff from the upper catchment produces the bulk of the flood water during large flood events with smaller sub-catchments on the north and south side slopes of the lower catchment contributing a minor proportion of run-off volume during flood events. A relatively steep range of hills directly north of the deposit area consists of many small but significant sub-catchments that have deeply incised creeks flowing south over the deposit. The deep incisions created by the creeks suggest that the range has been subjected to high water velocities and erosion.

Currently there are no stream flow or rainfall gauges within the Pebble Mouse Creek catchment. However the Tarina stream flow and rainfall gauge on Weeli Wolli Creek is located approximately 13 km downstream from the Pebble Mouse/Weeli Wolli confluence. The Wonmunna rainfall gauge is located approximately 8 km from the Pebble Mouse catchment centroid.

3. Regional and local climate

3.1 Regional climate characteristics

The Pilbara region spans across three Köppen climate zones: hot (persistently dry) grassland in the west, hot (winter drought) desert in the east and areas of hot (persistently dry) desert in the north and south (BoM, 2005a). It is typically classified as an arid to semi-arid climate, but annual rainfall totals are highly variable. Rainfall occurs predominantly in summer, with major falls caused by tropical cyclones, monsoon lows and convective thunderstorms. Rainfall is typically greatest around the Hamersley Ranges and decreases with distance from the coast. Tropical cyclones are a feature of the region and typically occur between January and March, with none expected between May and November. Extended periods of low rainfall can be common occurrences.

The spatial variability of rainfall across the Pilbara is high as a result of convective/cyclonic rainfall mechanisms. Average evaporation rates greatly exceed average rainfall rates and temperature variations can be extremely large (Ruprecht & Ivanescu, 2000). Mean annual evaporation rates range from 3000 to 4000 mm across the region, approximately an order of magnitude greater than the mean annual rainfall range of 200 to 500 mm.

3.2 Local climate

Based on the Köppen classification system the Baby Hope site is described as a grassland: hot (persistently dry)(BoM, 2005a). The Newman Bureau of Meteorology weather station (78 km southeast of Baby Hope) shows an average annual maximum temperature of 33° Celsius and summer maximum averages of 40° Celsius.

3.2.1 Rainfall

Long term daily gridded rainfall data has recently become available for Australia from the Bureau of Meteorology (Bo M, 2012b). The gridded data has been derived from recorded daily rainfalls and is provided for areas with sides approximately 5 km by 5 km.

A comparison between the recorded rainfall at Wonmunna (507012) and the gridded data at Wonmunna (700,633 mE/7,442,611 mN) indicated a strong correlation in larger rainfall days with a tendency to overestimate lower rainfall days, Table 3-1. The average number of rainfall days at Wonmunna (507012) is 57 as opposed to 74 days from BoM gridded data, with the majority of the difference coming from days with rainfall below 3 mm.

Table 3-1: Comparison of daily rainfall at Wonmunna (507012) and BoM gridded data (700,633 mE/7,442,611 mN)

Rainfall > (mm)	Average days per year 507012	Average days per year BoM gridded
1	35	43
2	29	33
3	25	27
5	18	19
10	11	10
20	5	4
25	4	3
35	2	1
50	1	1

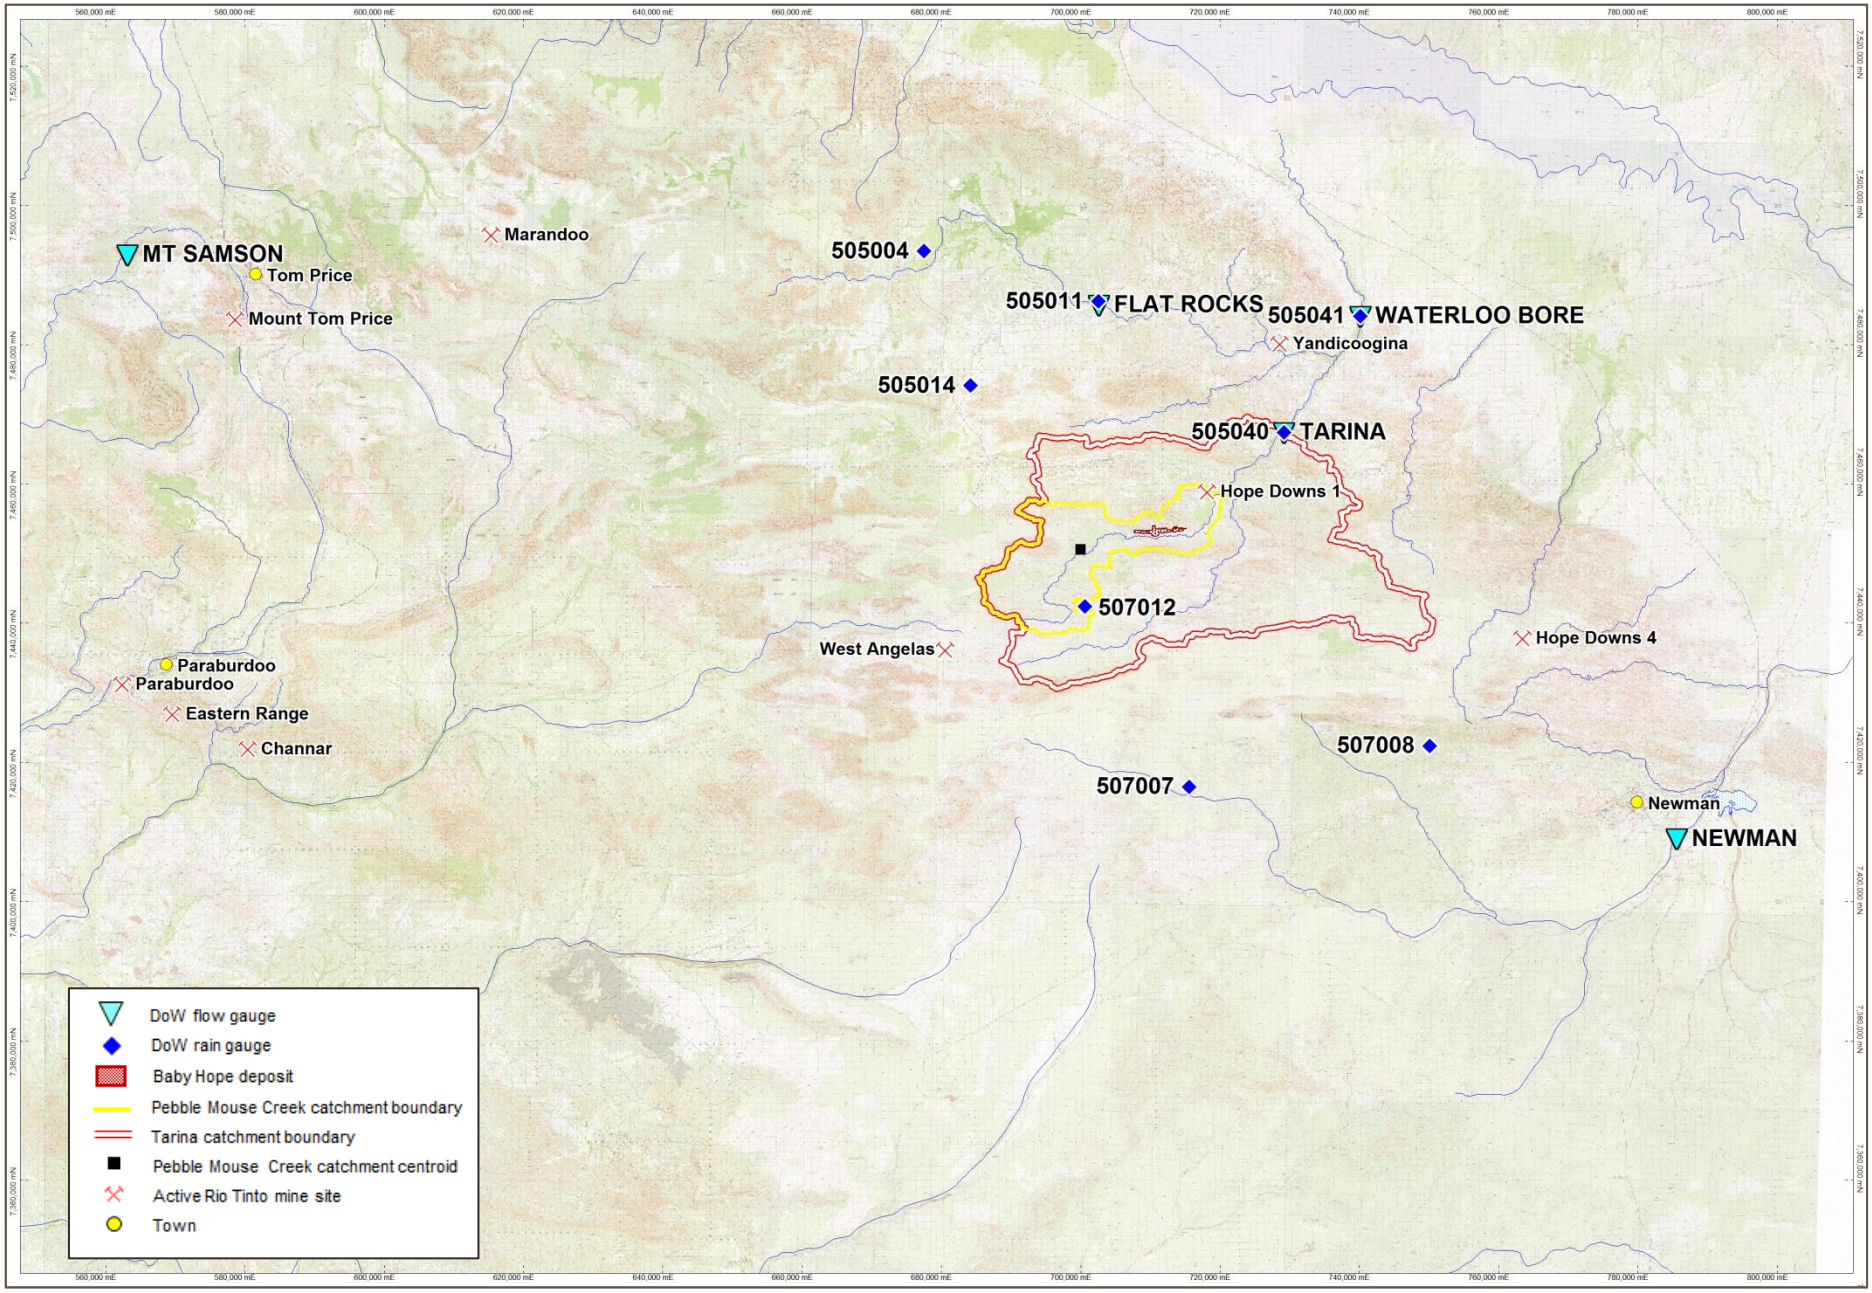

Figure 3-1: Pebble Mouse Creek catchment within the Tarina catchment

A comparison of monthly totals from the two data sets, Figure 3-2, revealed a strong correlation with a tendency to underestimate the larger rainfall months. Analysis of the differences in monthly recorded and gridded rainfalls showed that 90% of the gridded monthly totals were within +27 mm and -26 mm of the recorded totals.

In the absence of long term recorded rainfall data from within the catchment of interest the BoM gridded data was considered to be suitable for use as an estimate of Pebble Mouse Creek catchment rainfall. Baby Hope daily rainfall from 1906 to 2012 was obtained for the centroid of the Pebble Mouse Creek catchment, shown in Figure 3-1 (700,016 mE/7,450,612 mN), and used for analysis.

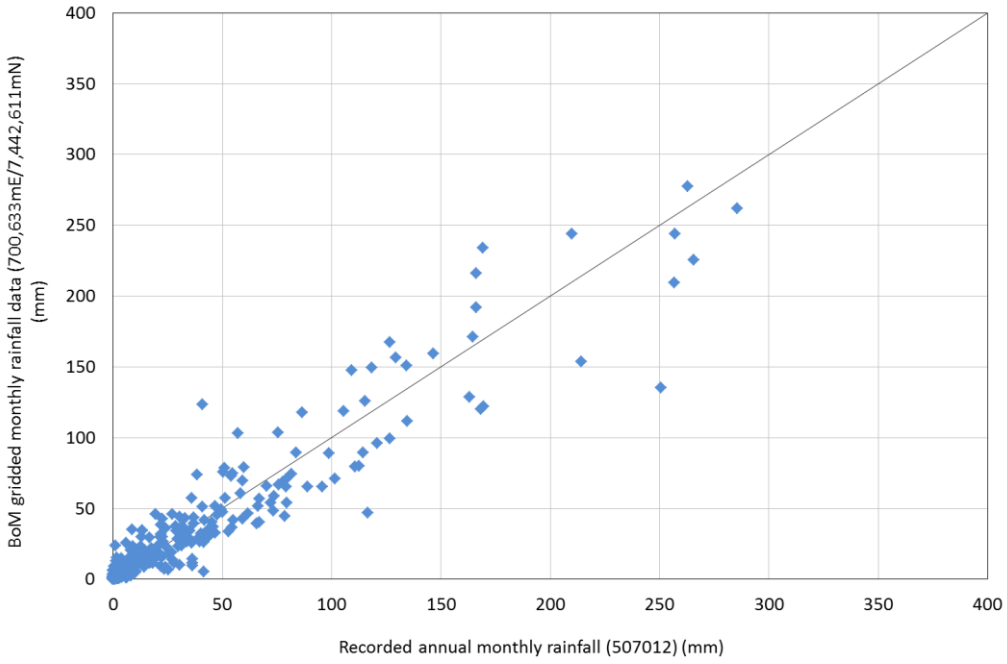

Figure 3-2: Relationship between recorded and gridded rainfall data at Wonmunna (Station 507012)

The monthly rainfall statistics for Baby Hope are provided in Figure 3-3. The rainfall is highly seasonal with 73% of the annual total occurring between December and April. Rainfall is typically associated with tropical low pressure systems and thunderstorm activity from the monsoonal trough that develops over northern Australia during summer. Winters are typically dry and mild though winter rain events can occur in June and July as a result of tropical cloud bands that intermittently affect the area. The high seasonality of rainfall has resulted in the adoption of a “water year” for the purpose s of hydrological analysis. The water year in the Pilbara Region is typically defined from 1 October to 30 September with the reported year stated as the year in which the water year commences. For example, the 1950 water year refers to 1 October 1950 through 30 September 1951.

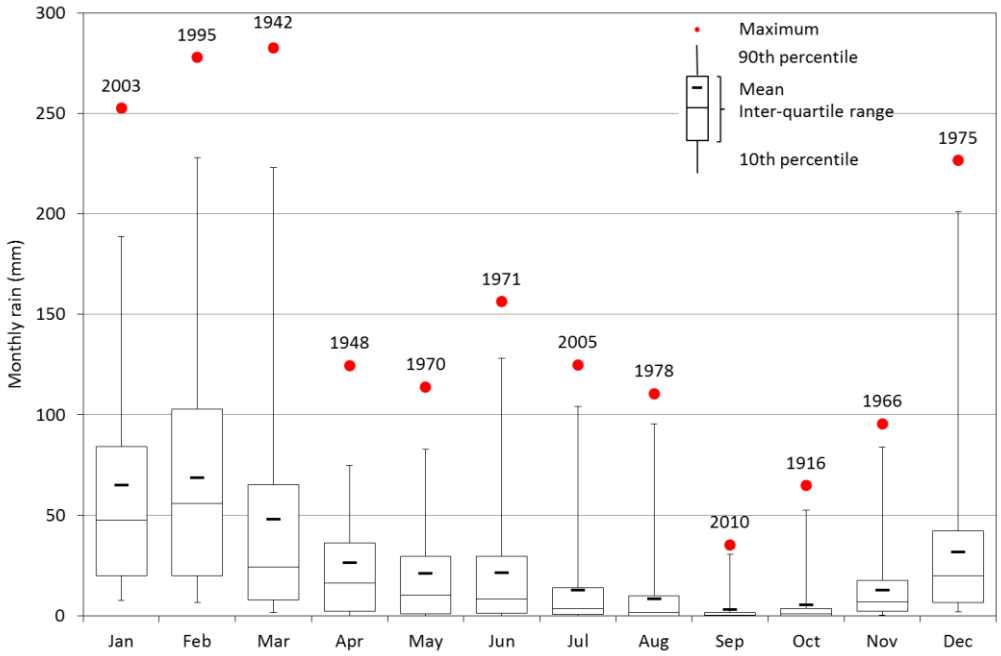

Figure 3-3: Monthly gridded rainfall distribution for Baby Hope (700,016 mE/7,450,612 mN)

The Coefficient of Variation (CV) of annual rainfall, used as a measure of inter-annual variability, is calculated as the ratio of the standard deviation to the mean annual rainfall. The CV of annual rainfall for the Baby Hope study area was calculated as 0.51, which is within the range of 0.4 to 0.7 reported for the Pilbara by Ruprecht and Ivanescu (2000).

An alternative methodology for characterising rainfall variability used by the Bureau of Meteorology calculates the rainfall *Index of Variability* (BoM, 2003) as:

$$index\ of\ variability = \frac{(90p - 10p)}{50p}$$

Where:

- $90p$ is the 90th annual rainfall percentile;

- $50p$ is the 50th annual rainfall percentile, or median annual rainfall; and

- $10p$ is the 10th annual rainfall percentile.

Under this classification scheme, the Baby Hope study area was calculated to have an Index of Variability of 1.28, which falls within the BoM's "high" variability range of 1.25 -1.50.

The long term mean annual rainfall for the study area is 317 mm with a range of 65 mm to 945 mm illustrating the high inter-annual variability. A trend analysis of annual rainfall indicates a long term increasing trend of 1.4 mm/year, Figure 3-4. The trend increases substantially to 7.1 mm/year when considering only the last 20 years. A similar rising trend has been observed at multiple locations in the Pilbara region.

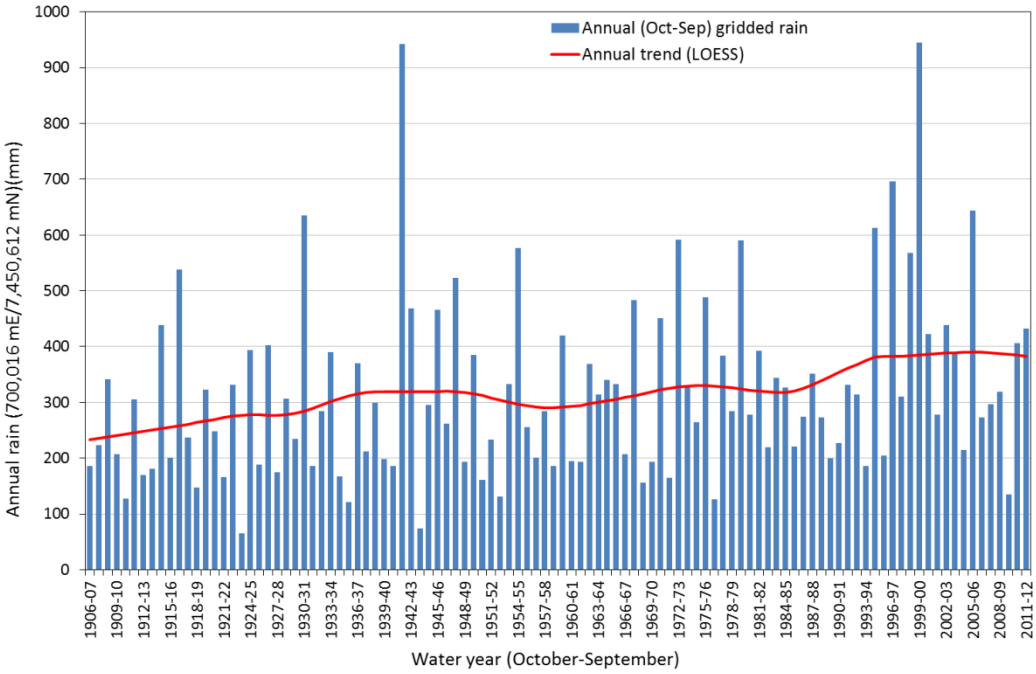

Figure 3-4: Trend for annual (October-September) rainfall, BoM gridded data Baby Hope (700,016 mE/7,450,612 mN)

Analysis of the daily gridded rainfall data indicates that rain events are infrequent and typically have low rainfall totals. Historically there are on average 39 rain days per year (rain greater than or equal to 1 mm) with majority of these days occurring from December to March. The daily rainfall statistics for the 107 year of record revealed; 76.4% of the daily rainfall totals are less than 5 mm; 96.4% are less than 25 mm; 98.2% are less than 35 mm; and 0.8% of daily rainfall totals are greater than 50 mm, an average of three days per year. Table 3-2 presents a summary of the gridded daily rainfall statistics for Baby Hope.

Table 3-2: 24 hour rainfall statistics BoM gridded data Baby Hope (700,016 mE / 7,450,612 mN)

	Statistics for days when rain occurred			**Statistics for all days**		
Month	Maximum (mm)	Mean (mm)	Standard deviation (mm)	Mean days of rain per year >=1 mm	Mean (mm) <10 mm only	Standard deviation (mm) <10 mm only

December	156	3.7	8.6	4	1.9	2.3

3.2.2 Evaporation and Evapotranspiration

Evaporation and evapotranspiration (ET) measures available for the Baby Hope study area are shown in Table 3-2. The mean annual Class A pan evaporation estimated for the study area is 3,333 mm (BoM, 2006), which greatly exceeds the average annual rainfall in the area, 317 mm/year, keeping it typically dry. Sheltered monthly evaporation was estimated using a pan evaporation conversion factor of 0.63, taken from a study by Luke et. al. (2003).

The annual mean point potential ET rate estimated for the study area is 3,030 mm/year (BoM, 2005b). Point potential ET is the ET that would take place, under the conditions of unlimited water supply, from an area so small that the local ET effects do not alter local air mass properties. The BoM advises that point potential ET may be taken as an estimate of evaporation from small water bodies such as shallow water storages, which may include surface water pools within a creek system.

The annual mean areal actual ET rate for the study area is estimated to be 361 mm/year (BoM, 2005b). This is the ET rate that actually takes place, under the condition of existing water supply, from an area so large that the effects of any upwind boundary transitions are negligible and local variations are integrated to an areal average. For example, this represents the evapotranspiration which would occur over a large area of land under existing (mean) rainfall conditions.

The annual mean areal potential ET for the study area is 1,518 mm/year (BoM, 2005b). This is the ET rate that would occur under the condition of unlimited water supply, from an area so large that the effects of any upwind boundary transitions are negligible and local variations are integrated to an areal average. For example, this represents the evapotranspiration which would occur over a very large wetland or large irrigated area, with a never-ending water inflow. A "large" area is defined as an area greater than one square kilometre.

Table 3-2: Evaporation rates estimated for the Baby Hope study area; evaporation estimates based on at least 10 years of data1975-2005, ET data based on 30 years of data 1961-1990.

Month	Mean Class A pan evaporation (mm)	Mean sheltered evaporation (mm)	Mean point potential ET (mm)	Mean areal actual ET (mm)	Mean areal potential ET (mm)
January	394	248	392	61	202

Annual	3333	2100	3030	361	1518

4. Hydrology

4.1 Regional flow

Ruprecht and Ivanescu (2000) describe the hydrology of the Pilbara as being one of extremes, ranging from severe droughts to major floods. Pilbara streamflow is predominantly short-lived, ephemeral and in direct response to rainfall, therefore it has a similar seasonality and variability to rainfall. Surface water runoff generation in the Pilbara region typically results from infiltration excess as opposed to saturation excess. Infiltration excess occurs when the rate of rainfall exceeds the infiltration capacity of the soil and is commonly associated with high intensity rainfall and impervious catchments. Conditions satisfying saturation excess runoff generation occur during prolonged rainfall influenced by cyclones and tropical depressions. With the low rainfall in the region and general lack of groundwater contribution to surface water flow, extended periods of no flow are common.

The Pilbara region is sparsely populated and areas of interest from a streamflow perspective are often long distances from townships, making it problematic to get to many creeks while they are flowing, especially small creeks. Large flow events are difficult to measure due to safety concerns and high velocities, and invariably result in changes to the geomorphology of creeks. As a result stage-discharge relationships in the Pilbara are particularly challenging to accurately define and frequently need to be updated following large flow events. It follows that there is a distinct lack of quality streamflow data in the region, on both a temporal and spatial scale.

4.2 Local flow

There are no local streamflow gauges within the Pebble Mouse Creek catchment. The Tarina gauging station is located on Weeli Wolli Creek, approximately 13 km downstream from the Pebble Mouse/Weeli Wolli Creek confluence and is the closest stream flow gauge to the Baby Hope deposit. Streamflow gauges in catchments surrounding the Baby Hope study area are shown in Figure 3-1 and Table 4-1. Characteristics of the Pebble Mouse Creek catchment to the Baby Hope deposit and HD1 SE pit are given in Table 4-2.

Table 4-1: Local stream gauges within 150 km of Baby Hope and with greater than 20 years of data

Station number	Gauge name	Catchment area (km^2)	Slope m/km	Distance from study area (km)	Period of record	Years of data	% record complete
706207	Mt Samson	250	8	140	1/1/1967 - 21/5/2001	33	96
708001	Flat Rocks	1,370	2.9	37	15/08/1967 - present	44	98
708011	Newman	2,824	1.67	95	09/01/1980 - present	32	100
708013	Waterloo Bore	3,991	2.65	53	30/11/1984 - present	28	100
708014	Tarina	1,512	3.65	34	10/05/1985 - present	27	100

The Depart of Water (DoW) has developed stage-discharge relationships for the gauges listed in Table 4-1. The strength of the relationship is dependent on the quality, number, range and date of measurements. Geometry of the cross section where flow measurements have been taken may change over time resulting in an altered relationship for the location and consequently it needs to be updated or redefined depending on the level of change. The latest stage-discharge relationships available have been used in this study and are shown in Appendix B.

Table 4-2: Characteristics of the Pebble Mouse Creek catchment

Catchment	Catchment area (km^2)	Slope (m/km)
Pebble Mouse Creek at Baby Hope	258	3.5
Pebble Mouse Creek at HD1 SE pit	297	3.5

4.3 Annual flow

It is reasonable to surmise that the streamflow regime at the Baby Hope study area is similar to the downstream flows at Tarina as the Pebble Mouse Creek catchment contributes to flow at the station. A total of 47 separate flow events have been recorded at the Tarina gauge over a 27 year period of operation, which represents an average of approximately 2 flow events per year. Analysis of the Baby Hope gridded rainfall data indicates that there were on average two rainfall events 35 mm or greater over the same period, suggesting that the minimum amount rainfall required to produce flow in the catchment is 35 mm. This is supported by Charles et. al. (2013) in their study on the Pilbara which included analysis of the Tarina catchment and found the minimum rainfall required to produce flow in the catchment is 36 mm.

The annual maximum flow time series (AMS) for the Tarina stream gauge is given in Figure 4-1. Based on the AMS large flow events are expected to occur on average once every five years. The CV of annual streamflow for Tarina is 2.08, indicating the stream flow is approximately 4 times more variable than rainfall. The AMS time series is dominated by the flow event as a result of Tropical Cyclone (TC) John in 1999 which is approximately 4 times greater than the next largest event. Analysis of large flows events within a catchment can provide an insight into the mechanisms that drive them.

Rainfall totals available for TC John and other large flow events at the Tarina gauge are shown in Table 4-3. The rainfall totals show that the Unnamed Tropical Low (UTL) in January 2003 produced a much higher rainfall than TC John particularly around the Tarina rain gauge (505040), yet resulted in much lower flows. Analysis of rainfall from the two events at the Wonmunna rainfall gauge (Appendix A) in the upper catchment reveals that rainfall from TC John at the gauge was equivalent to a 2% AEP rainfall event and rainfall from the January 2003 UTL at the gauge was equivalent to a 5% AEP rainfall event. The difference in intensity between the two rainfall events provides an explanation for the difference in flow as a result of them and highlights the spatial variability of rainfall and streamflow within the Tarina catchment.

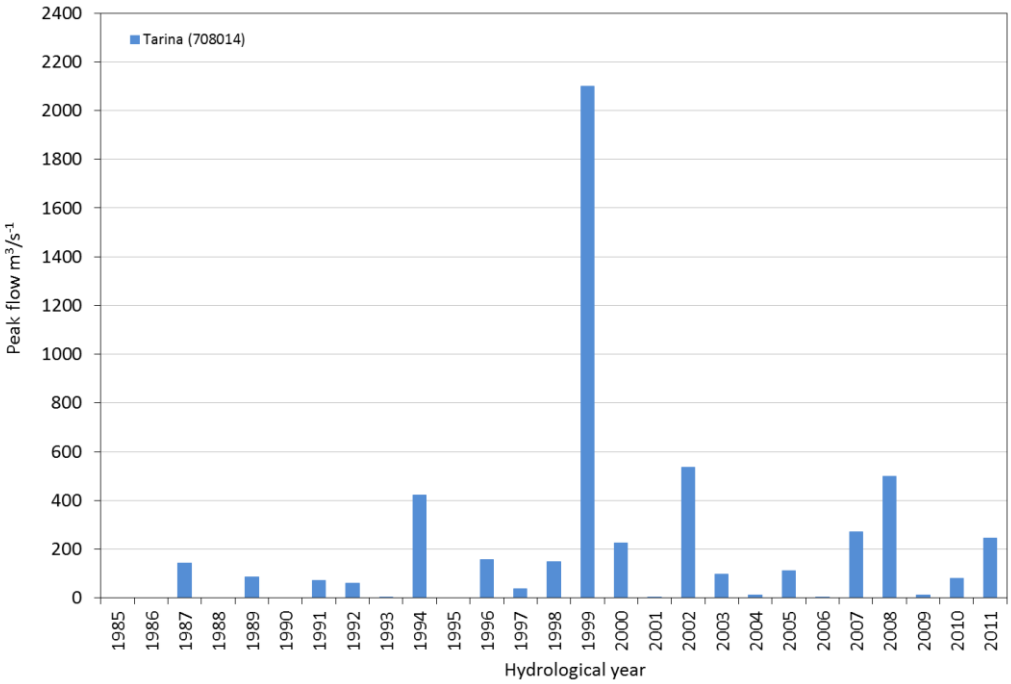

Figure 4-1: Annual maximum stream flow record for hydrological year (September to October)

Large streamflows in the Pilbara are almost always the result of tropical cyclones or tropical lows and large peak flows at Tarina correlate well with tropical cyclones or tropical lows that resulted in rainfall in the region as shown in Table 4-3.

Table 4-3: Significant rainfall events producing flows at Tarina; as a result of tropical lows and tropical cyclones

Event name	Date	Hydrological year (Sep-Oct)	Rainfall 505040 (mm)	Rainfall 507012 (mm)	BoM gridded rainfall* (mm)
TC Bobby	26/02/1995	1994	135	109	126
TC John	16/12/1999	1999	160	199	155
TC Wylva	22/02/2001	2000	140	79	72
Unnamed Tropical Low	25/01/2003	2002	317	203	246
Unnamed Tropical Low	01/03/2009	2008	116	130	93

** from centroid of Pebble Mouse catchment*

Monthly streamflow analysis and flow duration curves for Tarina are shown in Figure 4-2 and Figure 4-3. The mean monthly flow at Tarina indicates the creek flows year round; this is not typical in the Pilbara and is a result of the release of surplus mine dewatering water into Weeli Wolli Creek which began in 2007. The release of the surplus water has altered the flow regime of the creek system from an ephemeral to a perennial system. The flow duration curves also indicate a change in flow regime, however there is no indication that this has significantly impacted on the AMS, with the exception of low flows.

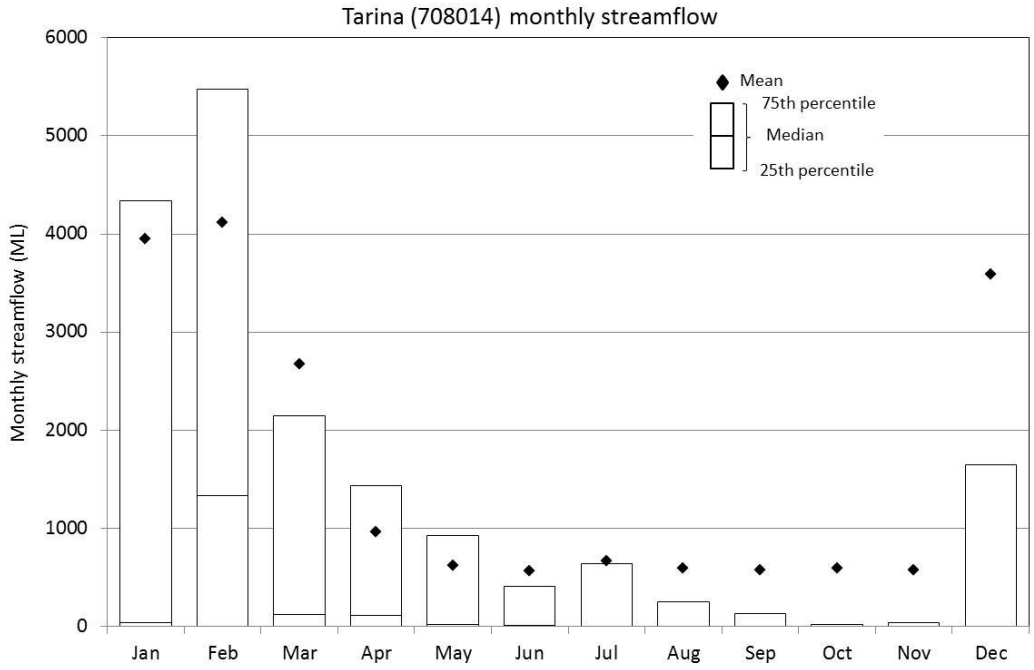

Figure 4-2: Monthly streamflow for Tarina 1985-2012

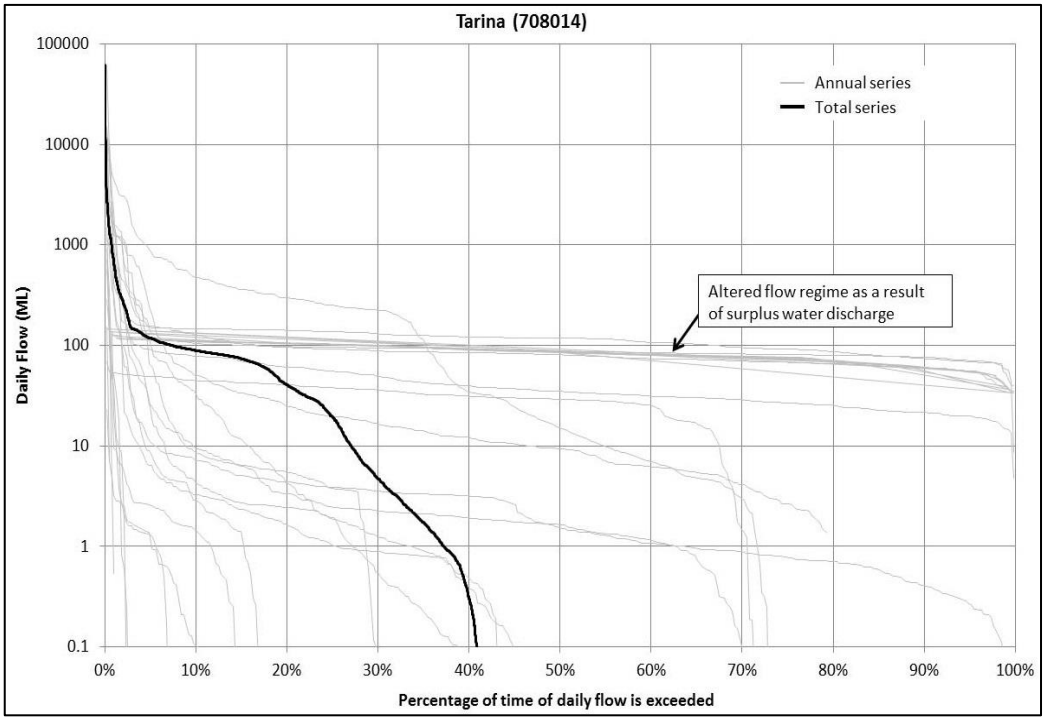

Figure 4-3: Flow duration curves at Tarina gauging station (708014) on Weeli Wolli Creek

4.4 Regional flood frequency analysis

Regional flood frequency analysis (RFFA) is the most commonly adopted technique to derive design flood estimates on ungauged catchments (Rahman et.al. 2012). A RFFA method attempts to transfer flood characteristic information from a group of gauged catchments to an ungauged catchment of interest. FFAs can be undertaken on flood volumes and/or peak discharges and may be carried out graphically or analytically

(Pilgrim, 1998). A FFA was performed on the annual maximum series (AMS) of peak discharges recorded at local regional streamflow gauges with more than 20 years of data, Table 4-1. The years in which data were missing were investigated further to determine if significant rainfalls occurred during the periods for which streamflow information was lacking. For years where it was determined that the missing data would not impact on the recorded peak discharge for that year, the peak was included in the analysis.

An analytical FFA using the HEC-SSP flood frequency analysis program (USACE, 2010) was undertaken. In accordance with Australian Rainfall and Runoff (AR&R) (Pilgrim, 1998) the 3-parameter Log Pearson III distribution was adopted for this study. A conditional probability adjustment was performed in HEC-SSP to account for zero values, missing data and low outliers. Additional low outliers were excluded where the fit of the distribution was considered poor for the rarer AEP events. The observed AMS is only one representation of the AMS from the total population of annual floods. To obtain an unbiased estimate of the true AEP the average of a large number of annual series, or the expected annual exceedance probability, is required. The expected annual exceedance probability was adopted for estimates of FFA quantiles this study.

During the FFA process it was noted that the fitted distribution at Waterloo Bore was a poor fit to the observed data. Comments made by the Department of Water (DOW), who developed the stage-discharge relationship, suggest that there is a great deal of uncertainty in its quality. Subsequently this gauging station was removed from any analysis. The FFA distribution, rating curve and comments for Waterloo Bore can be found in Appendix A.

Table 4-4: Results of FFA for gauges surrounding the Baby Hope study area

			AEP (%) (LPIII Expected design peak m^3/s)					
Station number	**Gauge name**	**Area (km^2)**	**50**	**20**	**10**	**5**	**2**	**1**
706207	Mt Samson	250	20	90	190	310	500	640
708001	Flat Rocks	1,370	80	230	420	710	1,340	2,110
708011	Newman	2,820	230	590	1,030	1,700	3,140	4,890
708014	Tarina	1,510	80	250	500	920	1,950	3,350

Results of the FFA on gauges surrounding the Baby Hope area are given in Table 4-4 and fitted distributions are shown in Appendix A. Tarina is the closest gauge downstream of the Baby Hope study area that could be used to calibrate a rainfall-runoff routing model. The FFA for Tarina is shown in Figure 4-4. The altered flow regime at the gauge as discussed in section 4.3 was not taken into account in the FFA due to the small period of record of altered flow (5 years) and no distinct affects observed on large flow events of the AMS.

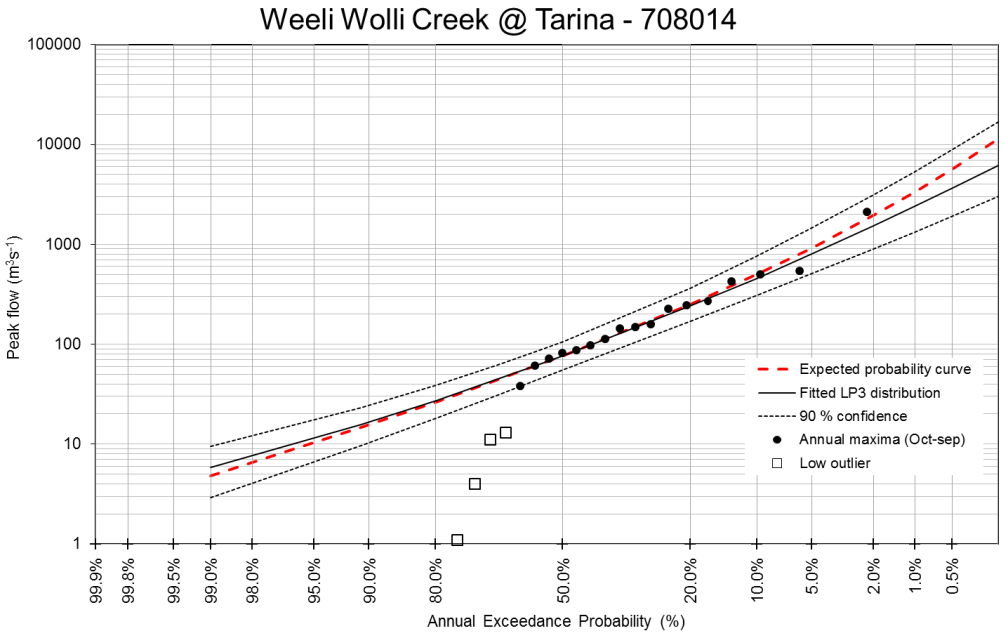

Figure 4-4: Tarina annual maximum stream flow flood frequency analysis

For FFA it is important to have a record which is representative of the total population, it follows that the period of record available for analysis influences the reliability of a FFA, this is highlighted by Table 4-5. The table was developed from data generated synthetically from a probability distribution, and outlines the number of years of record needed to estimate three AEP's with 95% confidence and the expected margin of error. From the table it can be seen that estimates of the 1% AEP from the 27 year record of data available for Tarina are subject to an expected error of greater than 25%. Although 27 years of data is a considerable period for a Pilbara streamflow gauge, it is important to understand the limitations of estimates made using it.

Table 4-5: Length of record (years) required to estimates floods of various AEP with 95% confidence (Gordon et. al.2004)

	Error	
Annual exceedance probability (AEP %)	10%	25%
10	90	18
2	110	39
1	115	48

4.5 Regional design flood estimates

Regional design flood estimates are typically based on equations developed from a RFFA. The probabilistic rational method (PRM) and the index flood method (IFM), published in ARR (Pilgrim, 1987), were design peak flow estimation techniques recommended for the Pilbara region. These methods were based on the limited data available at the time and in hindsight are considered to be conservative design flood estimation techniques.

Recently there have been a number of new methods developed for the Pilbara namely; a Regional Flood Frequency Procedure (RFFP) by Flavell, 2000 and updated in 2006 (Flavell 2012); an updated Pilbara Index Flood method (JDA) (Davies and Yip, 2014) and a Quantile Regression Technique (QRT) (Rahman et. al., 2012). The more recent methods

are based on a longer record of data and for this reason are considered to give a more reliable estimation of design flows. Estimates using the RFFP, JDA and QRT methods mentioned above were calculated for this study.

4.5.1 Regional flood frequency procedure for the Pilbara (RFFP)

A regional flood frequency procedure for the Pilbara was developed by Flavell in 2000 and updated in 2006 (Flavell 2012). The 2000 RFFP method was developed using 15 Pilbara catchments and is recommended for design events for 20 year ARI or larger, as it gives larger peak flow estimates. There are two equations for the 2000 method and again the recommended approach is to adopt the larger estimate. The two equations are as follows:

$$Q_{20} = 1.98 \times 10^{-23} (AS_e{}^{0.5})^{0.79} LAT^{-15.08} LONG^{20.91}$$

or

$$Q_{20} = Q_{10}(13.21A^{0.61})/(8.74A^{0.60})$$

Where:

Q_{20} = 20yr ARI (5% AEP) peak discharge (m^3/s);

A = catchment area (km^2)

S_e = equal area slope (m/km)

Q_{10} = $2.36 \times 10^{-34} \left(AS_e{}^{0.5}\right)^{0.81} LAT^{-15.24} LONG^{26.28} \left(\frac{L^2}{A}\right)^{-0.39}$

Table 4-6: RFFP 2006 frequency factors

Frequency factor	Catchment area (km^2)						
	0.1	1.0	10	100	1,000	10,000	100,000
Q_{50}/Q_{20}	1.66	1.72	1.78	1.83	1.88	1.93	2.00
Q_{100}/Q_{20}	2.44	2.61	2.75	2.87	3.03	3.20	3.42

The Q_{20} is subsequently adjusted to the Q_{50} and the Q_{100} design flood estimate by applying flood frequency factors shown in Table 4-6. Equations for estimating smaller design flow events are given in the Flavell (2012) paper shown in the references. Estimates of Q_{100} ($Q_{1\%}$) using the 2000 RFFP method are given in section 4.5.5.

4.5.2 Updated Pilbara index flood method (JDA)

An updated Pilbara index flood method based on data from 57 catchments from the Pilbara, Gascoyne and Mid-west regions was developed by Davies and Yip in 2012 and updated in 2014. The method separates catchments by size with individual equations developed for; catchments less than 1,000 km^2; catchments between 1,000 km^2 and 10,000 km^2; and catchments greater than 10,000 km^2. The design equation for Baby Hope (258 km^2) using this method is as follows:

$$Q_5 = 7.32 \times 10^{-8} A^{0.651} I_{1h,2yr}{}^{5.251}$$

Where:

Q_5 = 5yr ARI (20% AEP) peak discharge (m^3/s);

A = catchment area (km^2)

$I_{1h,2yr}$ = the design intensity frequency duration (IFD) (ARR 1987) value for a 1 hour 2 year rainfall (mm/hour) at the study area centroid.

Table 4-7: JDA frequency factors

ARI (yrs)	2	5	10	20	50	100
Frequency factor	0.31	1.00	1.70	2.58	126	5.82

Q_5 is subsequently adjusted to the design discharge by applying a flood frequency factor as shown in Table 4-7. Estimates of Q_{100} ($Q_{1\%}$) using the JDA method are given in section 4.5.5.

4.5.3 Quantile regression technique (QRT)

The recently completed ARR Project 5 Stage 2 study (2012) into design flood estimation has found that regression-based RFFA methods such as the QRT are preferable to PRM (Rahman et. al., 2012). The study was conducted on 12 Pilbara catchments and resulted in the following design equation:

$$\ln(Q_{100}) = 5.87 + 0.39[\ln(area) - 4.71] + 5.34[\ln(I_{12,2}) - 1.47]$$

Where $area$ is the catchment area (km²) and $I_{12,2yr}$ is the design intensity frequency duration (IFD) (ARR 1987) value for a 12 hour 2 year rainfall (mm/hour) at the study area centroid. Estimates of Q_{100} ($Q_{1\%}$) using the QRT are given in section 4.5.5.

4.5.4 Scaling of flood frequency analysis

A simple form of design flood estimation for ungauged catchments is performed using area to adjust peak flow estimates from gauged catchments close to the study area of interest. The strength of this method comes from the locality of catchments used, as proximity is frequently a strong indicator of hydrologic similarity (Lowe and Nathan, 2005). Estimates of $Q_{1\%}$ from the FFA on gauges in section 4.2 were scaled using the following equation from Grayson et. al., 1996:

$$Q_u = Q_g\left(\frac{A_u}{A_g}\right)^{0.7}$$

Where Q_u and Q_g are flow (m³/s) of ungauged and gauged catchments; A_u and A_g are area (km²) of ungauged and gauged catchments. The coefficient 0.7 accounts for the non-linear effects of catchment area on runoff. Results of the area adjusted local region FFA are shown in Table 4-8. The local area adjusted mean was calculated as the mean value of 4 scaled estimates from catchments surrounding the Baby Hope deposit. The local area adjusted mean estimate of 1% AEP peak flow for Pebble Mouse Creek to the Baby Hope deposit and to HD1 SE Pit was calculated to be 790 m³/s and 870 m³/s respectively.

Table 4-8: Area adjusted estimates of 1% AEP Pebble Mouse Creek at Baby Hope deposit

Station number	Catchment name	Catchment area (km²)	FFA Log Pearson III $Q_{(1\%)}$ (m³/s)	Pebble Mouse at Baby Hope $Q_{(1\%)}$ (m³/s)	Pebble Mouse at HD1 SE Pit $Q_{(1\%)}$ (m³/s)
706207	Mt Samson	250	640	650	720
708001	Flat Rocks	1,370	2,110	660	720
708011	Newman	2,820	4,890	920	1,010
708014	Tarina	1,510	3,350	910	1,010
		Local area adjusted mean		790	870

4.5.5 Regional flood frequency results

Estimates of 1% AEP for Pebble Mouse creek up to the Baby Hope deposit and HD1 SE pit, and surrounding local catchments using the preceding regional flood frequency methods are presented in Table 4-9. The results show a significant variation in estimates from the different methods for Pebble Mouse Creek ranging from 300 m^3/s to 790 m^3/s to Baby Hope deposit and from 320 m^3/s to 870 m^3/s to HD1 SE pit. Estimates of the 1% AEP using RFFP from surrounding catchments are within 20% of the FFA, with the exception of the Newman.

Table 4-9: Estimates of 1% AEP design flood using regional flood frequency analysis

Catchment	JDA (m^3/s)	RFFP (m^3/s)	QRT (m^3/s)	FFA (m^3/s)	Local area adjusted average (m^3/s)
Mt Samson	740#	760#	610*#	670	-
Flat rocks	1,560	2,400*#	1,440	2,110	-
Tarina	1,310	2,980*#	670	3,180	-

4.6 Hydrologic modelling

A hydrologic model of the Weeli Wolli Creek catchment was developed using the RORB (Laurenson et al., 2007) model in order to estimate design peak flows for Pebble Mouse Creek at the Baby Hope deposit and at HD1 SE pit. RORB is a rainfall runoff and streamflow routing model that calculates flood hydrographs from rainfall and other channel inputs. Rainfall excess, calculated by subtracting losses from rainfall, is routed through catchment storages to produce runoff hydrographs at any location; losses are processes that occur on the catchment surface before the water enters the channel network. In addition to catchment storage, RORB allows for storage reservoirs and channel inflow and outflow processes, such as baseflow, to be modelled. Channel inflows and outflows can be modelled using a hydrograph, constant value or discharge relationship. The project catchment has been divided into sub-catchments bounded by drainage divides. The sub-catchments making up the model are depicted in

Figure 4-5. A rainfall excess for each sub-catchment is assumed to enter the channel network at a point near the centroid of the sub-catchment, added to any existing flow in the channel and routed through a routing procedure based on continuity and a storage-discharge relationship:

$$S = 3600kQ^m$$

where S is the storage (m^3), Q is the outflow discharge (m^3/s), m is a dimensionless exponent that is a measure of the catchment's non-linearity and k is a dimensionless empirical coefficient. The coefficient k is calculated as:

$$k = k_c k_r$$

where k_c is an empirical coefficient applicable to the catchment and stream network and k_r is a dimensionless ratio called the relative delay time applicable to an individual reach storage. Channel storages are proportional to the reach length and hydrographs are combined at channel junctions (Laurenson et al., 2007).

4.6.1 Tarina RORB calibration

The Tarina RORB model was calibrated using the initial/continuing loss model, where loss processes are modelled by an initial loss followed by a continuing (constant) loss rate. A value of 0.8 was adopted for the exponent m, following recommendation by RORB developers (Laurenson et.al, 2007) for ungauged catchments in the absence of more relevant information. Design values of k_c, initial loss and continuing loss for the study catchment were determined through calibration. Calibration was achieved by fitting flows produced by RORB, from the developed catchment and observed rainfall, to observed flows from Tarina gauging station. Five events were used to calibrate the RORB model to Tarina and are detailed in Table 4-10.

Table 4-10: Events used to calibrate the RORB model

Flow event peak date	Hydrological year (Oct-Sep)	Peak flows (m^3/s)	AEP (%) (from FFA)	Rainfall gauge used in calibration
28/03/1988	1992	57	50	505040
25/02/1995	1994	224	20	505040
8/01/1997	1996	108	50-20	505040
15/12/1999	1999	2,100	2	505040
25/01/2003	2002	535	10	505040

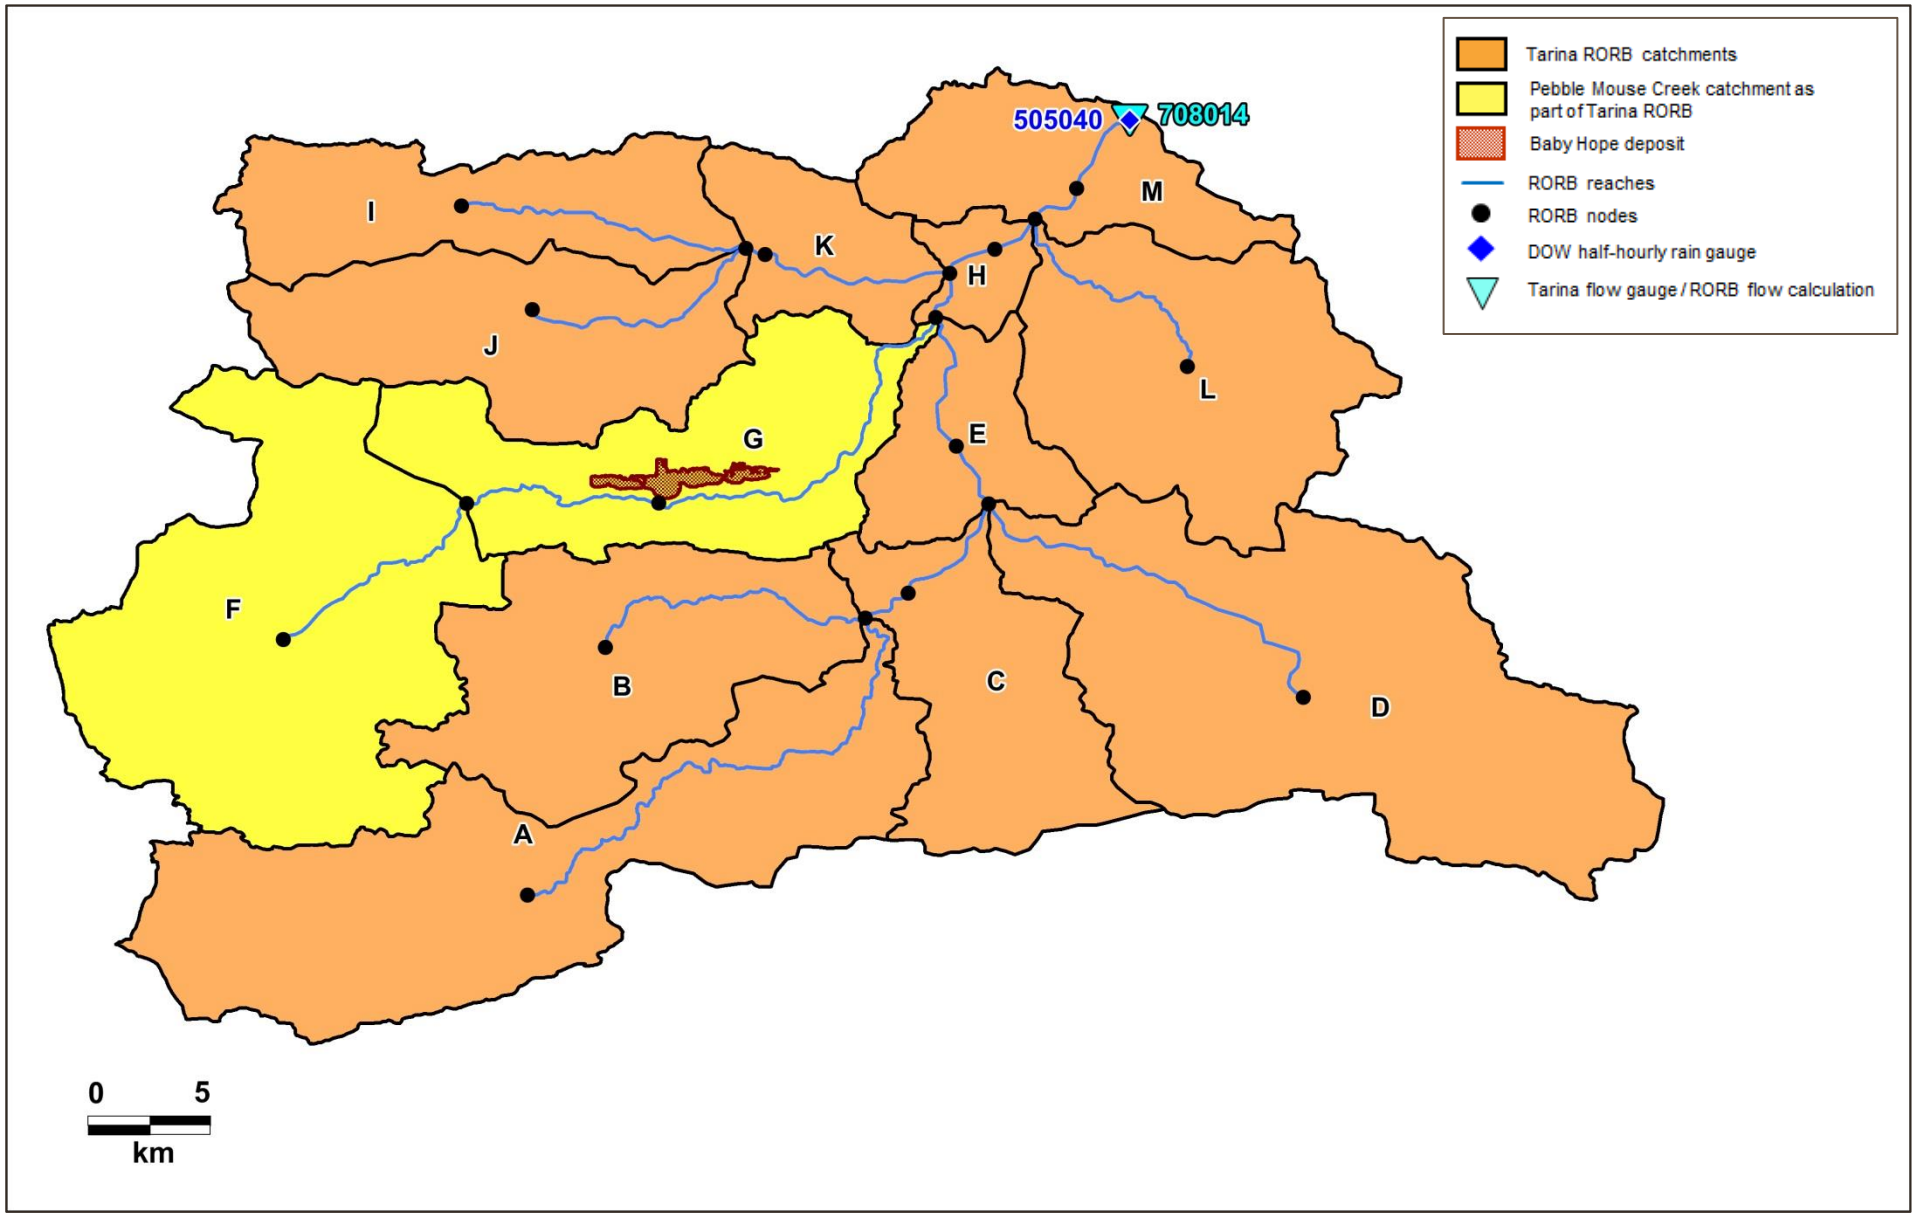

Figure 4-5: Tarina RORB model inputs; catchment sizes are listed in Appendix C

Considering the large catchment size and the use of only one rainfall gauge, the model was found to calibrate very well to observed hydrographs, as shown in Figure 4-6. The k_c parameter is the focus of calibration attempts as initial loss and continuing loss vary with antecedent conditions. The calibrated model parameters presented in Table 4-11 show some variation in the k_c value. Given the number of and range of calibration events an average value for the k_c parameter from the five events was adopted.

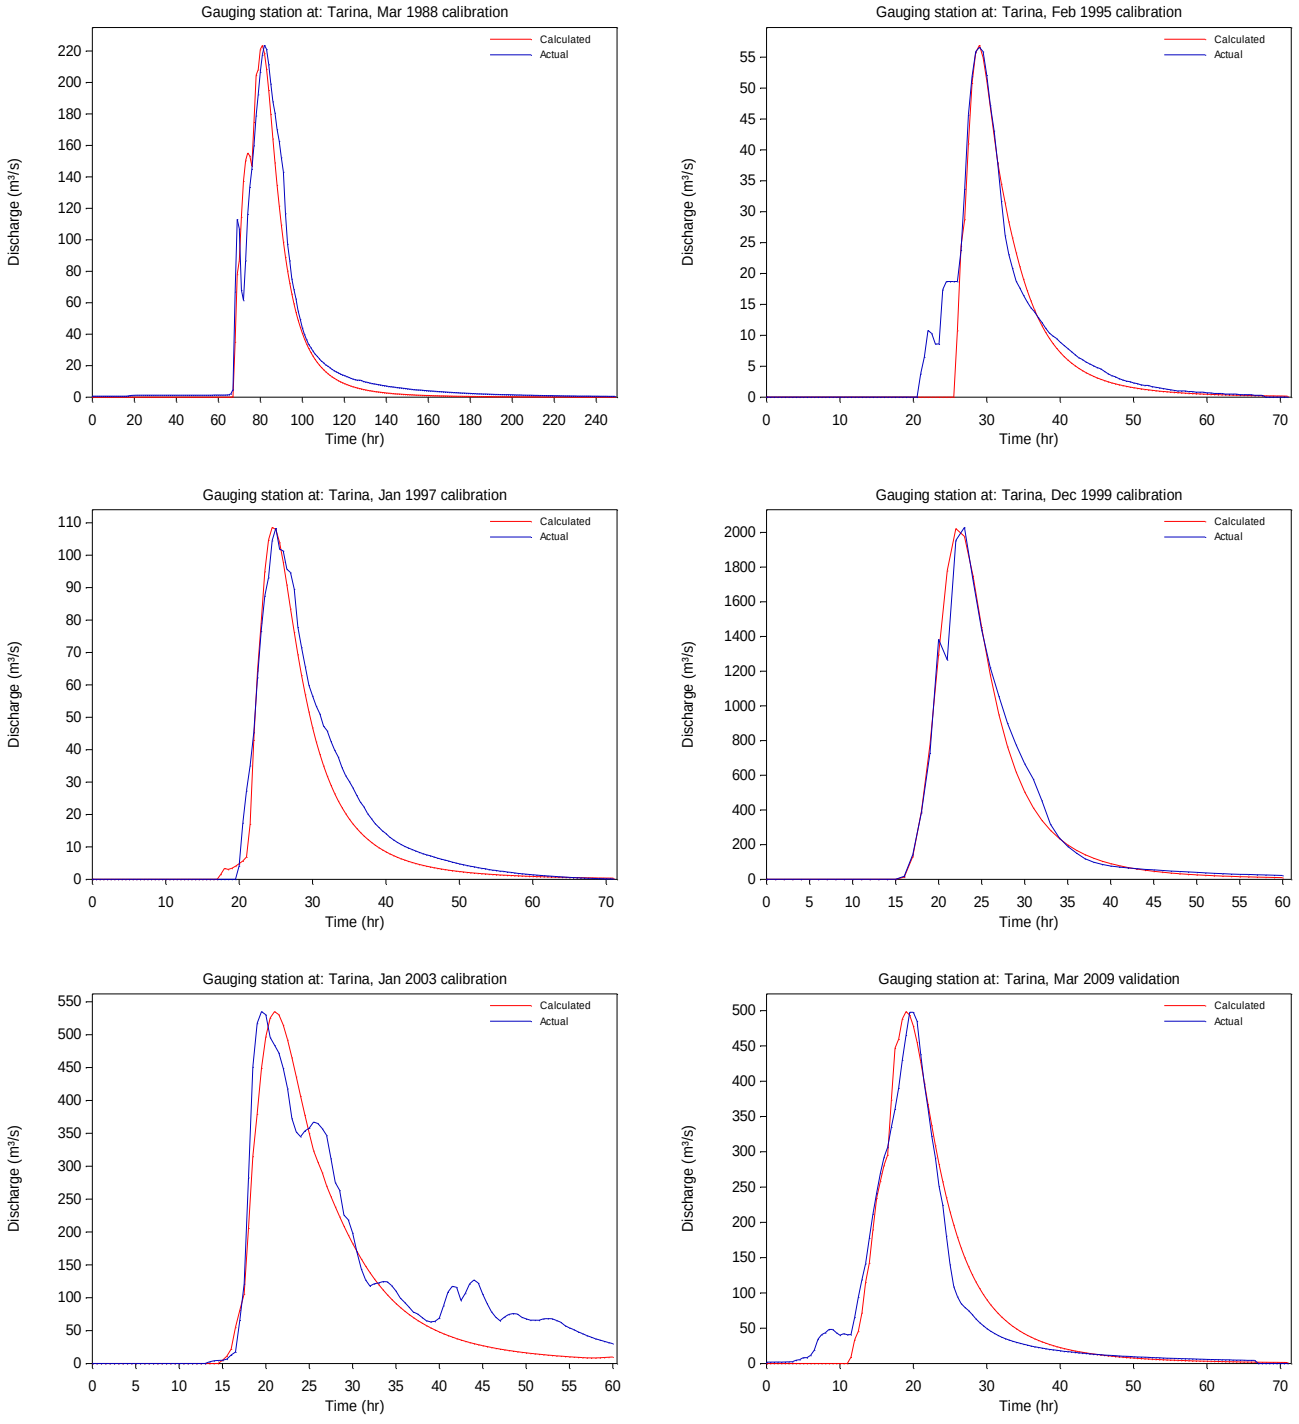

Figure 4-6: Five calibration and one validation event at Tarina stream flow gauge

To establish a level of confidence in the adopted k_c value a sixth event was used to validate the parameter. Validation was performed by assigning the adopted k_c value to the event and varying the losses to fit the peaks of the modelled hydrograph to observed hydrograph. Results of the validation are shown in Figure 4-6 and Table 4-11, and support the adopted k_c value.

Table 4-11: RORB parameters from calibration and validation

Flow event peak date	Peak flows(m^3/s)	Event use	k_c	d_{av}	$C_{0.8}$ value	Initial loss (mm)	Continuing loss (mm/hr)
28/03/1988	57	Calibration	9.7	30.5	0.32	80.3	1.4
25/02/1995	224	Calibration	27.8	30.5	0.91	70.0	8.7
08/01/1997	108	Calibration	12.9	30.5	0.42	57.0	8.9
15/12/1999	2,100	Calibration	21.0	30.5	0.69	45.0	11.1
25/01/2003	535	Calibration	21.4	30.5	0.70	62.2	11.0
01/03/2009	505	Validation	18.6	30.5	0.61*	46.0	10.0

*adopted K_c value, taken as the average of the five calibration events

The adopted k_c value of the Tarina catchment was transferred to the combined Pebble Mouse/Tarina catchment using a regional relationship developed for Pilbara catchments by Pearcey (2014). McMahon and Muller (1983) showed that k_c is directly proportional to d_{av} by the relationship:

$$C_{0.8} = \frac{k_c}{d_{av}}$$

Where d_{av} is the weighted average flow distance from all the nodes within the catchment to the catchment outlet; and where $C_{0.8}$ is characteristic (when m=0.8) of the catchment that is now independent of the scale or the size of the catchment. The calculation of an average regional $C_{0.8}$ value allows it to be used in ungauged catchments and gives confidence to values calculated in gauged catchments. The relationship between $C_{0.8}$ and catchment area for the Pilbara is given in Figure 4-7.

The $C_{0.8}$ calculated for the Tarina catchment using the adopted k_c value of 18.6 and a d_{av} of 30.50 taken from the RORB model, equates to 0.61 marginally higher than the expected $C_{0.8}$ of 0.59 for the Pilbara. This provides confidence in the adopted value of $C_{0.8}$ for the catchment.

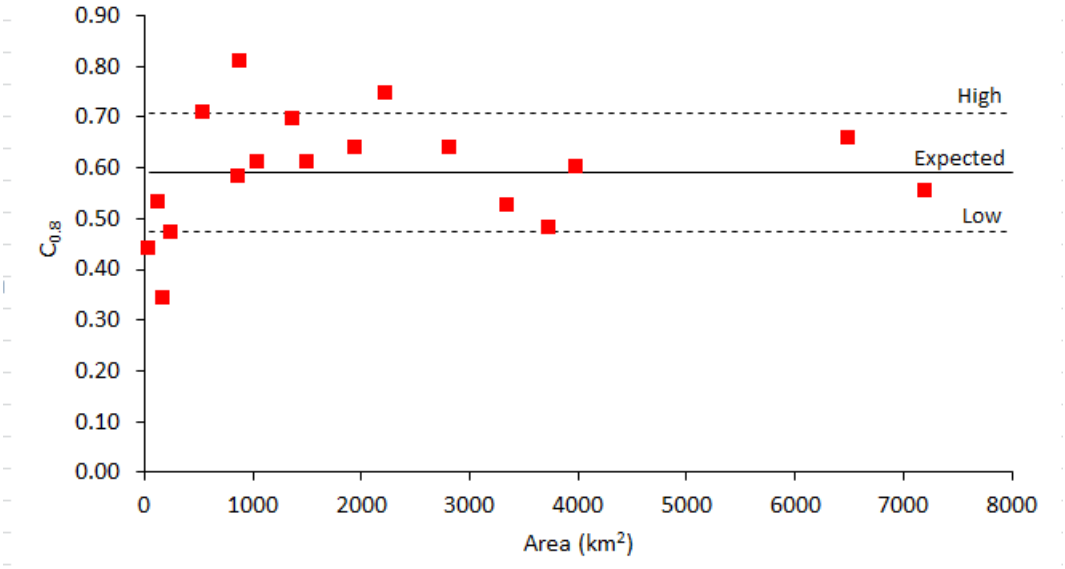

Figure 4-7: $C_{0.8}$ relationship for the Pilbara based on 18 catchments (Pearcey et al, 2014)

4.6.2 Combined Pebble Mouse/Tarina RORB

The existing RORB model was refined to include a number of sub-catchments upstream from the area of interest (Pebble Mouse Creek) as recommend by Laurenson (2007), Figure 4-8. This allowed the calibration of peak flows from design storm events at Tarina to the FFA at the gauge, whilst providing estimates of design peak flows at the Baby Hope deposit. Estimates of design peak flows approximately 9 km downstream of Baby Hope at Hope Downs 1 SE pit were also made using the same model. The calibrated $C_{0.8}$ value of 0.61 for the Tarina catchment was adopted for all events in the combined Pebble Mouse Creek/Tarina RORB model.

4.6.3 Design Event Critical Duration

The critical duration at a particular location refers to the duration of a design storm event that produces the maximum flood peak for a given annual exceedance probability. The combined RORB model was run for a range of AEP and design storm durations to determine the critical durations for Tarina. Design rainfall from the Tarina catchment centroid for events from 1% AEP to 20% AEP were applied to the model, with the $C_{0.8}$ value held constant, losses were adjusted to match peak flow estimates from the model to estimates from the Tarina FFA. Once it was established that the continuing loss value for the 1% AEP event calibration was 9 mm/hr, it was held constant throughout calibration of the rest of the AEP events, with initial loss being the only parameter adjusted. The continuing loss value of 9 mm/hr was the same as the average continuing loss value obtained from the calibration of actual rainfall events over the Tarina catchment, giving added weight to the adopted continuing loss value. Design rainfall for the 1% and 2% AEP events was taken from the CRC-Forge data for Western Australia (Durrant and Bowman, 2004). Design rainfall for 5% to 20% AEP events was taken from Intensity Frequency Duration (IFD) data provided by AR&R (Pilgrim, 1987). RORB applies the standard temporal patterns from AR&R (Pilgrim, 1987) to the design rainfall depths. Results of the Tarina calibrations are shown in Table 4-12.

Table 4-12: Parameter values for calibration of the Tarina RORB to design rainfalls

AEP (%)	Peak flows at 708014 from FFA (m^3/s)	Calibrated peak flow at 708014 from design rainfall (m^3/s)	Critical duration (hrs)	$C_{0.8}$	K_c	D_{av}	IL (mm)	CL (mm/h)
1*	3,180	3,180	9	0.61	22.1	36.2	0.0	9.0

*using CRC-Forge design rainfall

#using IFD design rainfall

To obtain design peak flow estimates of peak flow for Pebble Mouse Creek at the Baby Hope deposit and at HD1 SE pit the RORB model was run with the same parameters from the Tarina calibration of design rainfall to FFA. The design rainfall location was changed to the centroid of the Pebble Mouse Creek catchment and the areal reduction factors reduced to account for the smaller catchments upstream of the Baby Hope deposit and HD1 SE pit. Estimates of design peak flows at the Baby Hope deposit and the HD1 SE pit can be found in Table 4-13 and critical durations with areal reduction factors found in Table 4-14.

Table 4-13: Peak flow and critical duration estimates of AEP events for Pebble Mouse Creek at the Baby Hope deposit and HD1 SE Pits

AEP (%)	Peak flow at Baby Hope deposit (m^3/s)	Critical duration (hrs)	Peak flow HD1 SE pit (m^3/s)	Critical duration (hrs)	$C_{0.8}$	K_c	D_{av}	IL (mm)	CL (mm/h)

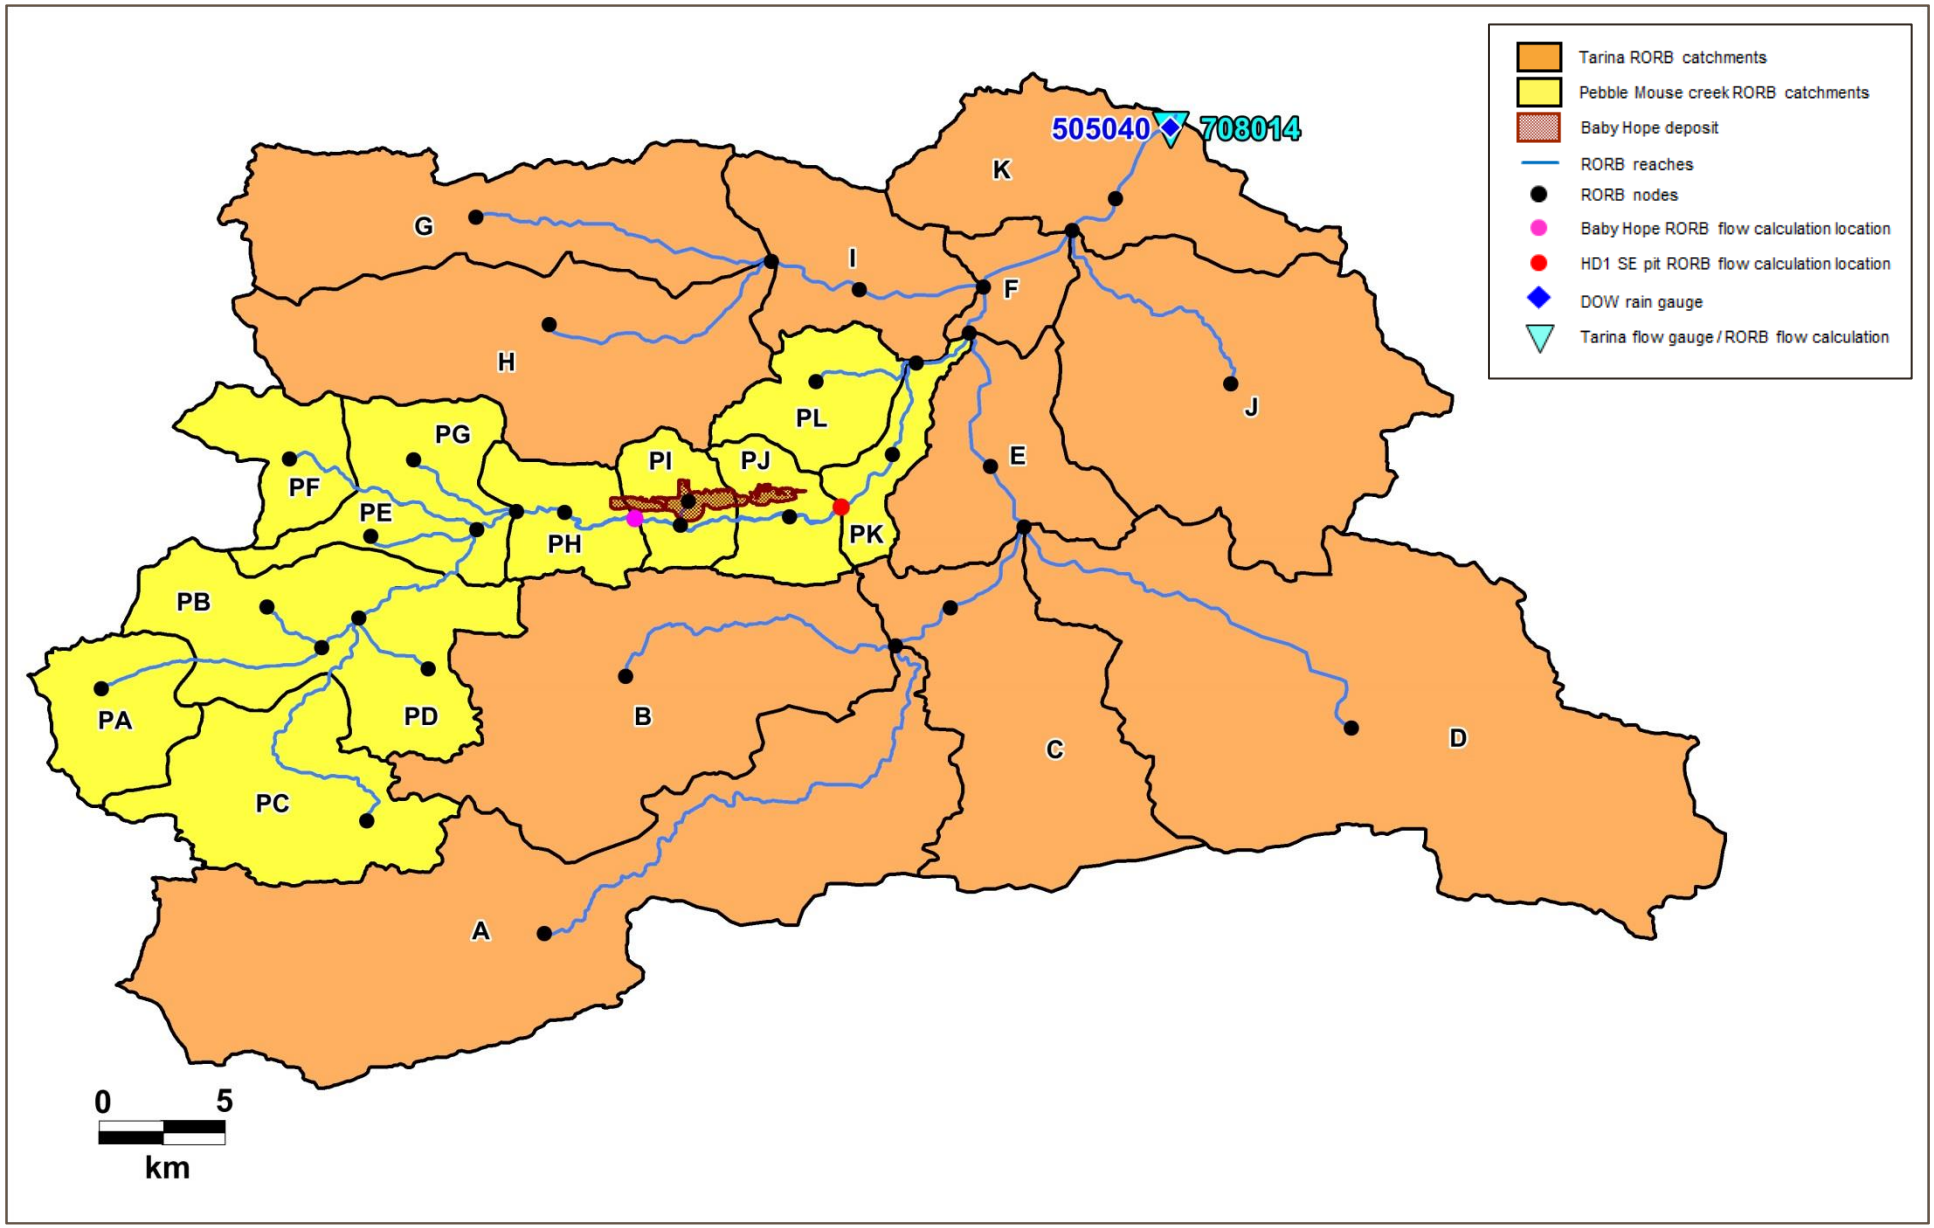

Figure 4-8: Pebble Mouse/Tarina RORB model inputs; catchment sizes are listed in Appendix C

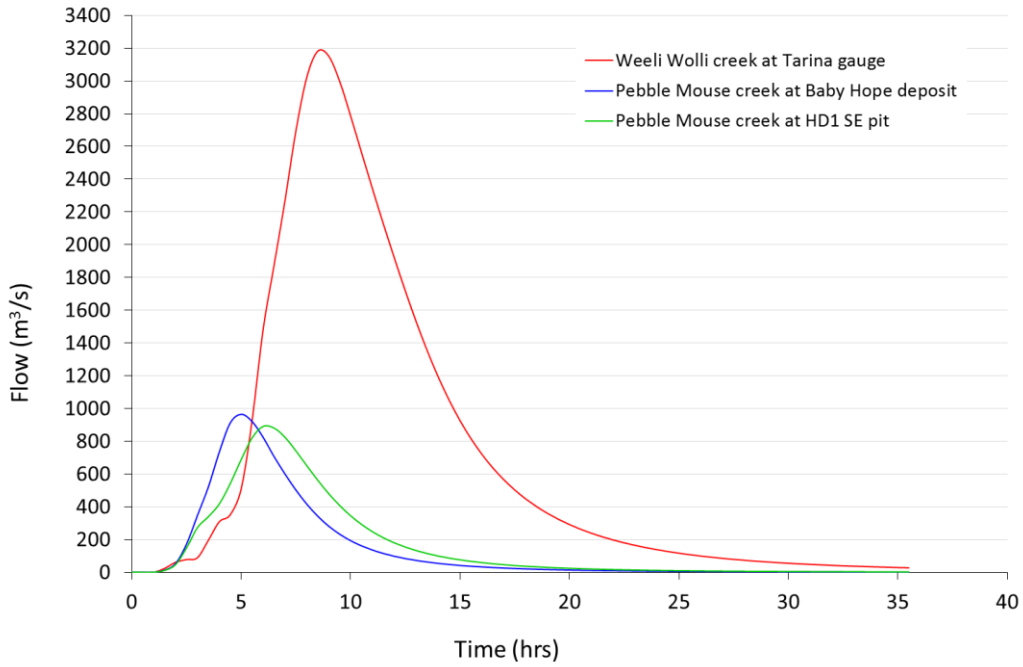

Figure 4-9: Hydrographs of estimated 1% AEP peak flows for Tarina gauging station and two locations on Pebble Mouse Creek

4.7 Recommended design flood estimation

Due to the lack of streamflow data within the Pebble Mouse Creek catchment results from the RORB model calibrated to Tarina were taken as the best estimate of design peak flows for Pebble Mouse Creek. Estimates of 1% AEP peak flows for Pebble Mouse Creek using this method were 970 m³/s at the Baby Hope deposit and 890 m³/s at HD1 SE pit.

5. Hydraulic modelling

5.1 2D hydraulic modelling

The TUFLOW/SMS two dimensional (2D) hydraulic software package was used to model existing flood conditions at the Baby Hope deposit. A 2D hydraulic model was considered to be the most effective way to model the Pebble Mouse Creek system, due to the ability to efficiently delineated detailed flood plains using high resolution topographic data.

5.2 Model Inputs

5.2.1 Digital terrain model

LiDAR topographic data is available for the Baby Hope area. The reported accuracy of the dataset is 0.3 m in the vertical direction and 0.4 m in the horizontal direction. A digital terrain model (DTM) of the LiDAR point cloud was built using the Global Energy Mapper software and a 5 m x 5 m grid of elevations was derived from the DTM to filter the large number of data points. The 5 m x 5 m elevation grid was used to build the DTM for the TUFLOW model. The extent of the DTM can be seen in Figure 5-1.

5.2.2 Boundary conditions

The location of boundary inputs is shown in Figure 5-1. The hydrograph calculated at the Baby Hope deposit from the combined Pebble Mouse and Tarina RORB model was used for Pebble Mouse Creek.

Table 5-1: Estimated 1% AEP flows.

Location	Critical duration	Estimated peak flow 1% AEP (m^3/s)
Pebble mouse creek at Baby Hope deposit	12 hour	970

Pebble Mouse Creek

The hydrograph was calculated at the edge of Baby Hope orebody, with boundary input location approximately 2 km upstream (SMS boundary description – Flow vs Time (QT)).

Downstream slope boundary

The downstream boundary was input as a slope (SMS boundary description - WSE vs Flow (HQ)) and calculated to be 0.0035 m/m.

Pebble Mouse Creek Tributaries

Design peak flows for the tributaries of Pebble Mouse Creek at Baby Hope were calculated using the regional flood frequency method developed by Flavell (2012) given in section 4.5.1. The time of concentration for these peak flows was calculated using the Bransby-Williams formula for ungauged catchments as recommended by ARR (1987):

$$t_c = \frac{58\,L}{A^{0.1} S_e^{0.2}}$$

Where:

t_c = time of concentration (mins)

L = mainstream length measured to the catchment divide (km)

A = catchment area (km^2)

S_e = equal area slope of the mainstream projected to the catchment divide.

Hydrographs were derived using a simple triangular relationship that has been calibrated against runoff volumes from RORB models in the Pilbara region. The hydrographs were added to the boundary locations along the northern and southern sides of the Pebble Mouse Creek valley, as shown in Figure 5-1. The hydrograph, peak flows and times of concentration for all tributary creeks are given in Appendix C.

All northern catchments were delineated into sub-catchments up to the pit outline in an effort to provide an estimate of pre-development flow velocities at all locations where surface water may enter the pit. The boundary locations of the northern catchments were placed before the edge of the proposed pit.

The southern catchments were not divided into smaller sub-catchments as it was determined that this was not a primary area of interest for the purposes of this study. Southern catchment areas were delineated to Pebble Mouse Creek and flows input upstream of this location.

Road

The road on the southern side of Pebble Mouse Creek valley was input as an added Z point line boundary, as it was built after the LiDAR data had been gathered and was not included in the DTM. The line coverage added 2.5 m to all elevation points along its alignment. It is understood that this does accurately reflect the actual elevation of the road; however it was determined to give sufficient representation in line with the level of interest in the area.

Culverts

One dimensional (1D) culverts where placed in the rail and road on the southern side of Pebble Mouse Creek valley for larger creeks of the southern valley catchments. The location and size of rail culverts was determined according to Pilbara Region Imagery photograph and through visual inspection during a site visit on 12/11/2013. The location and size of road culverts was determined by inspection of Pilbara Regional Imagery photograph. The low level of detail was considered acceptable given the magnitude of flows generated from the southern catchments and the expected low influence of flood flows from this area on the area of interest.

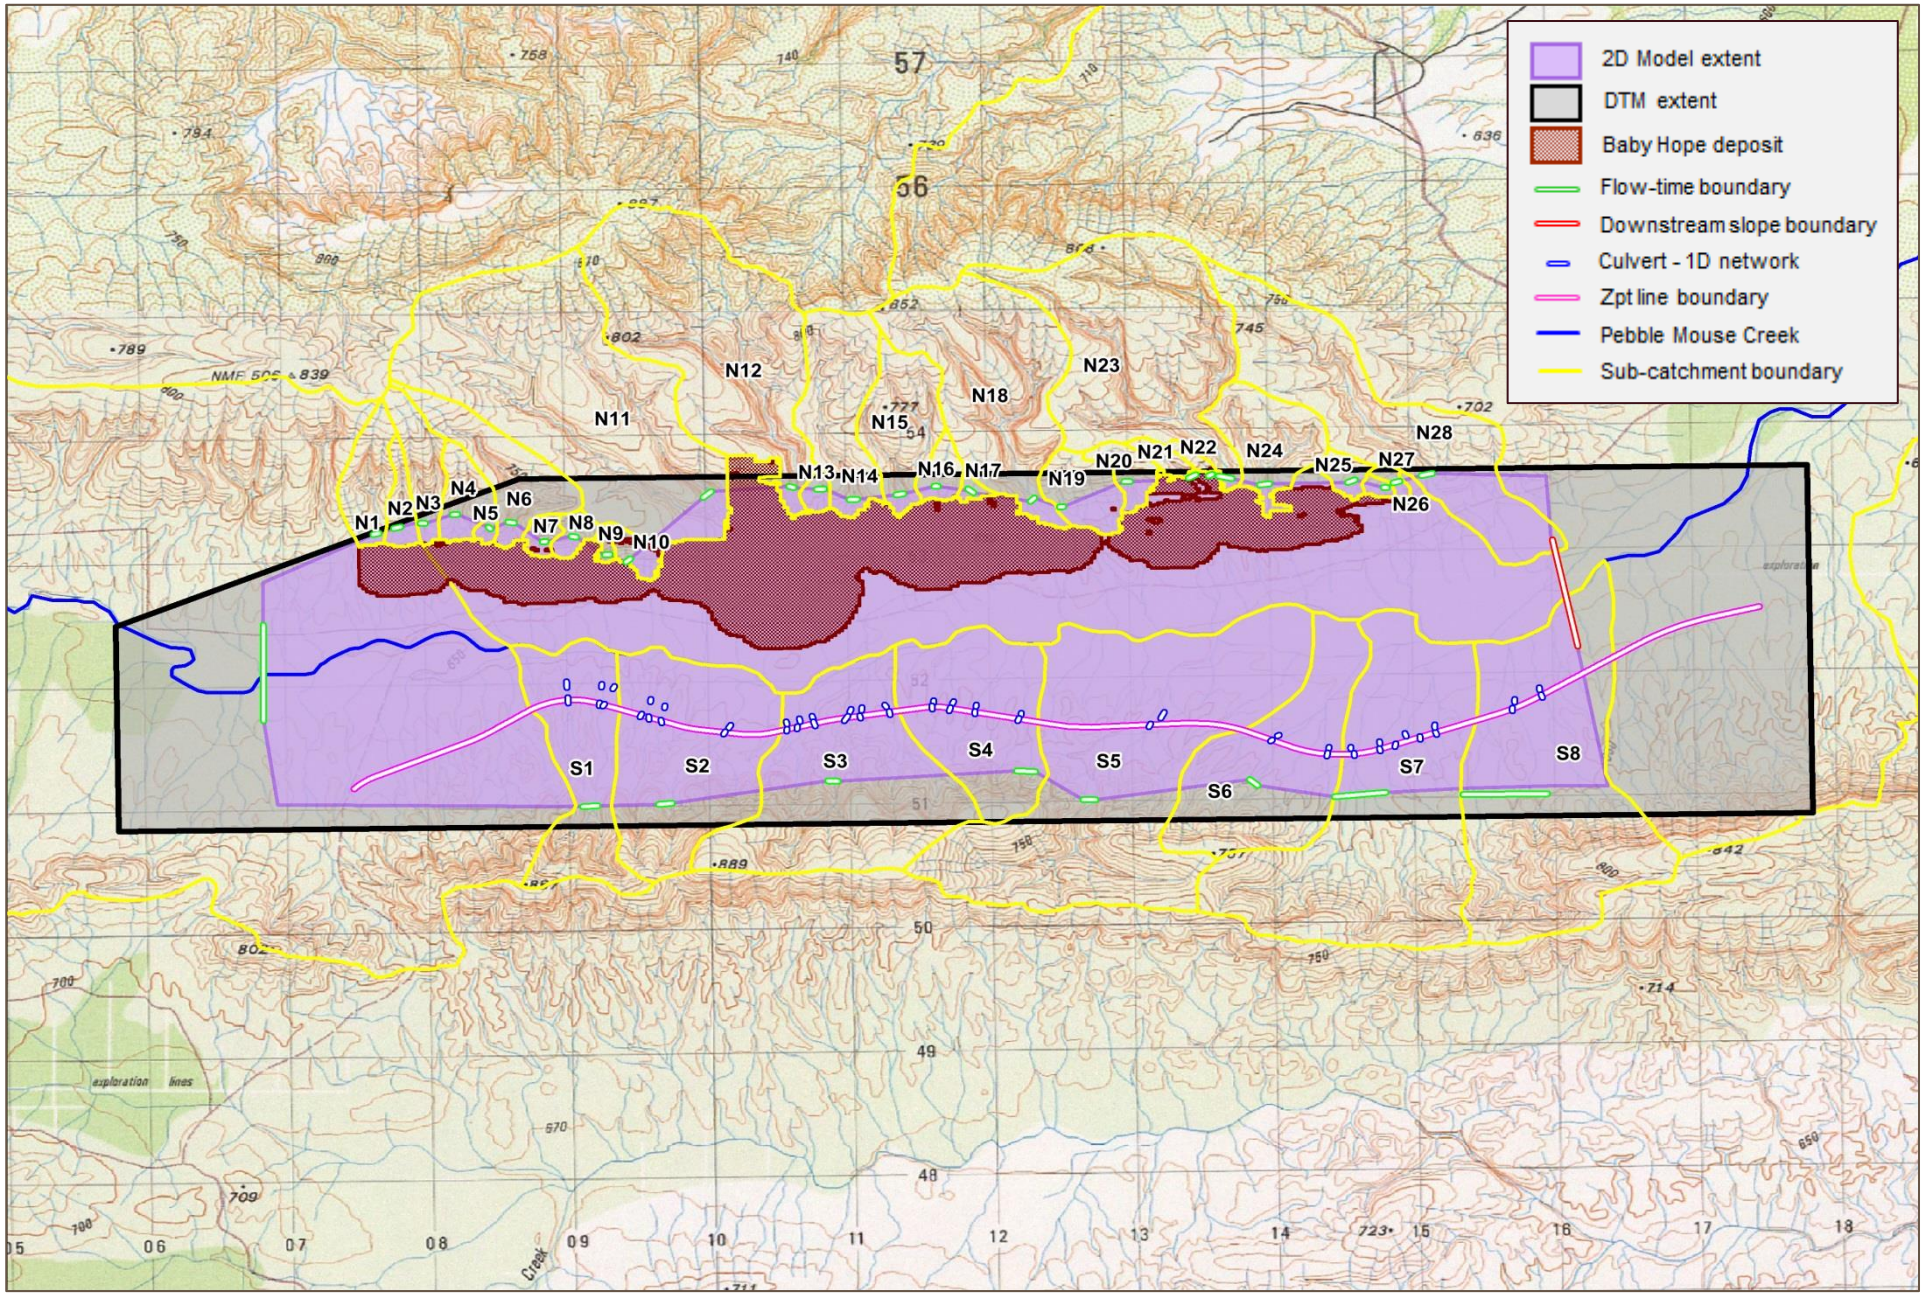

Figure 5-1: Baby Hope hydraulic model DTM extent and boundary locations

5.2.3 Bed resistance

Each cell in the 2D model was assigned a bed resistance value. The Land Unit Classification dataset (Van Vreeswyk etal, 2004) was used as a basis for bed resistance classification. Alterations to land unit areas were delineated through detailed examination of aerial photographs and raster maps. Areas were assigned a Manning's n value ranging from 0.035 (representing the road) to 0.055 (representing vegetated creek flood plain) to describe its bed resistance as shown in Figure 5-2.

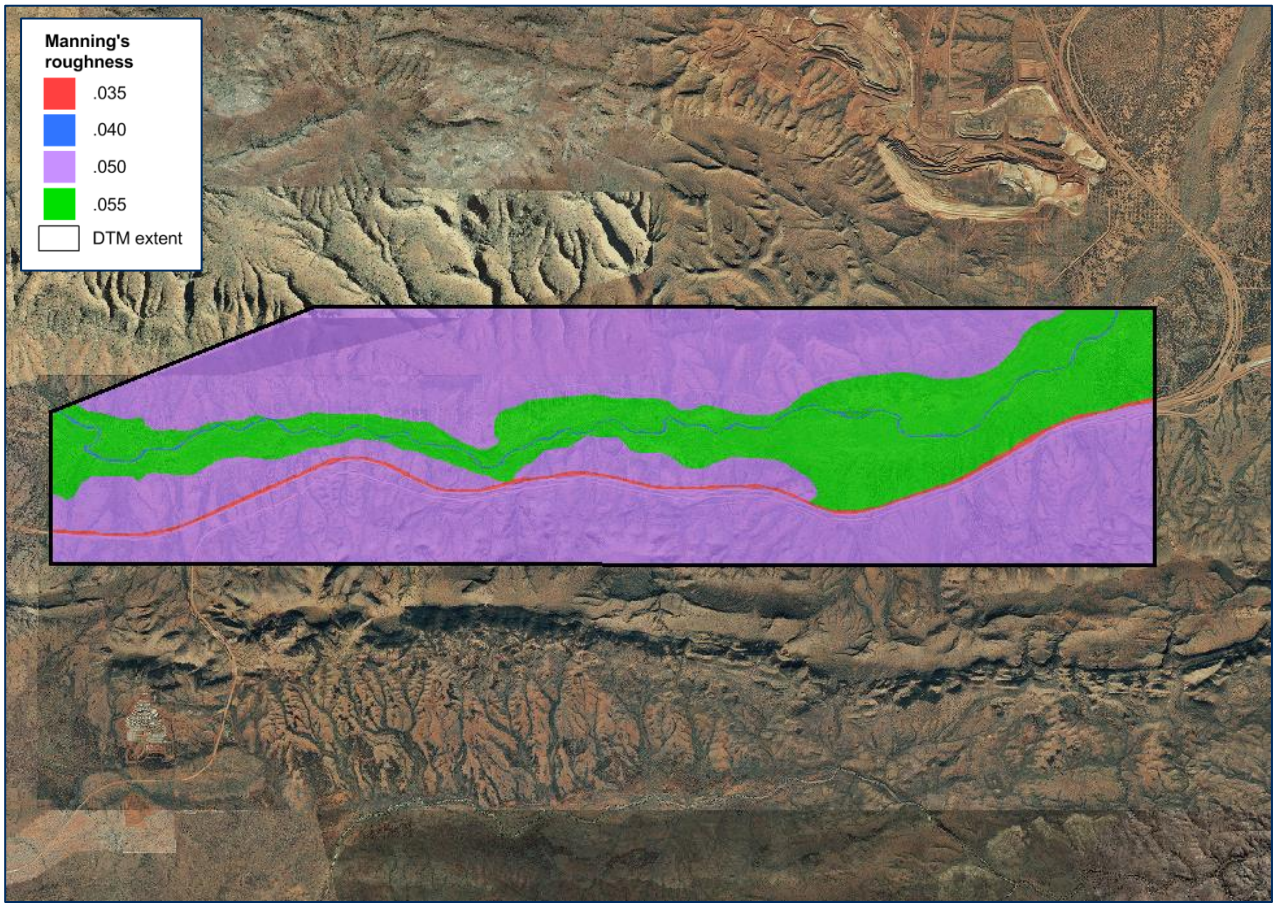

Figure 5-2: Bed resistance values used in the Baby Hope 2D model.

5.2.4 Cell size and time step

A cell size of 5 m by 5 m was used for all design events. A time step of 1.5 and 2 seconds was used for the 2D domain and 1D domain (culverts) respectively.

5.3 Modelled scenarios

The 1% AEP event was modelled for existing conditions and post pit development. There was no hydrology infrastructure development options considered in this study as the deposit is proposed to be developed without any major hydrology infrastructure. All pits are to remain outside of the 1% AEP flood plain. Maximum flood depths for existing conditions and post pit development are shown in Figure 5-3 and Figure 5-4 respectively. Maximum velocities for existing conditions are given in Figure 5-5. Throughout the modelling process it was observed that the northern and southern catchments had little to no effect on the flood extent of main flood plain of Pebble Mouse Creek.

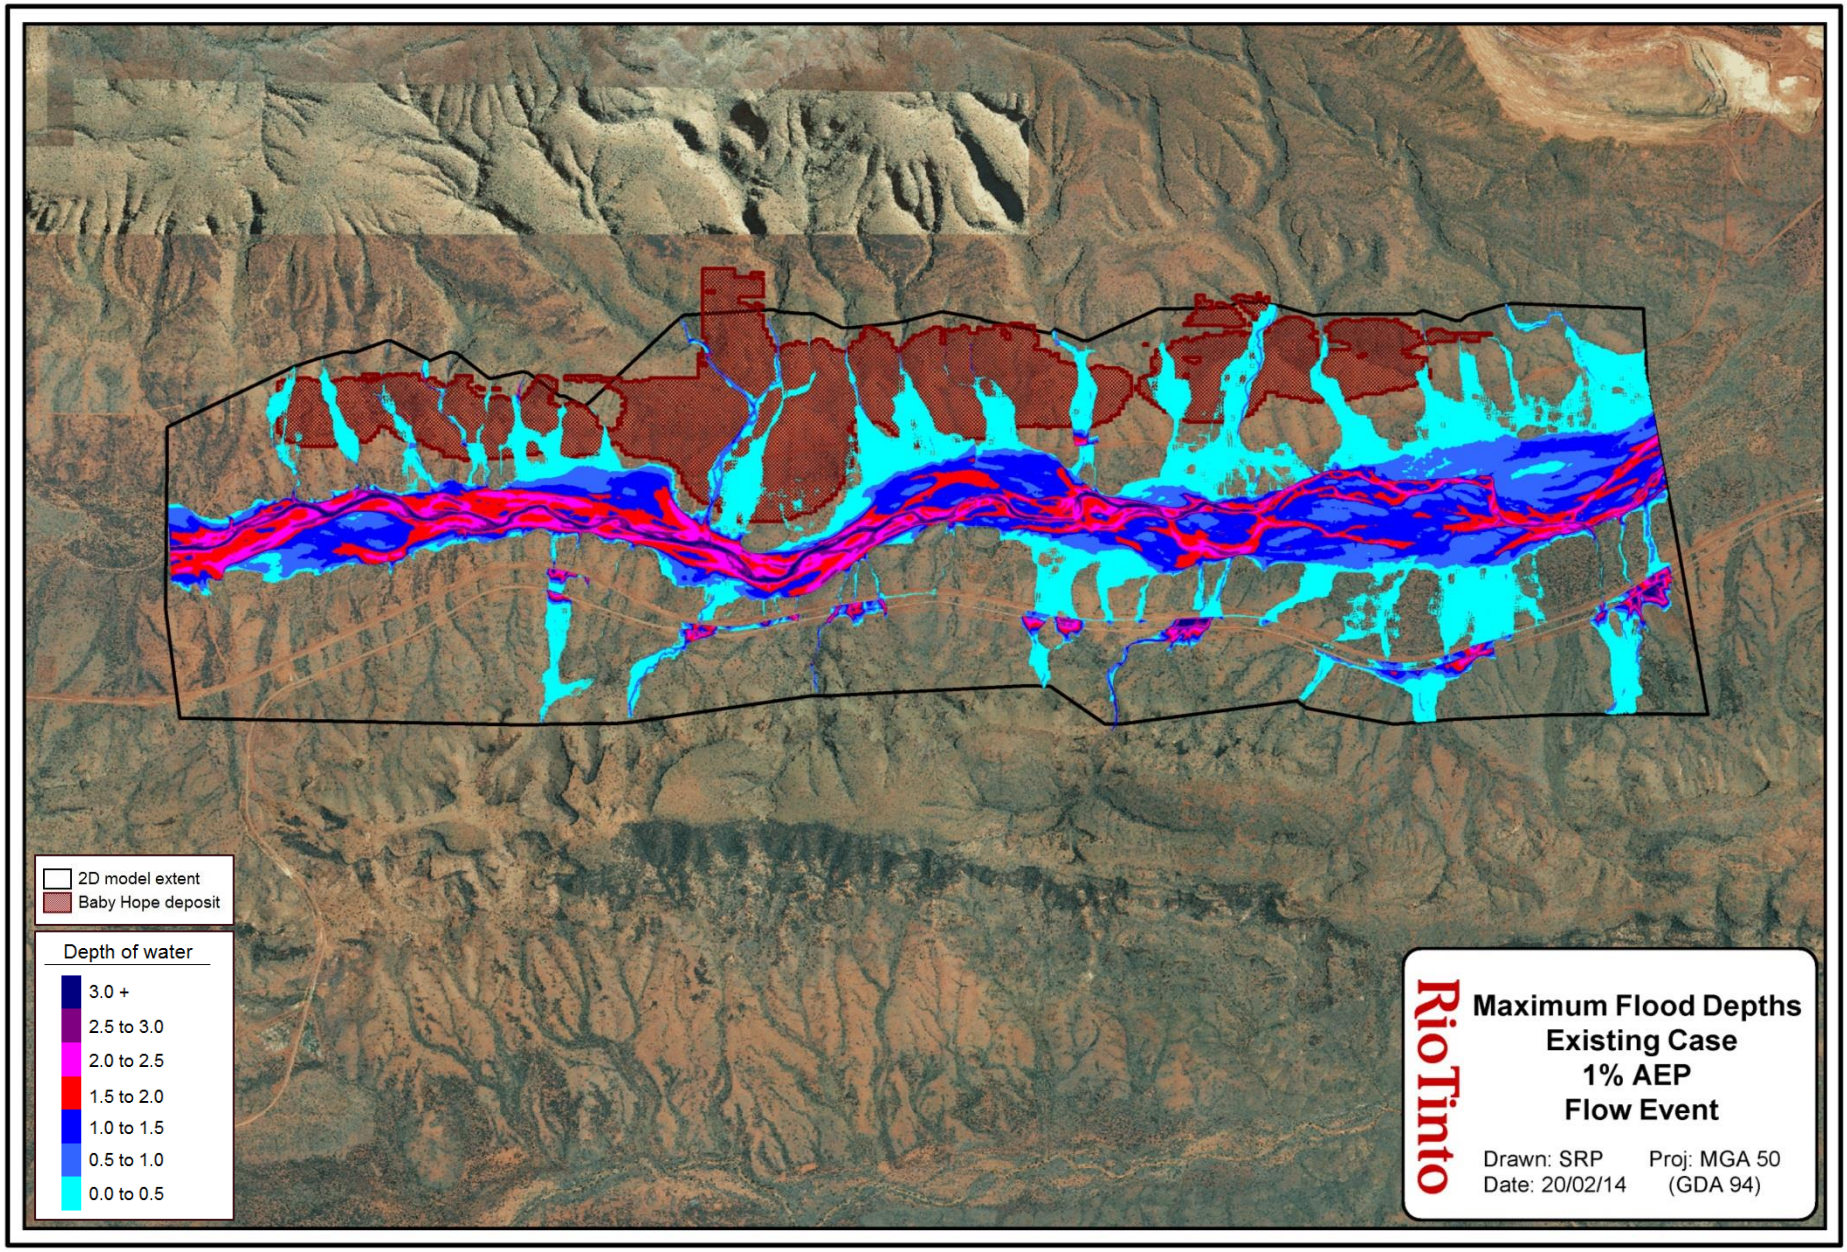

Figure 5-3: Estimated flood extent and depths for a 1% AEP event for existing conditions at the Baby Hope deposit

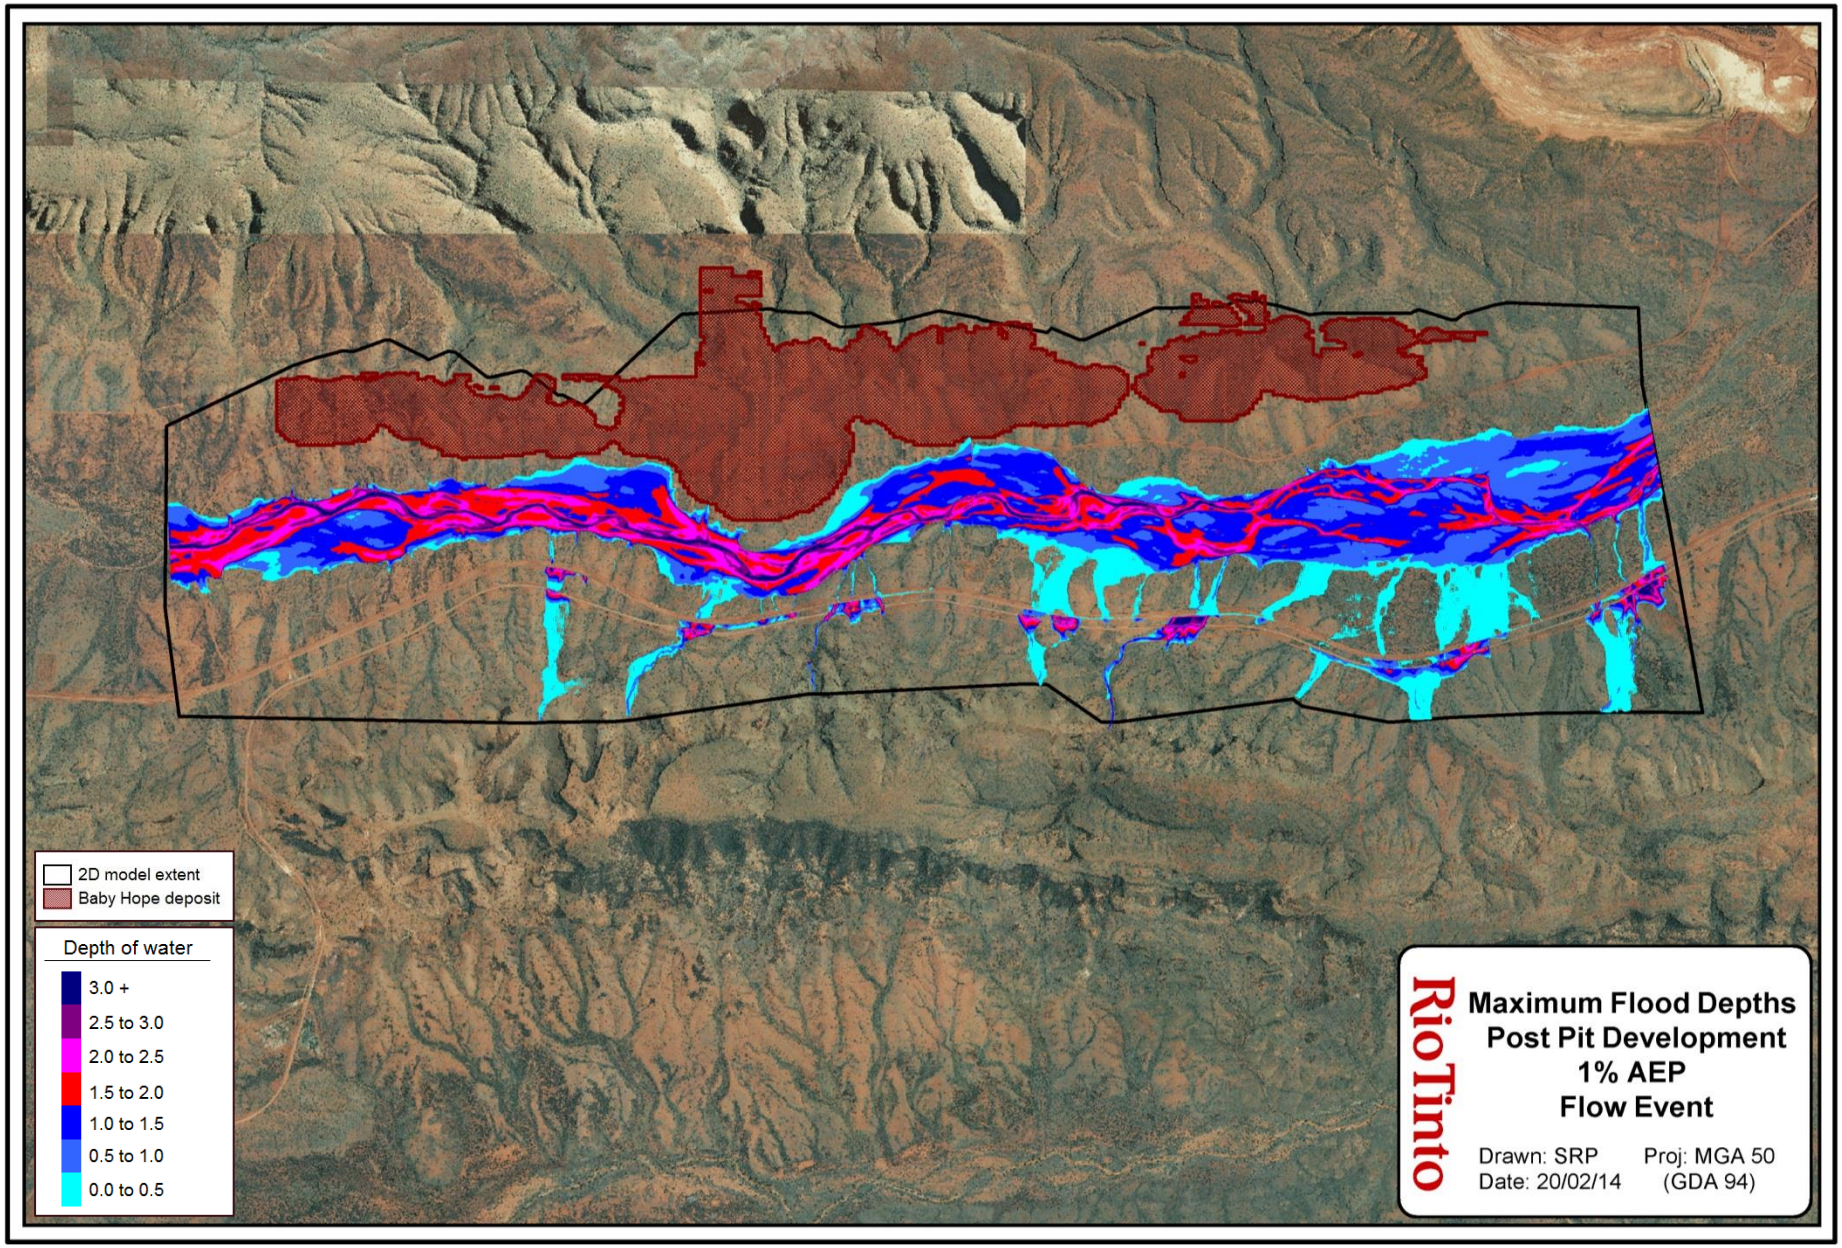

Figure 5-4: Estimated flood extent and depths for 1% AEP event at Baby Hope post pit development

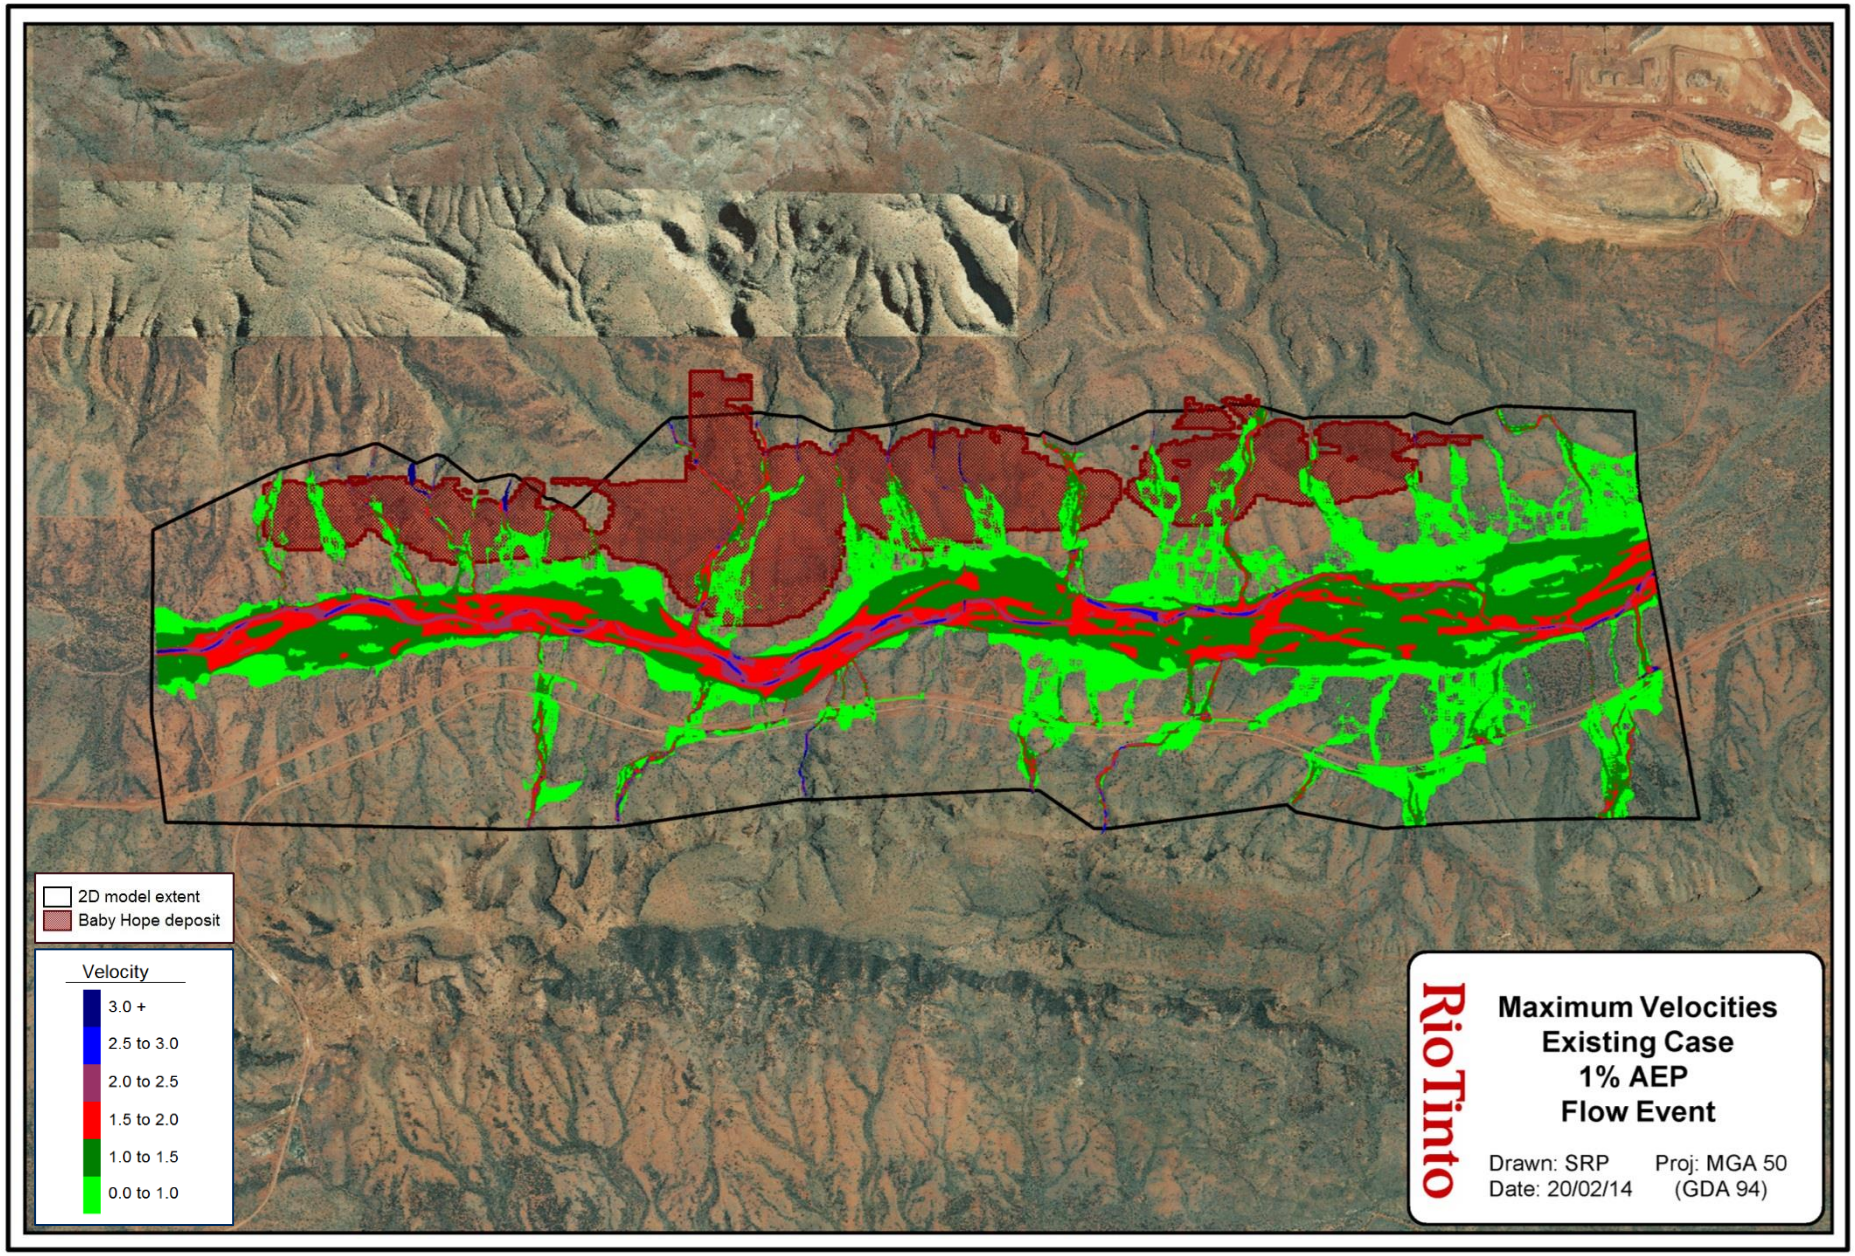

Figure 5-5: Estimated velocities for a 1% AEP event for existing conditions at the Baby Hope deposit

5.4 Model uncertainties

Peak flow estimates

Estimates of 1% AEP peak flow are calibrated to Tarina flow gauge FFA, 23 km downstream of the Baby Hope deposit. The Tarina FFA is based on 27 years of annual maxima and the 90% confidence interval of the distribution for the 1% AEP event is 1160 m^3/s to 7170 m^3/s. The lack of at-site streamflow and rainfall data also introduces a large degree of uncertainty in the estimates due to the high degree of spatial variability in rainfall exhibited in the Pilbara.

Sensitivity

A full sensitivity analysis was not performed on bed resistance values or flow inputs adopted in the model. However the 2D model was run with a 1% AEP design flow approximately 20% lower than the adopted value giving an insight to the sensitivity of the flood extent to peak flows. From this sensitivity assessment the area of the flood extent decreased by 2%, suggesting that it is relatively insensitive to changes in flow input.

6. Conclusion

An assessment of the baseline surface water hydrology of Pebble Mouse Creek up to the Baby Hope deposit, 23 km upstream of the Tarina streamflow gauging station on Weeli Wolli Creek (708014) has been undertaken through the application of annual, monthly and daily analysis of rainfall and annual analysis of streamflow at Tarina. Furthermore, a regional flood frequency analysis has been carried out on four local streamflow gauges within a 150 km radius of the catchment centroid.

The Pilbara Surface Water Management Strategy recommends flood protection to a minimum 1% AEP if construction is to take place in the 1% AEP floodplain. Development of the Baby Hope deposit is proposed to be undertaken without major flood protection infrastructure and therefore the pit outline is to be developed outside of the 1% AEP flood plain.

The 1% AEP peak flow event for the Pebble Mouse Creek at the Baby Hope deposit was estimated using the combined RORB model of Pebble Mouse and Weeli Wolli Creeks that was calibrated to the Tarina flow gauge. The hydrograph of the estimated 1% AEP event produced by the RORB model was used as a boundary condition in the Tuflow 2D hydraulic model and this enabled the 1% AEP event floodplain to be delineated. From this study it can be concluded that:

- The expected 1% AEP event peak flows for Pebble Mouse Creek at the Baby Hope deposit from the combined Pebble Mouse/ Weeli Wolli RORB model calibrated to Tarina is 970 m^3/s.

- Annual rainfall at the Baby Hope study area has 'high' temporal variability. Annual streamflow at Tarina (downstream from the Baby Hope study area) is 4 to 5 times more variable than Baby Hope rainfall.

- Large flow events that are integral to the estimation of large to extreme design flood events are predominately estimated using theoretical stage-discharge relationships.

- The Tarina FFA is based on 27 years of annual maxima and the 90% confidence interval of the distribution for the 1% AEP event is 1160 m^3/s to 7170 m^3/s

- Spatial variability exhibited in the area introduces a large degree of uncertainty in design flow estimates, as there are no at-site streamflow or rain gauges.

- Based on flow data from Tarina gauging station, flow events in Pebble Mouse Creek are expected to occur once every three years on average. Recent history suggests that large flow events are to be expected once every five years on average.

- There are many small but not insignificant creeks that flow from the northern range in a southerly direction over the deposit. The majority of the creeks will be intercepted by the pit and have deeply incised channels, indicating these areas are subject to high velocities and erosion.

- The tributaries of Pebble Mouse Creek in the area of the Baby Hope deposit have little or no influence on the flood extent of Pebble Mouse Creek. Additionally the floodplain of Pebble Mouse Creek is not highly sensitive to changes in flow input.

7. Recommendations

The following recommendations can be made as a result of this study:

- Due to the lack of data from within the Pebble Mouse Creek catchment, the RORB model calibrated to Tarina should be adopted for the estimation of design flood quantiles for the catchment.

- Pressure transducers should be installed within Pebble Mouse Creek, upstream and downstream from the Baby Hope deposit to estimate flows for calibration/validation of the RORB model and the 2D hydraulic model.

- The Bureau of Meteorology is currently undertaking work to revise the design rainfall temporal patterns. These design rainfall patterns have a large impact on design flows. It is expected that when published the revised temporal patterns will closer resemble those used in estimating the probable maximum precipitation (PMP). The impact of using the PMP temporal patterns on design flood estimates should be investigated.

1. SCOPE AND PURPOSE

This Progressive Rehabilitation Performance Summary (Summary) has been prepared primarily to support the Hope Downs 2 (HD2) Iron Ore Hub Proposal referred to the Environmental Protection Authority (EPA) for assessment under Part IV s38 of the Environmental Protection Act 1986 (EP Act) in August 2019.

This Summary has been developed in alignment with the Department of Mines, Industry Regulation and Safety (DMIRS) statutory requirements for MCP content and structure (DMIRS 2020a & b). It may also be used to support the submission of:

- Native Vegetation Clearing Permits; and
- Annual Environment Reports requirements for:
    - Iron Ore (Hamersley Range) State Agreement Act 1963 and Annual Compliance assessment reporting for Ministerial Statements to the Department of Jobs, Tourism, Science and Innovation (JTSI); or
    - Mining Act tenure to DMIRS; or
    - Native Vegetation Clearing Permits (to DMIRS).

As the HD2 Proposal is still under assessment and not yet operational, no progressive rehabilitation has been undertaken to date. This rehabilitation summary discusses the rehabilitation success, to date, at nearby Rio Tinto mine sites, Hope Downs 1 (HD1) and Hope Downs 4 (HD4), Yandicoogina and West Angelas, to provide evidence that current and future rehabilitation activities will be successful in establishing a self-sustaining functional native ecosystem (Table 2). Any relevant trials installed at other sites are also discussed.

2. GENERAL OVERVIEW OF PILBARA REHABILITATION

2.1. Progressive rehabilitation planning

Rio Tinto has a dedicated Rehabilitation and Closure team responsible for closure planning, progressive rehabilitation, ongoing development of closure knowledge, and closure cost estimation. This team is supported by a robust internal governance framework and embedded partnerships with multi-disciplinary technical experts.

Rio Tinto undertakes progressive rehabilitation across its network of Pilbara iron ore operations to actively reduce closure liability. A key driver for completion of progressive rehabilitation is growth in confidence in the ability to deliver quality rehabilitation and reduce associated closure liabilities. However, as the Rio Tinto Pilbara operations are typically large scale and long lived with multiple pits being mined simultaneously to meet grade and product requirements, the disturbance areas are usually active for long periods. Consequently, the pace of progressive rehabilitation is not always commensurate with the associated pace of clearing, and long periods of time may elapse between the construction and mining and the commencement of rehabilitation.

Lessons learnt, and information gathered, from progressive rehabilitation will be used to indicate the likely success of future rehabilitation and inform the development of final closure criteria. Local undisturbed vegetation is used as a reference to guide rehabilitation activities such as seed list development and rehabilitation quality assessment. Due to the nature of the mining activity undertaken, it must be recognised that rehabilitation will not reflect the pre-mining environment (i.e., as compared to ‘restoration’, as defined in SERA 2021).

To date, the success of the Rio Tinto rehabilitation in the Pilbara has been variable, with poor to moderately successful rehabilitation outcomes observed across historical and recent rehabilitation

areas. Significant improvements have been made recently in mineral waste characterisation and landform design and earthwork conformance to design practices, leading to closure designs with reduced erosion rates and related impacts and improved outcomes for rehabilitated areas. Generally, vegetation parameters in rehabilitation are good but are highly dependent on the rainfall volume received in the months and years following the completion of rehabilitation works coupled with the soil or growth media material utilised.

The Hope Downs operation is located in the Eastern Pilbara. Examples of successfully completed rehabilitation, particularly for high impact disturbance areas (such as waste rock dumps), are not as common in the Eastern Pilbara. This is due to most of Rio Tinto's operations in this area operating under Ministerial Statement approval conditions that require mine voids to be backfilled to above water table or greater, meaning waste rock dumps (as the source backfill material) are not rehabilitated progressively during operations unless it is clearly articulated in the Life of Mine plan that they can be.

Despite this limitation in the Eastern Pilbara, Rio Tinto has demonstrated in the greater Pilbara region their ability to undertake successful rehabilitation of a number of high impact disturbance areas at other operations. Rio Tinto anticipates that future rehabilitation activities will achieve more consistent outcomes, with a continually growing confidence in design selections driven by key learnings from progressive rehabilitation (Table 2) within the Pilbara.

2.2. Definition of land disturbance types

The following categories are applied to disturbance features at Rio Tinto operations.

2.2.1. Low impact disturbance

Low impact disturbance areas are defined as areas where vegetation has been cleared and there has been minimal disturbance to the soil profile. Examples include laydowns; above surface linear infrastructure corridors (pipelines, tracks etc.); topsoil stockpile footprints; and exploration disturbance. Rehabilitation of such areas includes backfilling sumps, contour ripping and spreading of topsoil (if available). Seed may also be spread, if required.

2.2.2. Moderate impact disturbance

Moderate impact disturbance areas are defined as areas requiring minor earthworks to either return the area to natural relief or create a compatible landform consistent with the surrounding natural relief and landforms. Examples include airstrips; buildings; infrastructure; mine access roads; and borrow pits. Typically, rehabilitation of such areas involves removal of infrastructure, services and road surfaces, deep ripping of compacted areas, re-contouring, spreading of topsoil, contour ripping and seeding.

2.2.3. High impact disturbance

High impact disturbance areas are defined as those areas that require extensive earthworks to either approximate surrounding natural relief or create a compatible landform consistent with the surrounding natural relief and landforms. Typically, such areas contain concrete footings that require cracking and covering with fill, voids that need to be filled with waste rock, and/or significant reshaping and contouring to create the required relief. All concrete and buried services are required to be removed to one metre below final surface. Examples of high disturbance areas include accommodation camps; fuel farm facilities; haul roads; bridges; dams; power stations; and processing plants. Constructed landforms (such as waste dumps and waste fines storage facilities) are also highly disturbed areas that require significant earthworks to achieve stable rehabilitation designs.

2.3. Rehabilitation methodology

Key learnings from the progressive rehabilitation undertaken to date across a range of Rio Tinto operational locations facilitate continual improvement within rehabilitation methodology. Examples relevant to the HD2 Proposal are provided in Table 1.

Table 1 Key learnings from progressive rehabilitation relevant to HD2 Proposal

Learning	Operational Control	Further Discussion Within the Summary
Rainfall is integral to the success of rehabilitation. Good results in plant density and spinifex cover are achieved if rainfall is received soon after seeding i.e., soil moisture assists in germination and establishment of seedlings. However, if the quantity of rainfall after seeding is too high, detrimental impacts upon rehabilitation success may occur.	Schedule seeding before the onset of wet season, rather than when the earthworks are completed, regardless of time of year. Planned trials to determine effect of timing of seeding.	2.3.2 Seed management 5 Summary of rehabilitation outcomes 6.1 Eco-engineering solutions to improve mine site rehabilitation outcomes
Ongoing intermittent rainfall is required through time to ensure that revegetation continues to develop on the desired trajectory to achieve closure criteria. In alignment, weed density generally decreases over periods of low rainfall.	Monitoring of reference sites to determine the effect of rainfall on natural systems Weed monitoring and management.	2.3.2 Seed management 5 Summary of rehabilitation outcomes 6.1 Eco-engineering solutions to improve mine site rehabilitation outcomes
The presence of weeds significantly impedes overall rehabilitation outcomes particularly within parameters native perennial species richness / density and native perennial cover.	Regular monitoring of weeds and prompt implementation of weed management actions when required.	5 Summary of rehabilitation outcomes
Generally, the addition of topsoil as a growth medium provides better revegetation results than those achieved at sites where no topsoil was available. However, there has been some successful revegetation at sites where no topsoil was utilised.	Ongoing review of topsoil management and monitoring of trials	2.3.1 Growth mediums 5 Summary of rehabilitation outcomes 6.5 Growth media trials
Current results indicate that waste materials with soil-like properties, collectively termed 'Alternate Growth Media' (AGM) can act as effective germination beds and be used as longer-term growth mediums.	Ongoing characterisation of potential AGM and monitoring of trials.	2.3.1 Growth mediums 6.5 Growth media trials
With the limited trials to date, application of fertiliser did not improve revegetation results.	Ongoing investigation of soil ameliorants to improve success of AGM, and of germination and survivability results for native species	2.3.1 Growth mediums 6.5 Growth media trials
Spinifex cover is closely associated with total plant cover and density values.	Ongoing monitoring to determine if association continues through time and with differing seed mixes.	5 Summary of rehabilitation outcomes

2.3.1. Growth mediums

There may also be a shortfall of topsoil and subsoil available for rehabilitation due to topsoil being naturally thin or absent on topography such as hillslopes and ridge lines, or steep underlying topography presenting safety risks preventing the collection of topsoil. Where a topsoil deficit exists at a site, consideration is given to the use of subsoil and alternative growth media in rehabilitation.

Throughout the Pilbara, there is an ongoing opportunity to utilise mineral waste as topsoil substitutes or supplements for rehabilitation activities. The waste materials with soil-like properties are referred to as 'alternative growth media' (AGM). It is anticipated that AGM will provide a suitable growth medium in rehabilitation areas where topsoil is unavailable or limited in quantity. Research trials are underway to determine if the revegetation success in areas rehabilitated with alternative growth media will be acceptable, and early indications are promising (Section 6.5). Waste types which are identified as potentially suitable are laboratory tested for key soil chemical and physical parameters. If the characterisation results are favourable, the material is stockpiled with location recorded on mine site survey records.

Alternative growth media material was identified and tested from several Rio Tinto sites in the Pilbara including: Marandoo; Tom Price; Western Turner Syncline; and Channar (Outback Ecology 2010, Stantec 2017, and Landloch 2018). Stockpiling of suitable material commenced, with additional investigations to incorporate materials into the mine plans for future recovery underway.

Results from ongoing monitoring of these trials will be used to inform future closure strategies. If required, seeding rates may be increased in areas receiving alternative growth media or subsoil material to compensate for the lack of a topsoil seedbank. The application of fertiliser, or other ameliorants, will also be considered for materials that have low nutrient status, although recent evidence suggests the addition of fertiliser is not always beneficial and can promote weed establishment (Stantec 2020).

2.3.2. Seed management

Locally collected seed assists in the revegetation and creation of a self-sustaining ecosystem. Over time, the viability of the seed within stockpiled topsoil may decrease, particularly if stored for long periods or if the stockpile does not become vegetated, and thus the quality of the seed bank in the topsoil may deteriorate. In addition, as topsoil is not always used in rehabilitation of areas it was salvaged from, the salvaged topsoil may not contain seeds of all the target species of its new location/habitat.

Seed mixes used during rehabilitation are of local provenance. Specific seed mixes are selected to provide a range of species appropriate to the landscape position and slope. Local colonising species are included in the mix aid to aid in quick vegetation establishment, and to thus compete with weed species that may establish from wind-blown seed. Rio Tinto is working towards ensuring culturally significant species are also considered in the selection of species and determination of proportion of seed numbers for each species in the mix.

Rio Tinto purchases seeds from commercial seed suppliers, with emphasis on ensuring that there are adequate seed of appropriate quantity and local provenance species available for planned rehabilitation at each of the mine sites or other assets. Stringent controls on seed quality, provenance and seed storage are in place and seed pre-treatments are used for a proportion of the seed of some species to maximise the potential of applied seed to germinate under field conditions. Seeds are stored in purpose-built, climate-controlled storage facilities to maximise long-term viability. Viability testing and species-specific pre-treatment occurs before seed are utilised in seed mix preparation and application onto rehabilitated sites. Increasing revegetation success through ongoing improvement projects and research partnerships in seed biology and seeding technologies is a key factor in the ability to successfully rehabilitate across all Pilbara mining operations.

As the opportunity to utilise rare and threatened species in rehabilitation programs is limited by various factors such as availability, the focus of rehabilitation programs is to restore vegetation complexes that include the more common species present in the habitat type, and to achieve a suitable range of strata considering the desired post-mining land use. Seed mixes may include species of conservation significance if available, but presence of these species in rehabilitation areas is more likely to result from natural recruitment from surrounding areas.

Legislative requirements regarding seed provenance are often included as conditions within Native Vegetation Clearing Permits obtained under the EP Act. A review of all legislative requirements for seed

provenance is conducted as part of the planning process for rehabilitation programs to ensure seed provenance conditions are met. All legal obligations related to rehabilitation and seed provenance for the HD2 area are summarised in the Legal Obligations Register appended to the MCP.

3. PROGRESSIVE REHABILITATION ANTICIPATED FOR HD2

Within the proposed HD2 closure boundary, all disturbed areas that can be accessed safely, with the exception of pit floors (unless backfilled to within 10m of the final surface), will be rehabilitated, either progressively through operations, or at closure.

This Summary references progressive rehabilitation undertaken at HD1, HD4, West Angelas and Yandicoogina disturbance areas but does not intend to capture an overview of all progressive rehabilitation conducted at these sites. Progressive rehabilitation conducted at these sites will be captured in specific Summaries and appended to each relevant MCP.

4. MONITORING PROGRAMME

Rio Tinto monitors rehabilitated areas across its Pilbara operations with the objective of obtaining data that will be used to evaluate the success of rehabilitation against biological completion criteria, as well as supporting adaptive management and continuous improvement of rehabilitation techniques as described in the Rio Tinto Rehabilitation Monitoring Procedure (Rio Tinto 2019b).

Analysis of monitoring results provides information to inform the development of realistic and achievable completion criteria, by examining changes in key parameters over time and comparing results from the rehabilitation with those from corresponding reference sites in undisturbed areas. Such analysis of monitoring results will also be used to indicate the likely success of progressive rehabilitation in achieving completion criteria and whether any areas of rehabilitation require rework due to poor performance.

4.1. Monitoring schedule and design factors

Rehabilitation monitoring is scheduled using a risk-based approach to determine the appropriate monitoring technique and frequency. Where possible, monitoring is completed annually for the first three years following rehabilitation, then in years 5, 7, 9, 12 and 15, and then every third year thereafter. Frequency of monitoring may be altered depending on the condition of the rehabilitated site and the availability of resources.

Rehabilitation monitoring is completed in the cooler months (June to September) of each year, noting that COVID restrictions modified the program in 2020 and 2021. The monitoring program design (i.e., monitoring technique and frequency) for each rehabilitated site considers the following factors:

- the level of complexity of the rehabilitation and subsequent risk to rehabilitation quality outcomes (e.g., generally waste dumps are a high risk due to their complexity whilst a lower risk for achieving desired rehabilitation outcomes exists for low disturbance areas).
- the regulatory requirements for rehabilitation monitoring.
- the age of the rehabilitation.
- the overall area of the rehabilitation (i.e., the larger the size, the higher the number of monitoring locations required).
- if there is a trial implemented on some of the rehabilitation (e.g., the ability to detect germination of seeded species requires early monitoring in the first year is especially important in analysis of trial results).
- natural disturbance such as fire or cyclonic rainfall (may reset the timing of monitoring to year 1).

- safe access for monitoring personnel.

Monitoring schedules for the rehabilitation sites are provided in Appendix A. In general, apart from the Yandicoogina Central Waste Dump rehabilitation (due to its completion being over 20 years ago), the rehabilitation monitoring schedules comply with the requirements of the Rio Tinto Rehabilitation Monitoring Procedure.

4.2. Rehabilitation monitoring methods

Monitoring methods utilised by Rio Tinto include:

- **Rehabilitation Quality Assessments (RQAs) and photo point monitoring**: These observational assessments are used on low to moderate disturbance areas, historical rehabilitation with no monitoring history, or on areas too small for transects. They can also be used in combination with the above transect methods on large rehabilitation areas to manage monitoring resources efficiently. The purpose is to gain an overview of the rehabilitation quality including erosion, growth medium, vegetation cover, species richness, vegetation structure, plant density, weed presence and general condition. Each characteristic is compared between the rehabilitation and local undisturbed native vegetation and given a score according to the RQA field book guidelines. A representative photograph is taken of both the rehabilitation and reference areas.
- **Vegetation, fauna habitat and erosion monitoring**: Vegetation monitoring involves establishing quadrats (2 m x 2 m) at 5 m intervals along a 50 m or 100 m transect. Within each quadrat, numbers of all native perennial plant species and weeds are counted, and individual percent cover estimated. The number of bare areas is assessed by dividing the edge of each quadrat on the transect baseline into eight x 25 cm sections and recording the number that has no perennial plant species cover. A subjective assessment of total native perennial plant cover (%) is also recorded for each quadrat. Notes are taken of the general condition of the rehabilitation, including new disturbance and fire damage. The term 'spinifex' in this report refers to *Triodia* species.

  Fauna and habitat monitoring comprises estimating litter cover, noting rocks and logs in each quadrat, and a whole-of-transect assessment of grazing extent, native animal scats, ant numbers, and other indicators of animal activity.

  Erosion monitoring entails an examination of a permanent vegetation transect to identify the presence and number of gullies that are greater than 30 cm in depth. Gully locations and associated measurements of total width and depth at the deepest point are recorded. Comparisons of data collected over time can determine if a landform has stabilised or if it is exhibiting rates of erosion which require intervention. Eroded areas that may require intervention are then investigated for potential rework opportunities.

4.2.1. Rehabilitation monitoring reference sites

To obtain meaningful information on rehabilitation outcomes, suitable reference sites are required for comparative purposes. The location, topography and vegetative structure of the rehabilitated area are the key considerations when selecting a reference site, which will ideally represent the natural landscape surrounding the operational area. Additional factors and potential limitations that are also considered during reference site selection include approval boundaries, exclusion areas, final landform designs, mine planning, accessibility and safety factors. Consequently, the distance between rehabilitation and reference sites can vary.

Reference sites are positioned within undisturbed native vegetation representative of the local area where the rehabilitation is to be conducted. Appropriately positioned monitoring reference sites will encompass the target vegetation community to provide the baseline vegetation criteria used for

assessing rehabilitation progress and outcomes and, where possible, enable a comparison to similar undisturbed areas. Reference sites are located on different topography types (upper slopes / hilltops, mid-slopes and lower slopes and flats) to account for spatial variations of mined landforms and their influencing factors.

The monitoring of reference sites provides a temporal record of natural variations in established vegetation through time which can offer valuable insights into the influence of non-mining related variables such as climate or fire events. Monitoring data obtained from reference sites also assists in the planning of rehabilitation by informing methodology, for example seed list selections. Using a range of reference sites is endorsed to better facilitate a comprehensive assessment of rehabilitation progress.

Reference sites will be established in the early development stage of HD2, after project approval. Details and vegetation parameter trends regarding the HD1, HD4, West Angelas and Yandicoogina monitoring reference sites cited in this Summary are provided in Appendix B of this Summary, with photos presented in Appendix C.

4.2.2. Revegetation completion criteria

Vegetation on rehabilitated land has been identified as a key outcome in evaluating the site condition at closure and compatibility with the post-mining land use. All progressive rehabilitation undertaken during operations is required to meet the associated closure outcomes / completion criteria described within the associated Mine Closure Plan (MCP). Broadly, the desired closure outcomes help align the rehabilitation methodology with the objectives of establishing a safe, stable, and non-polluting landscape vegetated with native species of local provenance, and ensuring the site is compatible with proposed post-mining land use.

Based on recent work undertaken by Rio Tinto and Stantec (Stantec 2020) on potential biological completion criteria for the Channar mine site, the following key parameters were selected to develop quantitative targets which are applicable across all rehabilitation areas and reference sites:

- **Native perennial species richness and species density**: Species richness is simply the total number of species in a defined area (i.e., the sum of quadrat species counts within entire transect). This differs from the more comprehensive measurement of species diversity which incorporates relative abundances.

  Species density was calculated as the mean number of species per quadrat and is a valuable measure for monitoring vegetation changes over the long-term. Although not significantly different to species richness, species density can better detect plant responses to a given management action, and unlike species richness, comparative analyses can still be made when transect lengths differ.

- **Native perennial plant density**: Plant density refers to the mean number of plants per transect. Total counts of native plants were documented for each quadrat and averaged for entire transect values.

- **Native perennial plant cover**: Values for this parameter were obtained with visual assessments for each quadrat of the percentage of surface area with vegetation (i.e., percentage that is not bare). Final values were calculated for each transect as the mean percentage of cover across all quadrats. Due to the subjectivity involved in visually assessing percentage cover, final values are considered estimates only.

The analysis of these parameters is standardised across all Rio Tinto operational sites and is considered appropriate in the development of a consistent approach to determining success of rehabilitation over time. Rio Tinto is undertaking further work on this approach and will also incorporate feedback when received from stakeholders on the preliminary Channar monitoring strategy present in the MCP (2020). Further refinements of completion criteria will be presented in future updates to closure plans and progressive rehabilitation performance summaries

The preliminary completion criteria for HD2 are presented in Table 2 below along with the associated monitoring methods and means of verification (vegetation parameters). These will be refined further as mining progresses to ensure they are Specific, Measurable, Achievable, Relevant and Time-Bound (S.M.A.R.T) (as defined by Young *et al* (2019)). Application of the S.M.A.R.T acronym facilitates a systematic and comprehensive framework for goal formation.

Table 2 HD2 Proposal preliminary completion criteria

CLOSURE OUTCOME	PRELIMINARY COMPLETION CRITERIA	UNIT(S) AND METHOD(S) OF VERIFICATION
Vegetation on rehabilitated land is self-sustaining and compatible with the post-mining land use.	Seed used in rehabilitation works is of local[1] provenance.	Seed management plan
	Native plants within rehabilitated areas are observed to flower and/or fruit.	Rehabilitation monitoring and site inspections Reproductive activity Species flowering/fruiting
	Recruitment of native perennial plants is observed	Rehabilitation monitoring and site inspections Number of native perennial plants per m^2
	Species richness of native perennial plants within rehabilitated areas is not less than reference sites.	Rehabilitation monitoring and site inspections Number of native perennial species per m^2
	Any weed species recorded within rehabilitation areas are present within the local area.	Analysis of weed species richness, estimated cover (%) within revegetation against baseline data. Proportion of weed cover to total perennial cover
The final landform is stable, and its design considers hydrological factors.	No erosion features that compromise landform integrity are present and if present, erosion features are stable	Rehabilitation monitoring program including quantitative evaluation of behavior of rills and gullies (if required) over time. Depth, width, and length of rills/gullies.
	The final landform has been designed and constructed with consideration given to its stability during intense rainfall and large flood events.	Analysis of aerial imagery to provide qualitative analysis of landform stability. Post-closure landform review to confirm that risks have been appropriately managed.
	Final landforms are outside predicted potentially unstable pit edge zones.	

[1] Local is defined as Pilbara IBRA and/or as defined in NVCPs

4.2.3. Climate data

Rainfall and temperature

Rainfall and temperature data is sourced, either directly or via the Bureau of Meteorology (BOM), from weather stations located at or in the vicinity of the relevant mine site. Generally, Rio weather stations are used to provide monthly localised data, with long-term averages sourced from BOM weather stations.

Yearly rainfall trends characteristic to the Pilbara region are generally that of extreme cyclone-associated rainfall throughout the summer months, with significantly less rainfall received during the winter months. Rainfall data referenced in this Summary was obtained from HD1 / HD4, Yandi and West Angelas weather stations, with long term averages sourced from the Marillana WS (005009) (BOM, 2020), located just under 50 km from HD2, and Turee Creek Station (007083) (BOM, 2020), approximately 85 km from HD2.

Annual temperature trends observed in the Pilbara region show the most range between maximum and minimum values during winter months, with the highest summer maximum usually recorded in November. Summer temperatures regularly exceed 35°C, with maximums above 40°C not uncommon. Temperature data within this Summary was sourced from the Newman Aero WS (007176) (BOM, 2020), despite it being 100 km from HD2, as monthly values were inconsistently recorded at closer stations. As such, the temperature data in this Summary is used to provide a general indication of trends over time rather than as source of specific values for comparisons with monitoring results.

Climate change

Climate change is a complex issue, with inherent uncertainty about the timing, pace, and severity of possible impacts. Risks from climate change to the stability of landforms, mobilisation of contaminants and revegetation are some of the identified vulnerabilities that have been considered in closure planning.

Based on climate change projections rainfall reduction will be relatively small in the Pilbara. However, the sensitivity of hydrological processes to small changes in rainfall coupled with the expected rise in temperatures (particularly during winter months, which may impact monitoring schedule and design) and potential evaporation will have a large impact on the hydrology of the Pilbara region (Charles *et al.*, 2015). The materialisation of these climate projections is likely to make successful rehabilitation in the Pilbara more challenging.

5. SUMMARY OF REHABILITATION PERFORMANCE

Examples of monitoring outcomes of key rehabilitation areas at adjacent Rio Tinto mine sites provide contemporary scientific evidence of the success of rehabilitation undertaken to date in the region.

Interpretations and analyses of rehabilitation monitoring results were limited to a moderate extent by deficiencies in pre-2010 records of rehabilitation methodology. For example, the use of ameliorant was rarely documented so any potential correlation with successful rehabilitation outcomes will not be evident. Data and document management is currently undergoing a significant upgrade to alleviate the issue. Detailed close-out reports will be completed for all future rehabilitation works, following a standardised approach which utilises up-to-date databases and document control methods.

5.1. Rainfall

Hope Downs

A sustained period of above average rainfall was received in the 2013/2014 summer, theoretically promoting seed germination and establishment at sites rehabilitated in 2013 (HD4 Powerline, Railway and Mine Access Road, Mine and Camp). Plant growth may have been limited in subsequent years due

to periods of below average rainfall recorded during the summer of 2015/2016, between December 2018 and April 2019, and in the six months leading up to the 2020 assessment.

A substantial summer rainfall event was recorded in January 2021, with rainfall being 102 mm above the long-term average. These trends are evident within Figure 1 which plots the monthly rainfall recorded at HD1 and HD4 against long-term averages.

Yandicoogina

In the time since the Central Waste Dump rehabilitation works were completed in 1999, rainfall has been mostly consistent with the long-term average, with above average rainfall recorded from 2003 to 2006 and 2011 to 2017 (Figure 2 and Figure 3). There were no severe and/or prolonged drought periods and while conditions during the periods of below average rainfall were sub-optimal for seed germination and plant recruitment, the Yandicoogina Central WD rehabilitation was old enough to tolerate the dry conditions.

Rainfall following completion of the Rubber Dump rehabilitation in 2013 was generally consistent with the long-term average, although minor periods of low rainfall were recorded from February to May 2016 and several months prior to the 2018 monitoring assessment, which may have adversely influenced vegetation parameters including plant cover and presence of annuals.

West Angelas

The monthly rainfall (mm) for West Angelas is presented in Figure 4, with observed trends being generally consistent with those expected for the Pilbara region. Yearly rainfall totals recorded since the completion of the East and South Waste Dump rehabilitation in 2012, were consistently above the long-term average of 253 mm, potentially aiding seed germination and plant establishment. An exception to this trend was observed during the twelve months prior to the 2019 assessment, with both annual and summer rainfall being well below the long-term average.

5.2. Temperature

Temperature data sourced from Newman Aero WS, approximately 100 km away from the Hope Downs mine site, is provided in Figure 5 as an indicator of yearly temperature variations and trends in the general area of HD2.

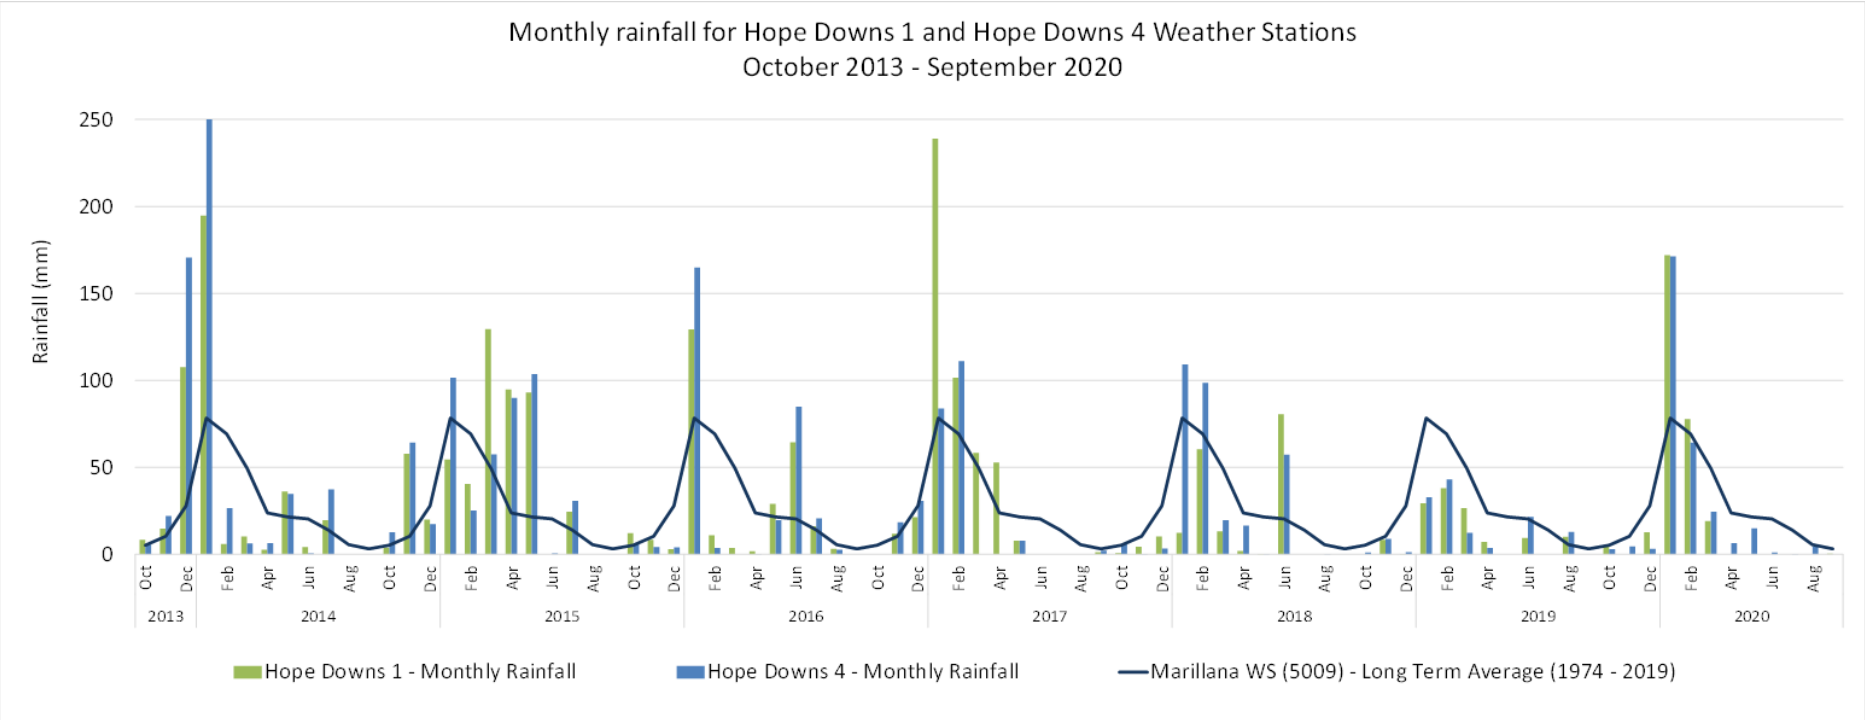

Figure 1: HD1 and HD4 monthly rainfall from January 2013 to September 2020, with long-term monthly average from Marillana WS (1974-2019).

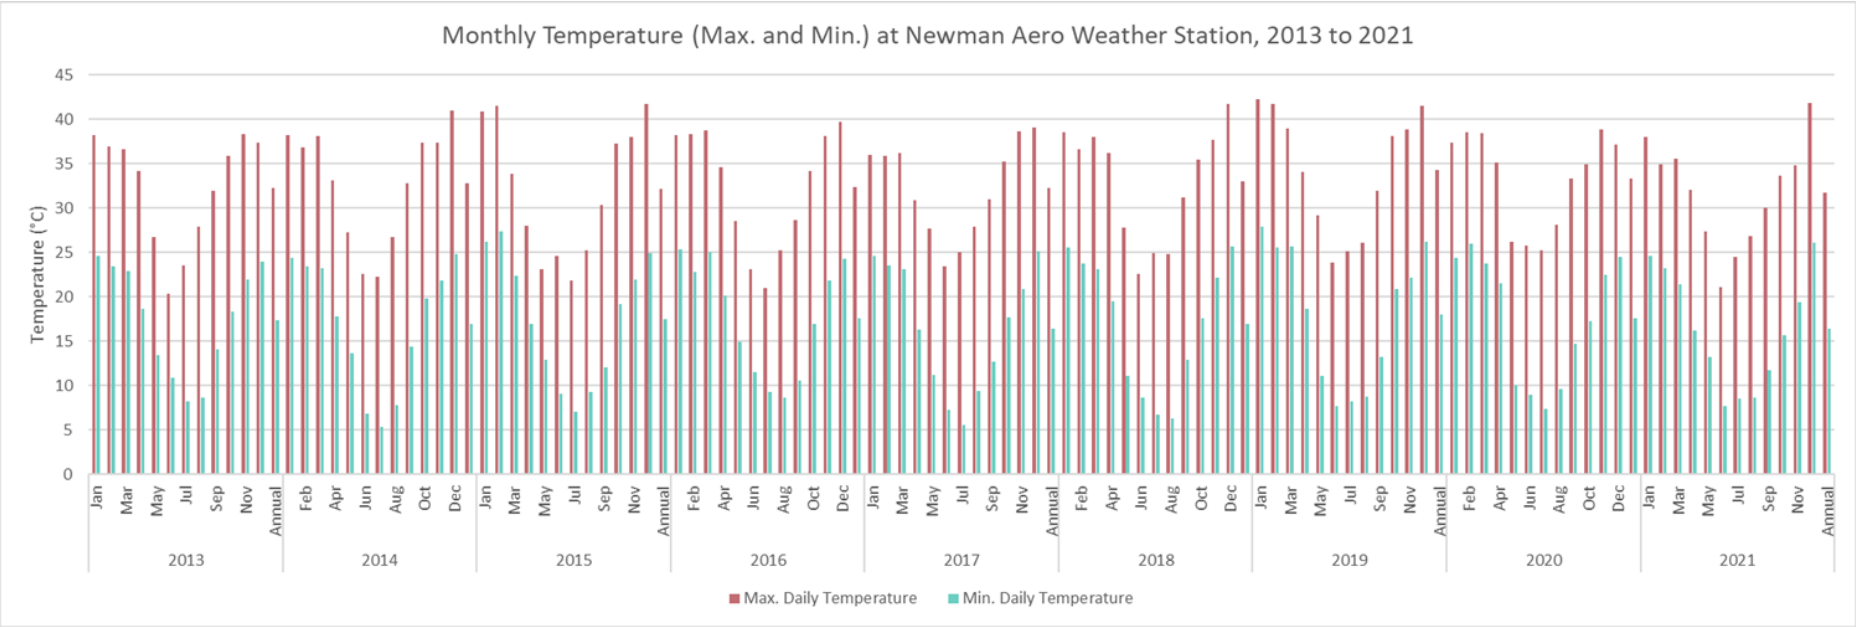

Figure 5: Monthly maximum and minimum temperature from 2013 to 2021 recorded at Newman Aero WS (007176).

5.3. Fire

Obtaining a comprehensive understanding of vegetation parameter dynamics in post-fire communities is highly valuable for rehabilitation in Western Australia due to the climate-induced, increasing prevalence of fire. The parallels observed between vegetation parameter trends at early rehabilitation sites and at burnt sites are also cause for furthering the current knowledge base on fire-affected communities, and to facilitate this, exploring the potential for undertaking additional monitoring at burnt sites.

Burnt reference sites do not provide appropriate targets for rehabilitation due to post-fire impacts on vegetation parameters, which were evident at nine reference sites (see Table 3 for details, Appendix B for trend analyses, with photos provided in Appendix C.

As fire is a natural and common occurrence in Pilbara ecosystems, and considering most sites were burnt in different years (Yandicoogina reference sites being the exception), vegetation quadrat data obtained from burnt reference sites can still facilitate meaningful comparisons on the premise that the trends observed reflect a vegetation community in post-fire recovery, and do not represent the target community for rehabilitation.

Photos of the only burnt rehabilitation transect are provided in Appendix C and resulting impacts to vegetation parameter trends are discussed within Section 5.4.2.

Table 3 Overview of burnt reference sites

REFERENCE SITE	MONITORING YEARS BETWEEN WHICH BURNING OCCURRED	PERCENTAGE OF QUADRATS BURNT
WAN_C3	2015 and 2017	100%
WAN_C4	2015 and 2017	100%
WAN_C7	2016 and 2018	95%
WAN_C8	2010 and 2012	45%
WAN_C9	2016 and 2017	90%
HD4_Flat_C12	2016 and 2018	85%
HD4_Flat_C6	2014 and 2015	60-80%
YAN_C6	2016 and 2017	100%
YAN_C9	2016 and 2017	100%

5.4. Monitoring results

5.4.1. Low impact disturbance sites

Anticipated disturbance areas for the HD2 Proposal will largely fall under moderate or high impact categories. There will be some low impact disturbance areas designated for rehabilitation, which will be monitored with the RQA method. This Summary focuses on vegetation quadrat monitoring data (typically used for moderate and high disturbance) as it provides greater analytic value for informing HD2 rehabilitation methodology. For this reason, no low impact disturbance areas have been included in this Summary.

5.4.2. Moderate impact disturbance areas – borrow pits

Prospective moderate impact disturbance areas within the HD2 Proposal boundary are likely to consist of borrow pits. A summary of rehabilitation methodology implemented at two HD4 borrow pit sites is provided in Table 4 provide an overview of general borrow pit rehabilitation undertaken in the region.

Ultimately, this will help inform methodology for future rehabilitation efforts, facilitate an increasing assurance in successful outcomes for rehabilitation, for example, through an enhanced risk management process resulting in less requirements for rework. Strategies and design parameters can be refined through the continual input of new data, facilitating a continually growing confidence in the chosen methodology for borrow pit rehabilitation.

Table 4 Rehabilitation overview for borrow pit sites

REHABILITATION PARAMETER	SITE	
	HD4 Railway	**HD4 Mine Access Road, Mine and Camp**
Initial no. transects monitored	15	10
Current no. transects monitored	5	9
Area (ha)	Unknown	Unknown
Closure domain	Borrow pit	Borrow pit
Year of rehab	2013	2013
Growth medium	Topsoil	Topsoil. Note: Camp_T4 had very little topsoil applied, substituted with coarse rocky substrate
Depth of growth medium application (mm)	200 mm	200 mm
Seeding mix	Not applicable	Not applicable
Seeding rate (kg/ha)	0	0
Soil ameliorant (type)	Unknown	Unknown
Contour ripping (depth)	200 mm	200 mm

Hope Downs 4 railway borrow pits

Rehabilitation of the HD4 Railway borrow pits, which included contouring, topsoil application and ripping, was completed in 2013 with 15 Railway transects (all 50 m in length and located on flat terrain) first monitored in 2014. The last monitoring assessment was conducted for five Railway transects only. LHRX_T5 was the only transect affected by fire, with burning occurring prior to the 2018 assessment (photos showing the transect pre- and post- burn are provided in Appendix III).

A visual assessment of rehabilitation outcomes at HD4 Railway borrow pit monitoring indicates variable results, with a notable increase in total cover observed at LHRX_T1 (Figure 6 and Figure 7). Species density and plant density at most rehabilitation transects follow mostly declining trajectories showing some stabilisation in later years The initial declines observed for species and plant density appear to be loosely correlated with considerably high initial densities. The impacts of fire at rehabilitation site LHRX_T5 are most evident within the plant cover parameter, with trends in species density and plant

density not notably different to the unburnt transects. Rehabilitation outcomes are further discussed below, with inferences based on comparative analyses of rehabilitation and reference site vegetation quadrat data. For clarity of results, only the transects monitored in all years were assessed.

Figure 6: HD4_LHRX_T1 (start) 2014 (one year after rehabilitation)

Figure 7: HD4_LHRX_T1 (start) 2018 (5 years after rehabilitation)

Native perennial species density and species richness

Species density values recorded at all rehabilitation transects from 2014 to 2018 were considerably higher than species density values recorded from 2015 to 2018 at reference sites Flat_C11 and Flat_C2 (Figure 8). Inclining trends in species density were observed at 4 rehabilitated transects between the first two monitoring assessments (steepest inclines occurred at the two sites with the lowest density in the first year of monitoring recorded at LHRX_T4, whilst the other 2 showed declines. Burnt reference sites Flat_C6 and Flat_C12 showed the most variability to the rehabilitation species density trajectories.

Decreases in species density occurred at all sites between 2015 and 2016, with LHRX_T1 best reflecting the reference site's gradual rate of decline. Based on the 2020 monitoring assessment all rehabilitation transects show significant similarity to the 1.6 species per quadrat recorded at the reference site. However, species density increased at the reference site between 2018 and 2020 yet decreased at all rehabilitation transects (except LHRX_T2 which remained constant). This may be attributed to the below average rainfall recorded in 2017 and 2019 as well as losses of early coloniser species, which is consistent with the age of the rehabilitation. All species density values recorded in 2020 at the rehabilitation transects were within the range of values recorded in 2021 for the reference sites (noting reference sites weren't monitored in 2020).

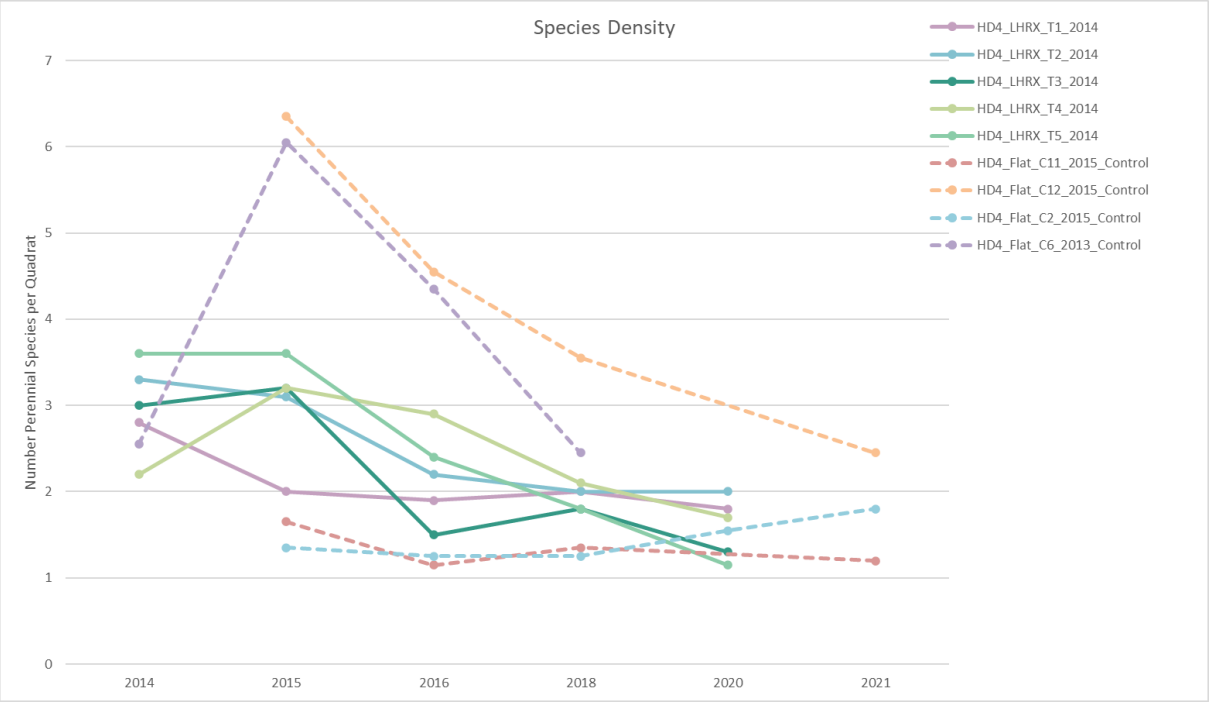

Figure 8: Native perennial species density (species/ quadrat) for the Railway borrow pits rehabilitation and reference sites over time.

Species richness decreased at all rehabilitation transects over the duration of monitoring, with the largest decline of seven species recorded at LHRX_T3. At the time of the last assessment, total numbers of species ranged from four at LHRX_T3 to 10 at LHRX_T5, with the latter a reflection of impacts from fire. The majority of native perennial species recorded across the rehabilitation can be plausibly assumed to have returned through applied topsoil, or wind born seed, as no seeding was carried out. Common species between the rehabilitation sites included spinifex and shrub species such as *Acacia pruinocarpa*, *Triodia basedowii*, *Triodia wiseana*, and *Acacia bivenosa* which was the only species present at all sites (rehabilitation and reference).

Native perennial plant density

The rehabilitated transects show a general declining trend in plant density over five years, with steep declines observed from 2015 to 2016, and, excluding LHRX_T2, from 2018 to 2020 (Figure 9. Note: y-axis has been adjusted for clarity of rehabilitation trajectories).

Two notable increases in plant density were observed, one at LHRX_T5 (which can be attributed to fire) between 2016 and 2018, and another at LHRX_T1 between 2018 and 2020. Differences between plant density values recorded in 2020 for the rehabilitated sites and the reference sites were only statistically significant when Flat_C12 and Flat_C6 were included in the analysis.

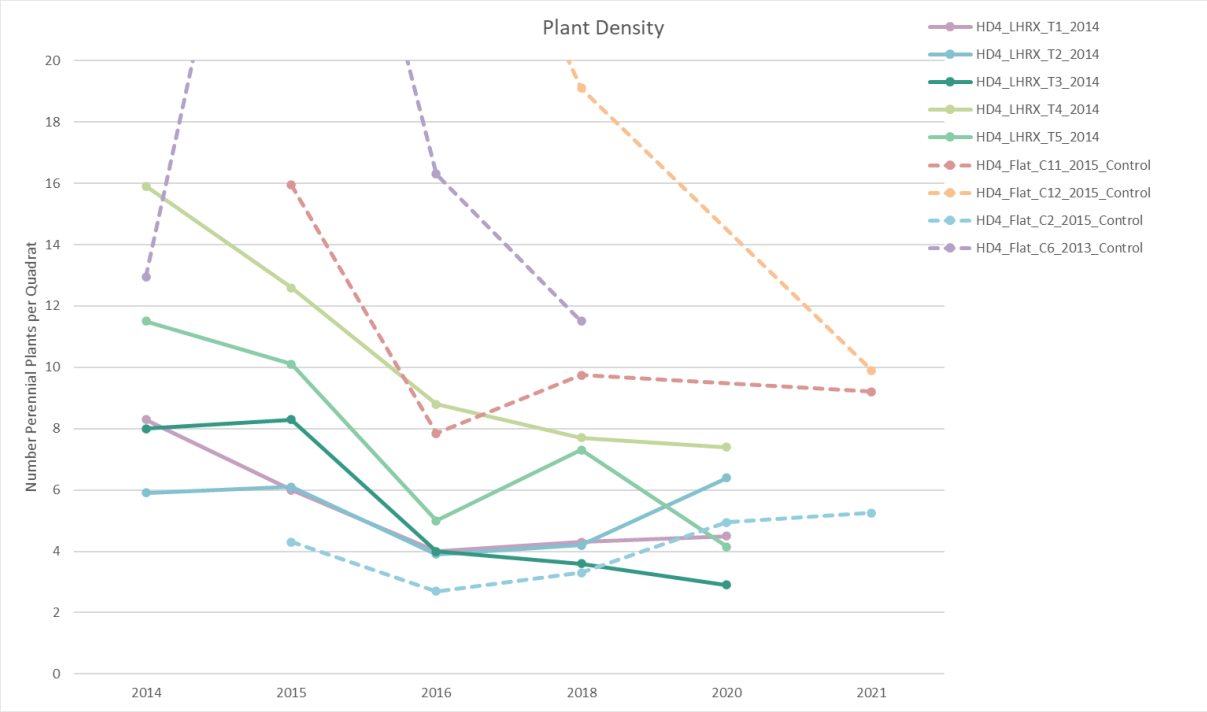

Figure 9: Native perennial plant density (plants/quadrat) for the Railway borrow pits rehabilitation and reference sites over time[1]

Native perennial plant cover

Similar native perennial plant cover trends are observed between 2014 to 2018 for all rehabilitation sites except LHRX_T5 where a steep decline is observed between 2016 and 2018 (Figure 5 10) due to fire disturbance. The site had begun to recover as of the last monitoring assessment in 2020, with plant cover increasing by approximately 5%. Perennial weeds were included in plant cover estimates in 2018, although their contribution to total cover across the rehabilitation was absent or minimal.

All rehabilitated transects saw an increase in plant cover from 2018 to 2020, in contrast to an 11% decline observed at the reference site. The greatest increase during this time occurred at Powerline_T1, where cover increased from 21% to 36%. In 2020 all rehabilitation transects except LHRX_T2 had less than the range of values (42% to 65%) recorded at reference sites Flat_C2, Flat_C11 and Flat_C12 (no data collected for Flat_C6). Similarly, reference values recorded in 2018 were above those recorded for all rehabilitation transects except LHRX_T2. Significant variations to reference site values were found for LHRX_T5, which can be attributed to fire disturbance.

[1] Reference sites not fully graphed on x-axis due to scale limitations. Refer to **Error! Reference source not found.** for full results.

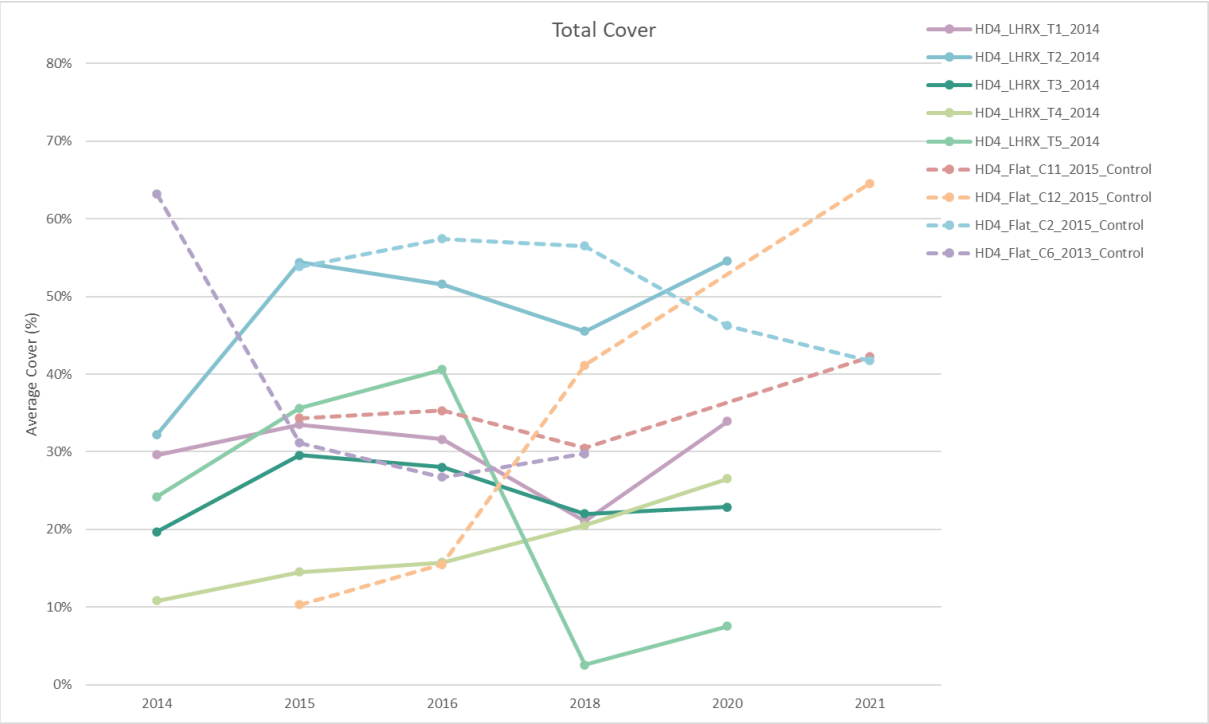

Figure 10: Native perennial plant total cover (%) for the Railway borrow pits rehabilitation and reference sites over time.

Hope Downs 4 Mine Access Road, Camp and Mine borrow pits

Rehabilitation at the Hope Downs 4 Mine Access Road, camp and mine borrow pits was completed in 2013, with an initial monitoring assessment the following year. Rehabilitation transects are located on flat topography and rehabilitation works (summarised in Table 4) included contouring, spreading of topsoil (excluding Mine_T4) and deep ripping, followed by contour ripping.

Variable rehabilitation outcomes were observed at the Mine Access Road, Camp and Mine borrow pits (Figure 11 to Figure 14), with low values in all three vegetation parameters recorded at Mine_T2 and Mine_T1. Rehabilitation trajectories for species and plant density were generally of a declining nature which can predominately be attributed to the natural senescence of native colonising species and low rainfall. The modified growth medium applied at Camp_T4 resulted in less satisfactory results compared to the three other Camp borrow pit transects, indicating that better rehabilitation outcomes are derived from sites with sufficient topsoil applied.

The impact of fire at reference sites Flat_C6 and Flat_C12 appeared to mimic the observed early rehabilitation trends, with both sites showing declines in vegetation density parameters. As expected, the most variation between the rehabilitation and the reference sites was observed for total plant cover, as reference values are not usually obtained until rehabilitation is sufficiently mature. Emergent trends based on analyses of vegetation quadrat data for the Mine Access Road, camp and mine rehabilitation and reference sites are further discussed below.

Figure 11: HD4_Camp_T3 (start) 2014 (1 year since rehabilitation)

Figure 12: HD4_Camp_T3 (start) 2018 (5 years after rehabilitation)

Figure 13: HD4_Mine_T2 (end) 2014 (one year after rehabilitation)

Figure 14: HD4_Mine_T2 (end) 2018 (5 years after rehabilitation)

Native perennial species density and species richness

A high variation in initial species density values was observed across the rehabilitation, ranging from 0.2 at Camp_T4 and Mine_T2 to 4.8 at MAR_T1 (Figure 15). Excluding Camp_T2, all rehabilitated sites

saw notable increases in species density between 2014 and 2015, signifying satisfactory primary establishment and germination rates. Transects with high initial species densities (MAR_T1, Camp_T1, Camp_T3 and Mine_T3) generally experienced greater rates of decline over the entire monitoring period, particularly between 2015 and 2016 when low rainfall likely exacerbated the losses. In contrast, the rehabilitated sites with the lowest starting densities (Mine_T1, Mine_T2, Camp_T4) showed steady increases of species density up until 2018.

Between 2018 and 2020, species density declined across all rehabilitation transects except for Camp_T1 which increased marginally by 0.1 species per quadrant. The below average rainfall received throughout 2019 may have played a role in the diminishing species densities but was unlikely the main contributing factor as Flat_C2 saw an increase in species per quadrat over this time. The greatest loss for this period was recorded at Camp_T3 which had declined from 3.5 (the highest species density value recorded in 2018) to 1.7 species per quadrat. The loss corroborates the potential correlation between high rates of species density decline and high pre-decline values (previously inferred based on the 2015 and 2016 monitoring assessments). Despite these declines, all but two rehabilitation transects (Camp_T4 and Mine_T1) had final density values above 1.6 recorded at reference site Flat_C2 and were not significantly different to the range of reference values recorded in 2021.

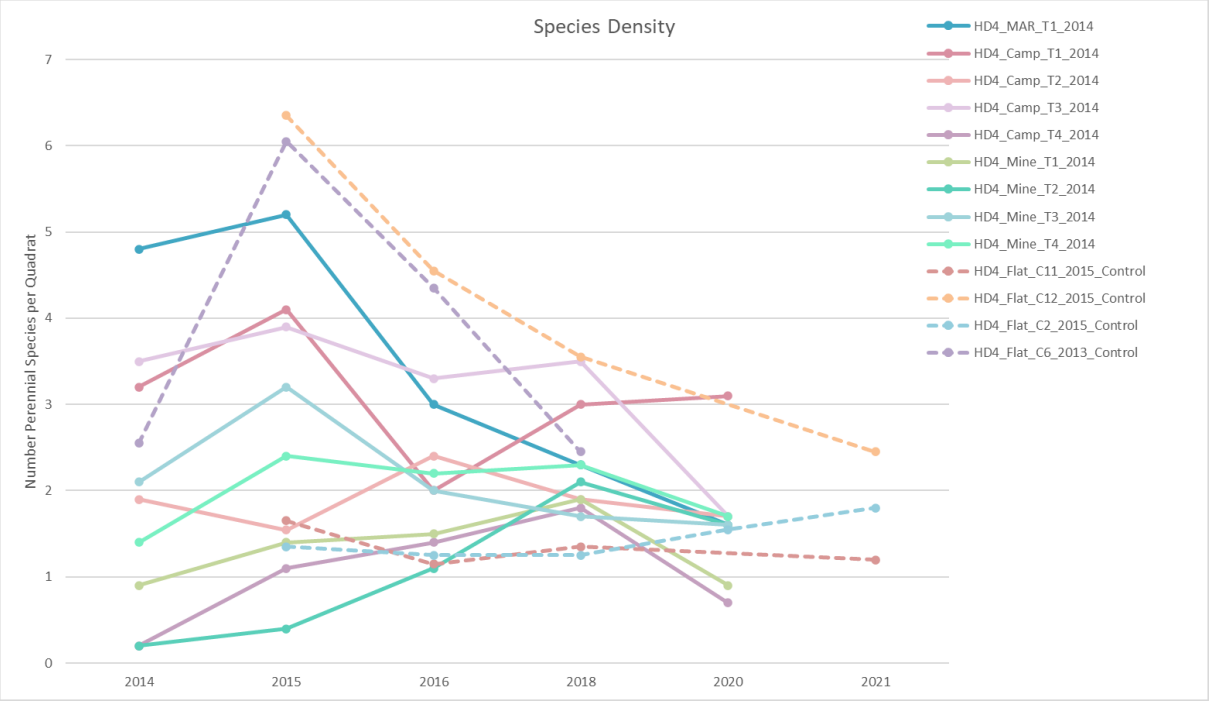

Figure 15: Native perennial species density (species/ quadrat) for Mine Access Road, Camp and Mine borrow pits rehabilitation and reference site over time.

Most rehabilitation transects showed declining species richness from 2014 to 2020, although an increase of 6 and 3 species were recorded at Mine_T2 and Camp_T4 respectively. Common native perennial species recorded in 2020 included *Acacia ancistrocarpa*, *Acacia bivenosa*, *Triodia basedowii* and *Triodia pungens*. Seven rehabilitation sites also identified *Eucalyptus leucophloia* and *Acacia bivenosa*, both also present at the reference site. No seed was applied to any of the rehabilitation sites, so the presence of these species is predominately attributed to the application of topsoil or windblown seed.

Native perennial plant density

The relatively stable plant density trajectories observed at Camp_T2 and Mine_T4, and to a lesser extent Camp_T4, Mine_T1 and T2, reflect reference site trends seen at Flat_C2 and at Flat_C11 from 2016 onward (Figure 16 – y-axis has been adjusted for clarity of rehabilitation trajectories). Congruent with

species density (Figure 15), a large range of initial plant densities were recorded at the rehabilitation, with transects exhibiting high initial densities (MAR_T1, Camp_T1, Camp_T3 and Mine_T3) but showing steeper declines in the subsequent year. The lowest numbers of plants per quadrat in the first monitoring year were recorded at Mine_T2, and at Camp_T4 where plant density remained low until 2018, likely due to the poor quality of the growth medium applied (a substrate of very coarse rocky material and minimal topsoil).

Inclining trends in plant density were observed at most rehabilitated transects between 2014 and 2015, and again between 2016 and 2018. Between 2015 and 2016 plant density increased for half of the rehabilitation sites and decreased for the other half. Considering corresponding declines occurred at all reference sites, plant losses may be attributed to the below average rainfall received during these years.

Plant density trajectories between 2018 and 2020 vary, with three rehabilitation sites increasing, and six decreasing. The steepest decline occurred at Camp_T3 which was mostly attributed to losses of Aristida and Acacia species. Losses of shrub and grass species were observed across the rehabilitation in 2020, accounting for a significant proportion of plant density declines.

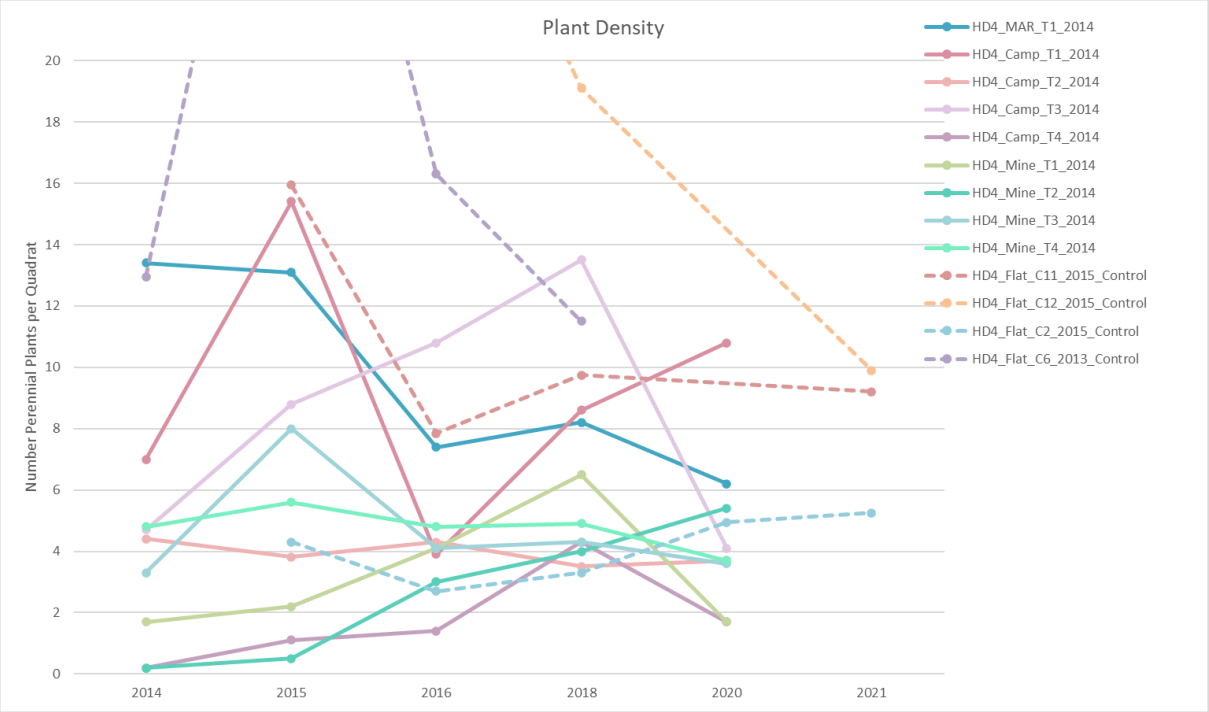

Figure 16: Native perennial plant density (plants/ quadrat) for the Mine Access Road, Camp and Mine borrow pits rehabilitation and reference sites over time.

Native perennial plant cover

Rehabilitated transects show general inclining trends in native perennial plant cover over the monitoring period (2014 to 2020), whilst the reference site remains relatively constant from 2015 to 2018 before gradually declining (Figure 17). The three transects showing most variability along their trajectory (MAR_T1, Camp_T1 and Camp_T3) also had high initial plant cover

Notable decreases between 2018 and 2020 were observed at Camp_T1 and Camp_T3, with the later remaining within the range of reference site values. Conversely, a significant increase in cover between 2018 and 2020 was recorded in MAR_T1 which was the only rehabilitation transect where perennial plant cover was above all reference site values at the time of the last monitoring assessment. This may be attributed to the development and maturing of Triodia hummocks at the site. Consistent with species density and plant density, the lowest cover values documented during the 2020 assessment occurred in Mine_T2 and Mine_T1.

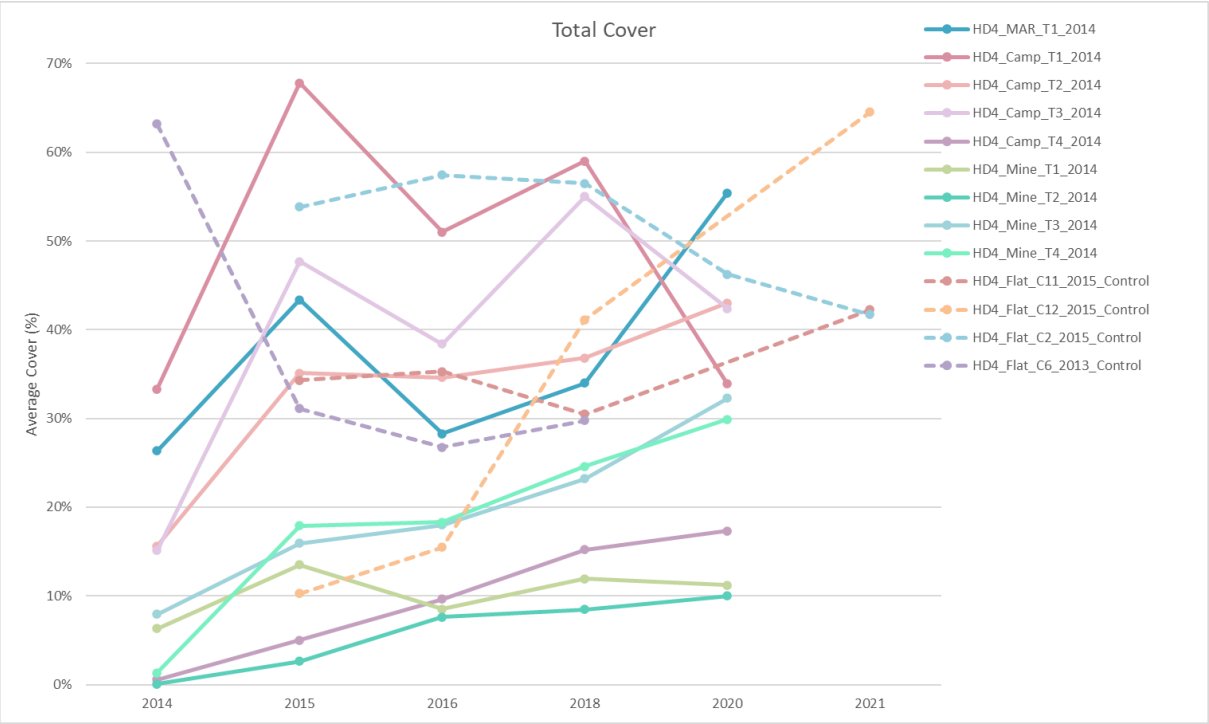

Figure 17: Native perennial plant density (plants/ quadrat) for the Mine Access Road, Camp and Mine borrow pits rehabilitation and reference sites over time.

5.4.3. Moderate impact disturbance areas – infrastructure

Additional moderate impact disturbance areas within the HD2 Proposal boundary are likely to consist of infrastructure corridors. Table 5 outlines the rehabilitation undertaken at two HD4 infrastructure sites – the Dewatering Pipeline and Powerline, with works completed in 2014 and 2013 respectively.

Table 5 Rehabilitation overview for infrastructure sites

REHABILITATION PARAMETER	SITE	
	HD4 Dewatering Pipeline	HD4 Powerline
Initial no. transects monitored	2	4
Current no. transects monitored	2	2
Area (ha)	Unknown	Unknown
Closure domain	Infrastructure	Infrastructure
Year of rehab	2014	2013
Growth medium	Topsoil	Topsoil
Depth of growth medium application (mm)	200 mm	200 mm
Time of storage of growth medium (yr)	Unknown	Unknown
Seeding mix	Not applicable	Not applicable
Seeding rate (kg/ha)	0	0
Contour ripping (depth)	200 mm	200 mm

Hope Downs 4 Dewatering Pipeline and Powerline

Transect monitoring commenced in the year following rehabilitation completion. The rehabilitated area is relatively narrow and located on a flat to gently sloping terrain. Works included contouring, topsoil application and ripping, with neither site receiving seed.

Noticeable increases in plant cover at both Dewatering Pipeline rehabilitated transects are evident in Figure 20 and Figure 22 and confirmed by vegetation quadrat data (Figure 25). Similar trends were observed at Powerline_T1, juxtaposed with subpar outcomes at Powerline_T2, which had unsatisfactory results across all three parameters due to a weed infestation one to two years post-rehabilitation. The lack of progress is apparent in Figure 18 and Figure 19, although a moderate increase in cover is observed. Further analyses of vegetation parameter trends at Hope Downs 4 Dewatering Pipeline and Powerline rehabilitation are discussed below.

Figure 18: HD4_Powerline_T2B (start) 2014 (one year after rehabilitation)

Figure 19: HD4_Powerline_T2B (start) 2018 (5 years after rehabilitation)

Figure 20: HD4_DewateringPL_T1 (end) 2016 (2 years after rehabilitation)

Figure 21: HD4_DewateringPL_T1 (end) 2018 (4 years after rehabilitation)

Figure 22: HD4_DewateringPL_T2 (start) 2016 (2 years after rehabilitation)

Figure 23: HD4_DewateringPL_T2 (start) 2018 (4 years after rehabilitation)

Native perennial species density and species richness

Species density over the full (2015 to 2018) monitoring period declined marginally for each rehabilitation transect, with an initial increase (between 2015 and 2016) observed at T1 (Figure 24). A similar rate of

decline was observed between 2016 and 2018, with species per quadrat decreasing by one at T1 and by 0.7 at T2. This can be attributed to a combination of the low summer rainfall received in 2017/18 and the natural plant senescence of coloniser species and short-lived perennials. Initial species density values at the rehabilitation transects were higher than the reference site Flat_C11, indicating successful early establishment and germination rates, likely due to the use of topsoil and the above average rainfall received over the 2014/15 summer period. Reference site Flat_C12 follows a steep declining species density trajectory, reflecting the short-term influence of fire on species density.

Between 2018 and 2020 the steepest decline in species density occurred at Powerline_T2, leaving the transect with a lower number of species per quadrant than when first monitored one year after rehabilitation. The presence of weeds may, in part, explain the transects trajectory as it is the only one where weeds were observed at high densities. Although no weeds were recorded for Powerline_T2 in 2020, prior assessments document an infestation of Spiked Malvastrum (*Malvastrum americanum*) (Table 6). Values for species density recorded during the 2020 assessment ranged from 0.3 at Powerline_T2 to just over 2 species per quadrat at Powerline_T1.

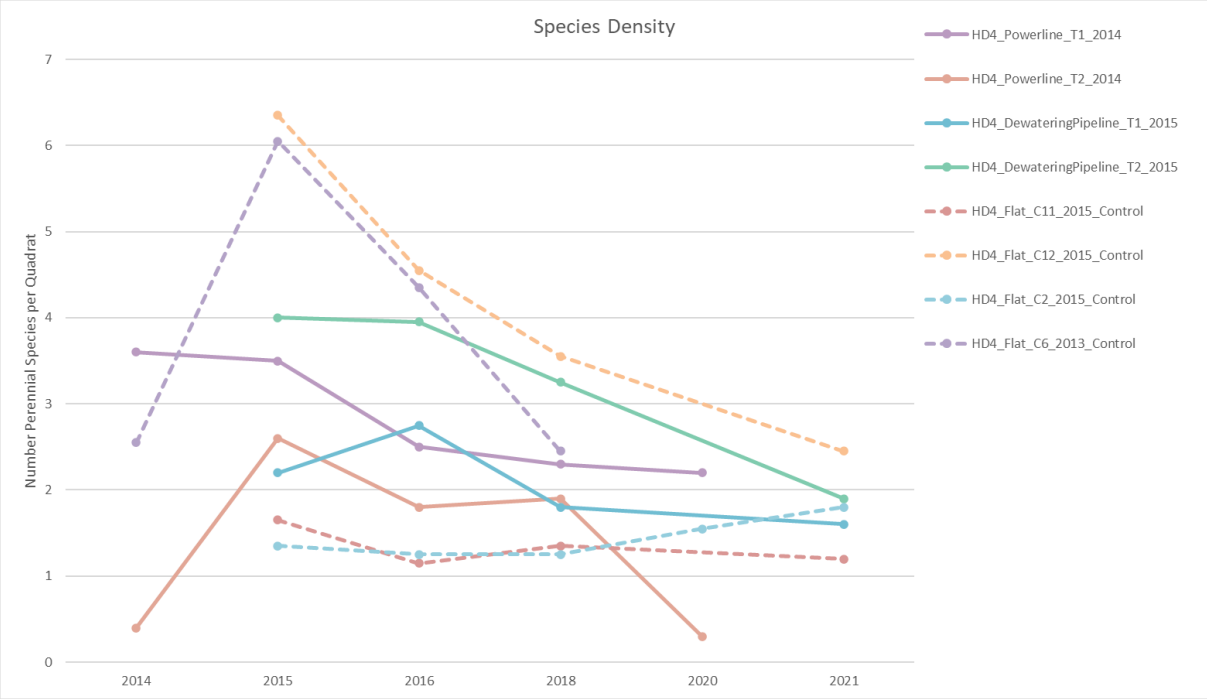

Figure 24: Native perennial species density (species/ quadrat) for the Dewatering Pipeline and Powerline rehabilitation and reference sites over time.

Table 6 Powerline T2 weed overview (*Malvastrum americanum*)

Species/Parameter	Year	Powerline_T2
Malvastrum americanum		
Density (plants/quadrat)	2020	0
	2018	4.8
	2016	14.4
	2015	41.8
	2014	26
Cover (%)	2020	0
	2018	0.2
	2016	0.7
	2015	16.7
	2014	Unknown

Native perennial plant density

Plant density trajectories at the rehabilitated transects remained relatively constant over the monitoring period, with T1 fluctuating between 7.2 and 8.2 plants per quadrant and T2 between 9.2 and 11 (Figure 25). Plant density at the rehabilitated areas remained higher than Flat_C11 over the entire duration of monitoring, but less than Flat_C12 where post-fire germination and regrowth resulted in an increased number of plants per quadrant. Although plant density did not increase at either Pipeline transect between 2016 and 2018, it is of value to note that spinifex density did increase, indicating a growing dominance of spinifex in the vegetation community.

A notable decline was observed at Powerline_T2 from 2015 to 2016, with weeds considered a likely a factor in the loss of three plants per quadrat. Increases in plant density were observed at Powerline_T2 from 2014 to 2015 and from 2016 to 2018. Differences between plant density values recorded in 2020 for the rehabilitated sites and the reference sites were only statistically significant when Flat_C12 and Flat_C6 were included in the analysis.

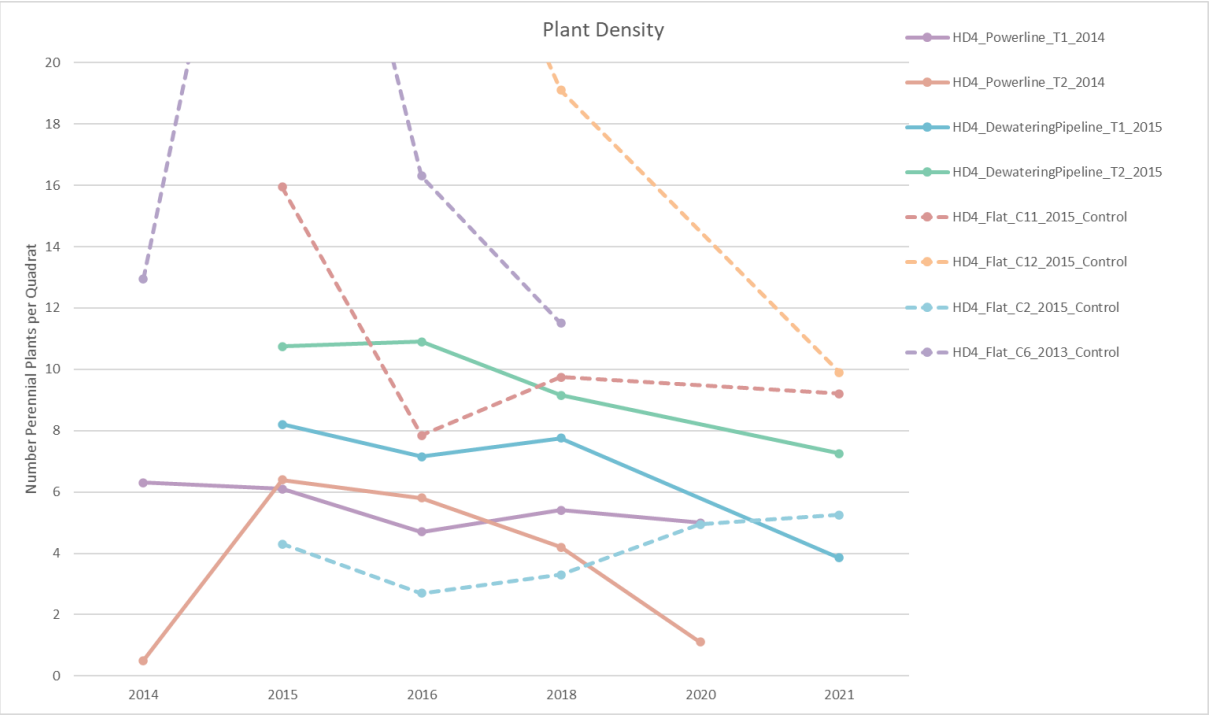

Figure 25: Native perennial plant density (plants/ quadrat) for the Dewatering Pipeline and Powerline rehabilitation and reference sites over time.

Native perennial plant cover

Inclining trajectories of perennial native plant cover (exclusive of weeds) are observed at both rehabilitated transects (Figure 26). A doubling in cover occurred across the rehabilitation between 2016 to 2018 and a substantial increase was recorded for the reference site Flat_C12. As per species density, the increase at Flat_C12 is a result of enhanced shrub regrowth following fire and as such, does not provide meaningful comparison for the unburnt rehabilitation (but may be useful as an example of post-fire successional states). Cover at the rehabilitation transects in 2018 was statistically similar to the unburnt reference site Flat_C11 and if current trajectories are maintained, cover across Dewatering Pipeline rehabilitation will soon be representative (for this parameter) of the reference vegetation community. Native plant cover at Powerline_T2 remained under 10% for the entire trajectory, potentially due to the presence of weeds (as described for species density).

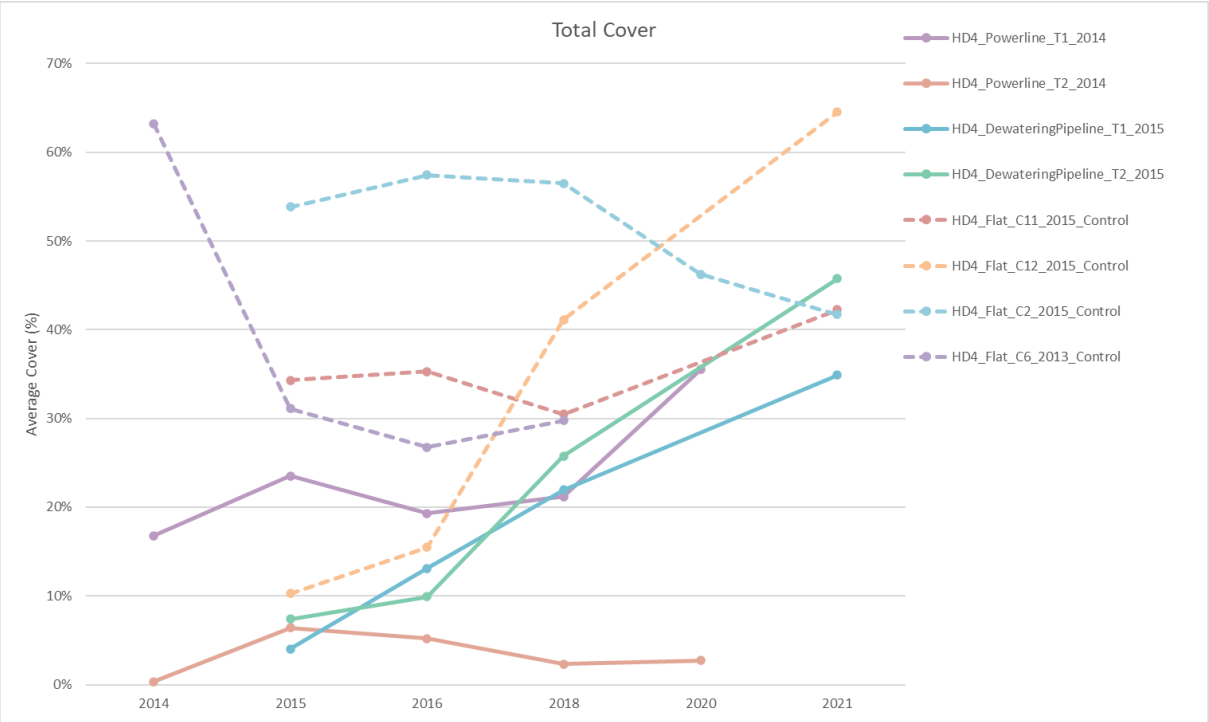

Figure 26: Native perennial plant total cover (%) for the Dewatering Pipeline and Powerline rehabilitation and reference sites over time.

5.4.4. Moderate impact disturbance areas – landfill

The HD2 Proposal will also include the construction of a site landfill, which is also considered to be a moderate impact disturbance area. Examples of regional landfill rehabilitation are provided below from HD1 and Yandicoogina which will help inform rehabilitation techniques that may be successful at HD2. Available information on the landfill rehabilitation methodology is outlined in Table 7 below.

Table 7 Rehabilitation overview for landfill sites

REHABILITATION PARAMETER	SITE	
	HD1 Old Landfill	**Yandicoogina Landfill**
Initial no. transects monitored	1	4
Current no. transects monitored	1	2
Area (ha)	3.4 hectares	1.9 hectares
Closure domain	Landfill	Landfill
Year of rehab	2013	2018 (YL3 and YL4) 2009 (T1 and T2)
Growth medium	Topsoil and subsoil	Topsoil
Depth of growth medium application (mm)	Unknown	100 mm
Time of storage of growth medium (yr)	Unknown	Unknown
Seeding mix	Six native species, East Pilbara provenance, 8.4kg total weight. Seed numbers and quality documented	Fourteen native species of local provenance. Seed numbers and quality documented
Seeding rate (kg/ha)	Spread by hand at 4.95 kg/ha over half of area	7kg/ha, with a total of 41.12 kg applied.

Contour ripping (depth)	Unknown	100-200 mm

Hope Downs 1 Old Landfill

Rehabilitation of Hope Downs 1 Old Landfill site was completed in October 2013, with the above average rainfall received in the 2013-2014 summer facilitating successful initial plant establishment and germination. Monitoring of the only established transect (100 m in length) commenced in 2014 and was last monitored in 2020. The site was surface ripped and contoured to align with the surrounding natural environment. Native seed was spread over half of the site, with the intention of comparing the outcomes for areas where seed is applied versus areas without. This resulted in double the recommended seeding rate being applied to the seeded area, which may have impeded early establishment and germination outcomes.

Observational comparison of Figure 27 and Figure 28 reveals minor improvements in vegetation cover at the Hope Downs 1 Old Landfill rehabilitation, although plant health appears to be poor and there is little to no vegetation structure. Initial plant establishment at the Old Landfill rehabilitation was less than satisfactory, evident by the significant differences to the corresponding reference values observed in Figure 29 and Figure 30.

The Old Landfill rehabilitation was most comparable to reference sites Flat_C2 and Flat_C11, particularly for species density with no significant differences detected until the 2020 monitoring assessment. The most variation between rehabilitation and reference quadrat values occurred within the plant cover parameter (Figure 31). This is not unusual for rehabilitation less than 10 years old, however the stabilising trajectory post 2017 indicates deteriorating conditions, suggesting plant cover is not improving. Rehabilitation outcomes within the selected vegetation parameters observed at Hope Downs 1 Old Landfill rehabilitation are further discussed below.

Figure 27: HD1_OldLandfill_T1 (start) 2014.

Figure 28: HD1_OldLandfill_T1 (start) 2017.

Native perennial species density and species richness

There was minimal change in the number of species per quadrat recorded at the Old Landfill site between the first two monitoring assessments, with a decline of just over 50% recorded between 2017 and 2020 (Figure 29). It should be noted that the trajectory observed between 2014 and 2017 at the Old Landfill site may not be a true reflection of the species density trajectory for this period due to the three-year gap between assessments. The rehabilitation was most comparable to reference sites Flat_C11 and Flat_C2, with the latter being the only transect where an increase in species density was observed between the two most recent assessments, indicating that the declines observed at the other transects were influenced by factors other than rainfall or temperature.

Species richness at the Old Landfill site decreased from nine species in 2014 to 5 species in 2020. Three of the six seeded species were recorded in 2020. An additional four, non-seeded native species were also present (*Acacia aneura*, *Acacia aptaneura*, *Solanum lasiophyllum* and *T. pungens*).

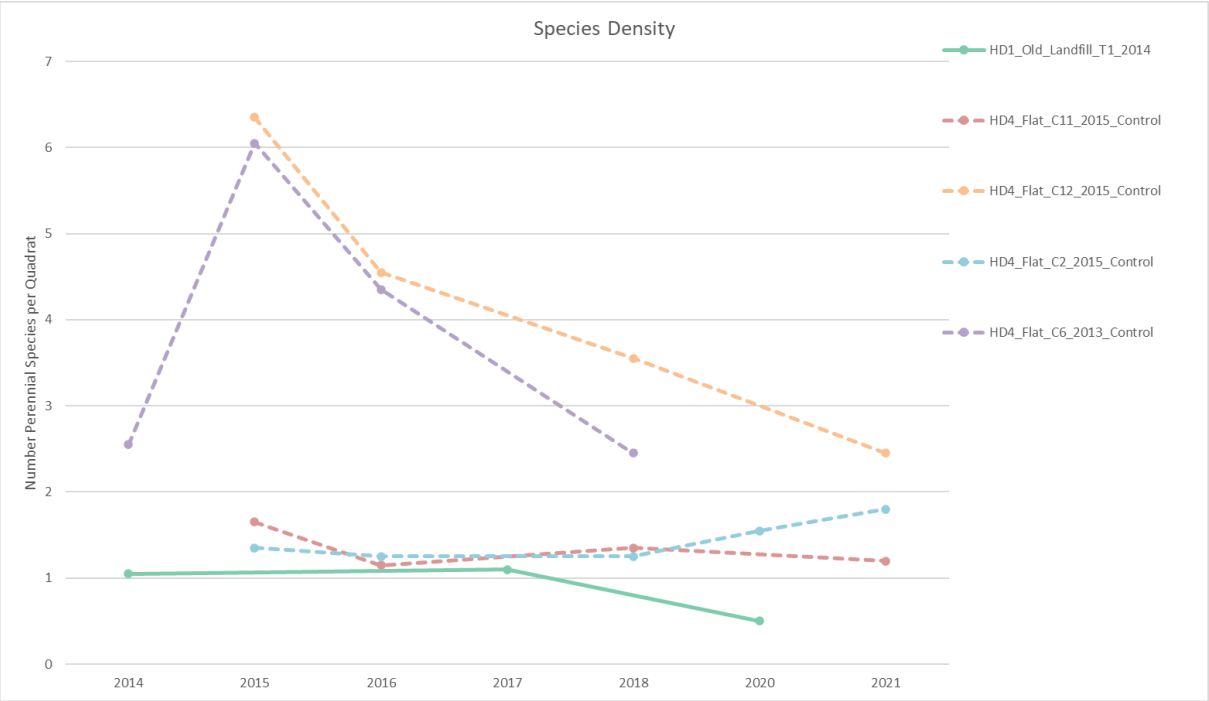

Figure 29: Native perennial species density (species/ quadrat) for the Hope Downs 1 Old Landfill rehabilitation and reference site over time.

Native perennial plant density

Plant density remained low in Landfill_T1 over the entire monitoring period, whilst reference sites Flat_C2 and Flat_C11 follow mostly inclining trajectories after initially decreasing between 2015 and 2016 (Figure 30). A slight decrease in plant density at the rehabilitation occurred between the 2017 and 2020 monitoring assessments, which, although the decline corresponds with a period of below average rainfall, is most likely a reflection of the natural loss of short-lived coloniser species. Low rainfall may have exacerbated plant loss but considering one reference site (Flat_C2) experienced increasing plant density during this time, it is improbable that it entirely accounts for the declines observed at the other transects.

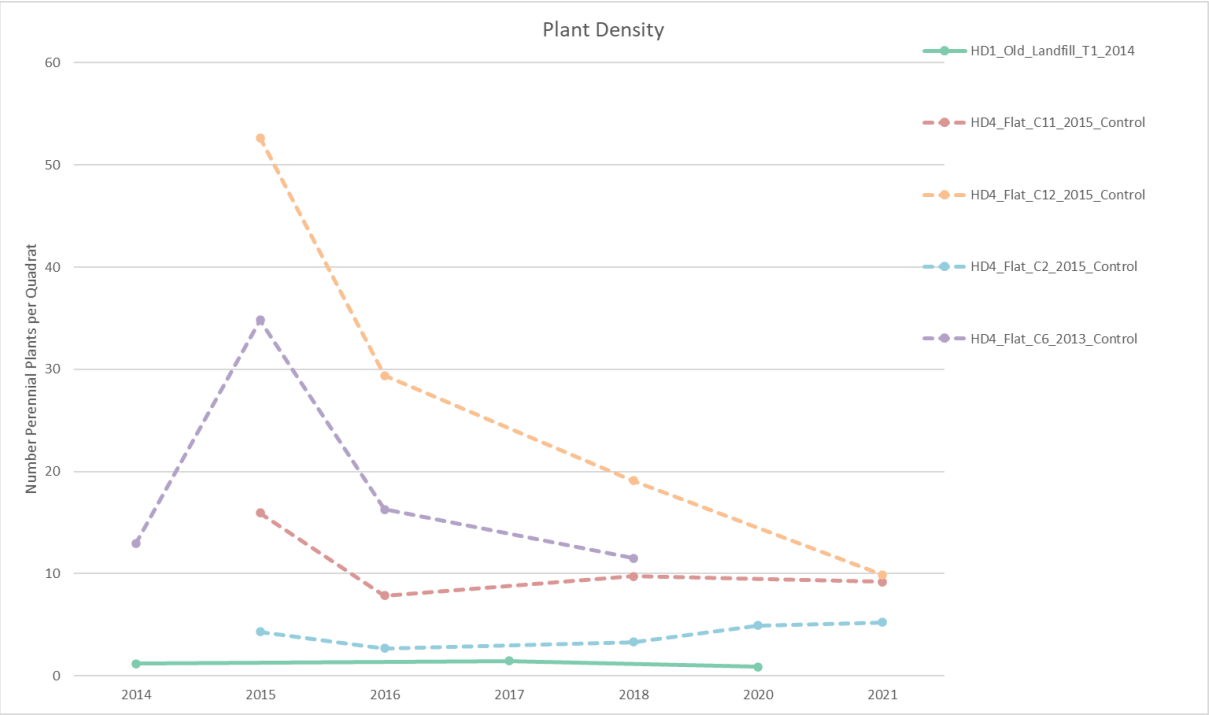

Figure 30: Native perennial plant density (plants/ quadrat) for the Hope Downs 1 Old Landfill rehabilitation and reference site over time.

Native perennial plant cover

Native perennial plant cover (%) at the Old Landfill rehabilitation increased from just over 0% in 2014 to 9% in 2020, showing some early similarity to burnt reference site Flat_C12 (Figure 31). However, cover at the rehabilitation plateaus in 2017 whilst continues to increase at a high rate in Flat_C12 indicating that environmental conditions are not a significantly limiting factor and other issues prevented further plant establishment at the rehabilitation. Statistically significant differences were found between the rehabilitation and reference sites for all monitoring years, although the 2014 value was comparable to Flat_C12 in 2015 when first monitored.

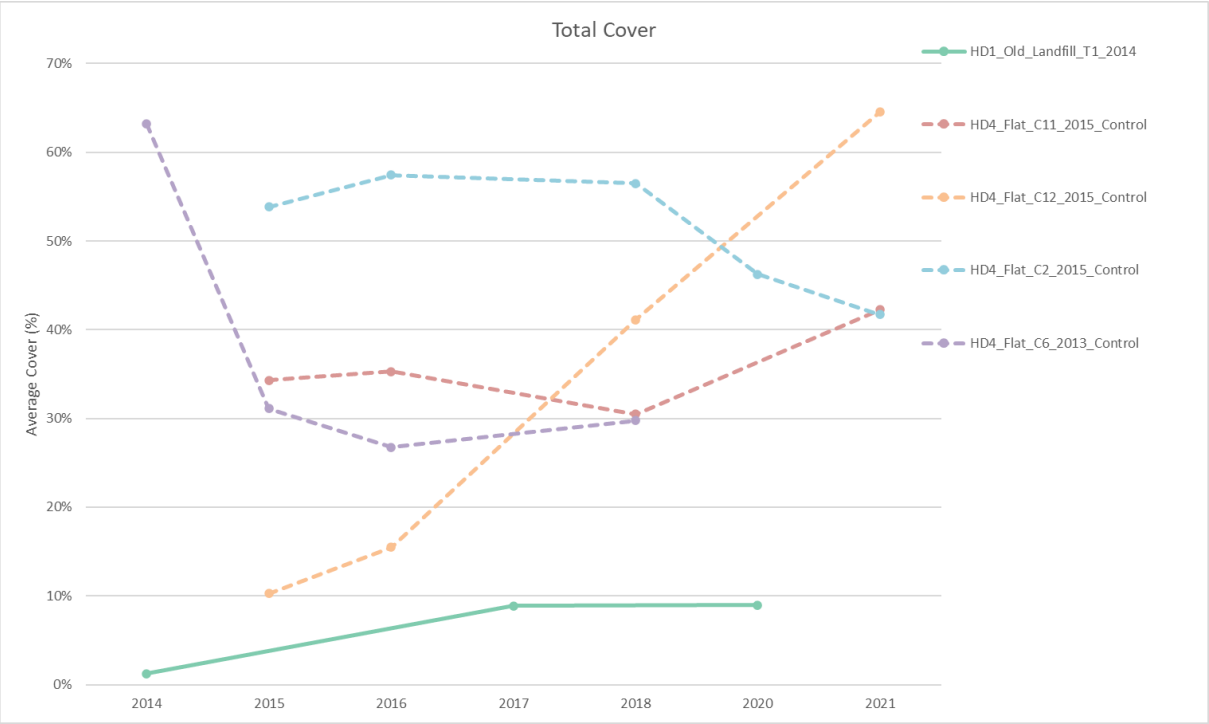

Figure 31: Native perennial plant total cover (%) for the Hope Downs 1 Old Landfill rehabilitation and reference site over time.

Yandicoogina Landfill

The first Yandicoogina Landfill rehabilitation event, which involved ripping and seeding, was completed in 2009, with monitoring of the two parallel 50m transects (YAN_Landfill_T1 and T2) commencing in 2013. Rehabilitation works at Landfill_YL3 and Landfill_YL4 were completed in 2018 and documented works include ripping (at a shallow depth to reduce water infiltration), seeding and topsoil/subsoil application. These sites were first monitored in 2019 and have not been burnt since monitoring began. Table 7 provides an overview of key rehabilitation parameter values for the Yandicoogina Landfill transects.

Rehabilitation transect Landfill_YL4 performed better than YL3 across all three vegetation parameters, recording higher total cover and species density in 2021 than the reference sites. The presence of two weed species at YL3 in 2019 may account for the lower values recorded. The rehabilitation varied most significantly to the reference sites in terms of plant density due to the post-fire germination observed at both reference sites in 2017. Declining trends in plant density were observed across the rehabilitation, although YL4 shows a promising incline as recorded during the last monitoring assessment.

Total plant cover increased across all four transects, with T1 achieving almost 70 % cover 10 years after rehabilitation. For all parameters, values recorded for T2 were marginally lower than those for T1, however they did not differ significantly from either reference site. Trends derived from the Yandicoogina Landfill rehabilitated and reference sites vegetation quadrat data are discussed further below.

Figure 32: YAN_Landfill_YL4 (start) 2019 (one year after rehabilitation).

Figure 33: YAN_Landfill_YL4 (end) 2019 (one year after rehabilitation).

Native perennial species density and species richness

Three out of the four rehabilitated transects show inclining trends between the first two monitoring assessments, with declines recorded in all ensuing assessments (Figure 34). The rate of decline

between 2020 and 2021 at Landfill_YL3 and YL4 was similar, decreasing by 0.7 and 0.3 species per quadrat respectively. The rates of incline (between 2019 and 2020) show more variation, with a steep increase (1.2 species per quadrat) occurring at Landfill_YL4 compared to a marginal increase of 0.2 at Landfill_YL3. There was no significant difference between rehabilitation and reference species densities in either 2020 or 2021, with all sites recording between 2.5 and 3.2 species per quadrat in 2020 and between 2.1 and 2.9 in 2021. However, the declining trends observed at the reference sites indicates they had not yet recovered to pre-fire values and do not currently reflect species density for the target vegetation community.

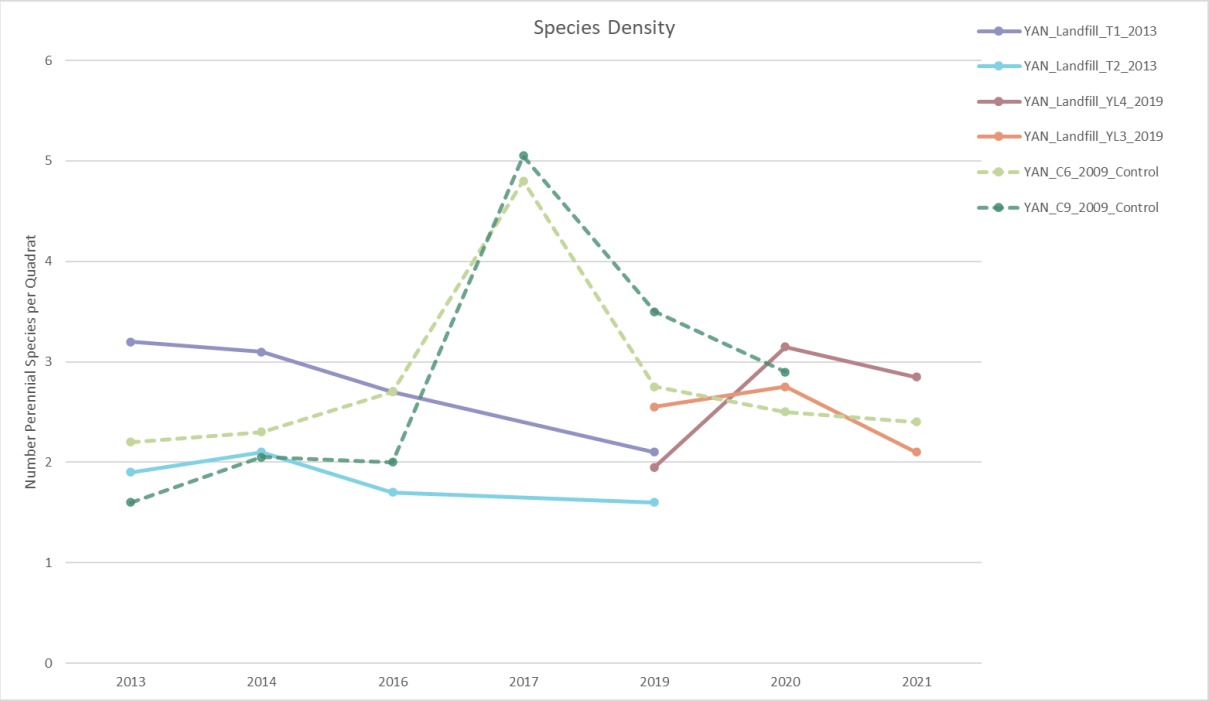

Figure 34: Native perennial species density (species/ quadrat) for Yandicoogina Landfill rehabilitation and reference sites over time.

Three of the 14 seeded species were recorded on the rehabilitated sites in 2020 (*Acacia bivenosa*, *Ptilotus calostachyus* and *Solanum lasiophyllum*) and total species count (based on transects and walk around assessment) had increased to 35 (from 22 species in 2019). Considering so few of the species recorded in 2020 were seeded, it is likely that most of the plants recorded were recruited from the growth medium applied and/or natural seed recruitment from the surrounding undisturbed landscape. Species present at all the rehabilitation and reference sites were *Acacia adoxa*, *A.bivenosa*, *Corchorus lasiocarpus* and *Triodia pungens*.

Native perennial plant density

Rehabilitation transects Landfill_T1 and T2 both decline over the monitoring period, with neither site being within the range of reference values recorded in 2019. However, this is attributable to the post-fire condition of the reference sites, where plant density was still declining towards pre-fire values as post-fire germination resulted in uncharacteristically high plant densities recorded in 2017.

Plant density trends observed between 2019 and 2021 differ between the two monitored transects, with Landfill_YL3 declining by 35 % and Landfill_YL4 increasing by 56 % (Figure 35). The rates of incline / decline were correspondingly higher between 2020 and 2021.

A decrease in plant density was observed at both reference sites between 2019 and 2020, with YAN_C6 showing a moderate increase the following year. Plant density at the rehabilitation remained below the

reference densities throughout the monitoring period, however this is attributable to the high rates of post-fire germination observed at both reference sites.

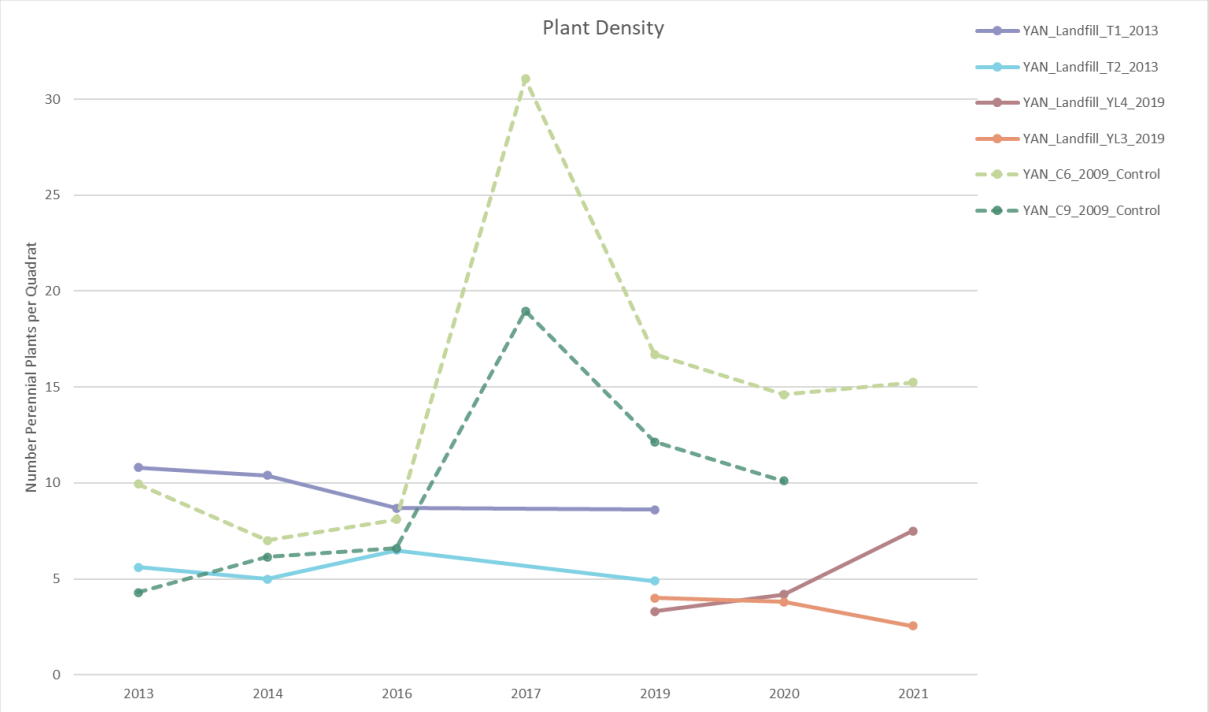

Figure 35: Native perennial species density (species/ quadrat) for Yandicoogina Landfill rehabilitation and reference sites over time.

Native perennial plant cover

Total plant cover increased over the duration of monitoring at all Yandi Landfill rehabilitation transects, with three out of four recording higher values as of their last monitoring assessment compared to the corresponding reference values (Figure 36). Conversely, less plant cover was observed at three out of the four rehabilitation transects during the first monitoring assessment compared to each reference site. Cover at Landfill_T2 had begun to stabilise when the transect was last monitored, whilst the inclining trends continued at Landfill_T1, resulting in almost two thirds of the transect being covered.

Landfill_YL4 saw a substantial expansion of cover between 2019 and 2020, increasing from 15% to 40%, whereas Landfill_YL3 increased from 10% to 20% making it equivalent to reference site YAN_C9. There was no significant difference in plant cover between the rehabilitation and reference sites in 2020. Cover at the rehabilitation and reference site YAN_C6 remained relatively constant between 2020 and 2021.

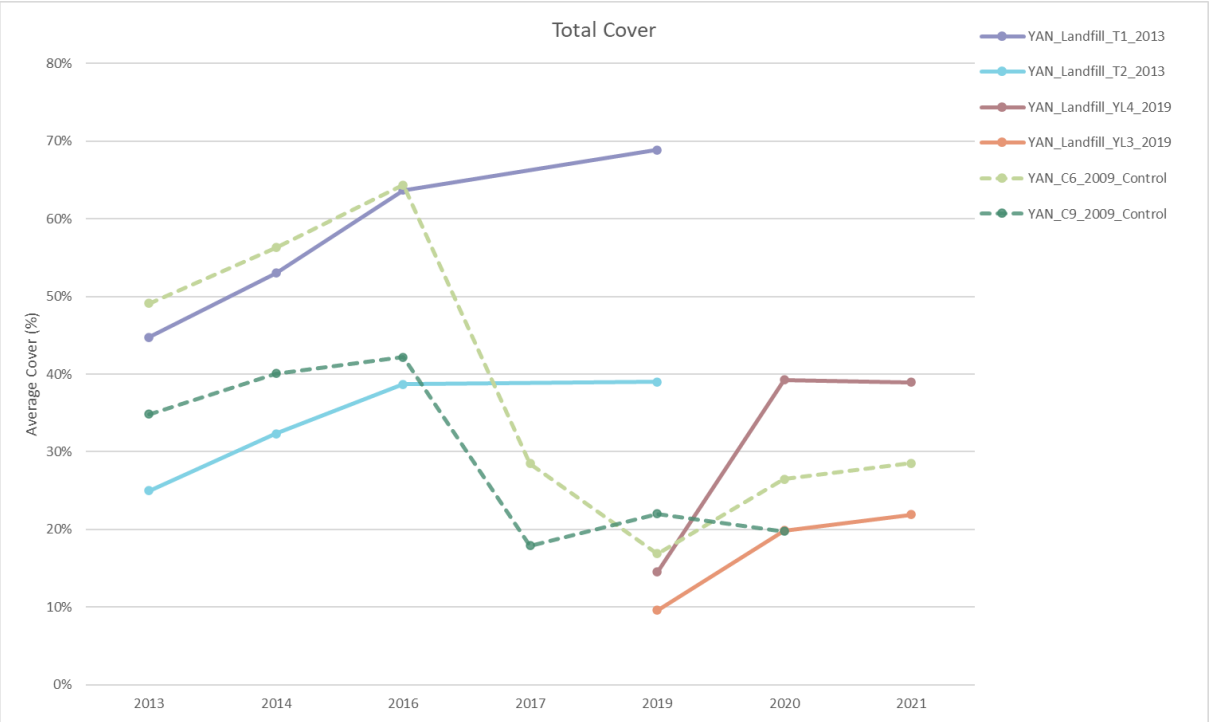

Figure 36: Native perennial species density (species/ quadrat) for Yandicoogina Landfill rehabilitation and reference sites over time.

5.4.5. High impact disturbance areas

As discussed in Section 2, there are a limited number of regional examples of rehabilitated high impact disturbance areas. Examples of completed rehabilitation of regional waste dumps have been discussed below, noting that learnings from these, as well as examples from the wider Pilbara region, will be used to guide rehabilitation techniques for high impact disturbance at the HD2 Proposal. Known rehabilitation methods for waste dumps included in this Summary are presented in Table 8 below.

Table 8 Rehabilitation overview for waste dump sites

REHABILITATION PARAMETER	SITE		
	YAN Central WD	YAN Rubber Dump	West Ang East and South WDs
Initial no. transects monitored	2	1	4
Current no. transects monitored	2	1	4
Area (ha)	3.31 ha	Unknown	7.5 hectares – 1.5 ha for East WD and 6 ha for South WD
Closure domain	Waste dump	Waste dump	Waste dump
Year of rehab	1999	2013	2012
Growth medium	Topsoil	None	Topsoil
Depth of growth medium application (mm)	Unknown	Unknown	200 mm

Time of storage of growth medium (yr)	Unknown	Unknown	Unknown
Seeding mix	Not applicable	Seven (7) native species of local provenance	Twenty-two native species (two annuals and twenty perennials) mixed with sandpit sand at 1:2 ratio.
Seeding rate (kg/ha)	0	7 kg/ha	Hand seeded at approximately 13 kg / ha.
Contour ripping (depth)	Unknown	Unknown	Maximum depth of 0.5 m

Yandicoogina Central Waste Dump and Rubber Dump

Rehabilitation works on the Central Waste Dump were completed in 1999 and two 100 m transects, CentralWD_T1 and CentralWD_T2, were installed and monitored for the first time in 2016. No methodology details are available due to rehabilitation occurring prior to 2010. As previously mentioned, recording of rehabilitation methodology has been improved since this time.

Rehabilitation activities on the Rubber Dump, which included ripping and seeding, were completed in 2013 and one 100 m transect, RubberDump_T1, was first monitored in 2014. An overview of the rehabilitation for Yandicoogina Central Waste Dump and Rubber Dump is presented in Table 8. These sites have been assessed in parallel for comparative value and to indicate general waste dump trends.

Photographic evidence shows a loss of cover and plant density at the Central WD rehabilitation between 2017 (Figure 39) and 2018 (Figure 40). Conversely, Rubber Dump photos (Figure 37and Figure 38) show some improvements in cover and density, with vegetation quadrat data for species density and total cover loosely confirming this but indicating poorer outcomes for plant density. Although lower values were observed at the Rubber Dump than the Central WD for all three vegetation parameters, the relatively stable trajectories and absence of significant declines indicate satisfactory outcomes regarding overall quality of vegetation and progression toward the target community.

Declining trends observed at the Central Waste Dump rehabilitation can be mostly attributed to low rainfall as the reference sites show corresponding declines. Plant density and species density trends were characteristic of early rehabilitation communities, with the increases reflecting high establishment rates, and the ensuing declines depicting the senescence of short-lived colonising species. Vegetation parameter trends at Yandicoogina's rehabilitated waste dump sites are further discussed below with comparative analyses to reference sites.

Figure 37: Rubber Dump T1 (lower slope) (end) 2014 (one year after rehabilitation).

Figure 38: Rubber Dump T1 (lower slope) (end) 2014 (five years after rehabilitation).

Figure 39: CentralWD_T1 (start) 2017 (eight years after rehabilitation).

Figure 40: CentralWD_T1 (start) 2017 (nine years after rehabilitation).

Native perennial species density and species richness

Declining species density trends are observed from 2017 / 2018 onwards at the rehabilitation and reference sites, corresponding with records of low rainfall (Figure 41). Statistically, CentralWD_T2

shows the highest similarity to the reference sites, however the overall trajectory observed for CentralWD_T1 is most reminiscent of the reference trajectories which illustrate post-fire vegetation dynamics. Species density in 2020 was significantly lower at CentralWD_T1 and RubberDump_T1 than reference site YAN_C9 but they were not significantly different by pairwise comparison to YAN_C6.

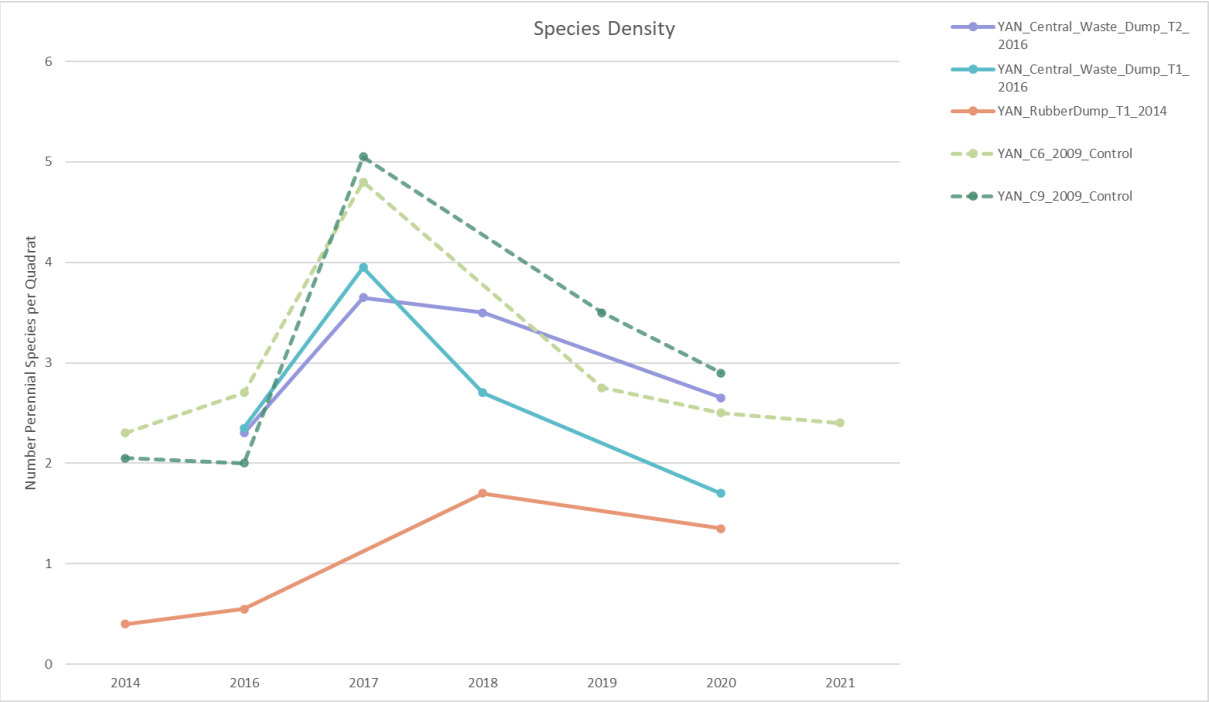

Figure 41: Native perennial species density (species/ quadrat) for Central Waste Dump and Rubber Dump rehabilitation and reference sites over time.

Species richness at the rehabilitated sites ranged from 12 to 15 in 2020, with only CentralWD_T1 showing a notable decrease from previous assessments. Six of the seven species seeded at the Rubber Dump rehabilitation were observed in 2020, indicating a relatively good degree of germination success from seeding. Additional species, *Eucalyptus gamophylla* and *Acacia pruinocarpa*, were recorded at the Rubber Dump in 2020 indicating upper strata development.

Native perennial plant density

Native perennial plant density at the rehabilitation sites decreased slightly between 2018 and 2020 assessments (Figure 42), with below average rainfall likely to be a contributing factor. Excluding CentralWD_T1, rehabilitation plant density values remained below those of the reference sites in 2020, with the lowest number of plants per quadrat (two) recorded at the Rubber Dump site and highest (15) at reference site YAN_C6. Both reference sites recorded plant densities in 2020 that were above their pre-fire values.

All rehabilitation sites shared similarity with YAN_C9, and any differences detected between sites were not significant by pairwise comparison.

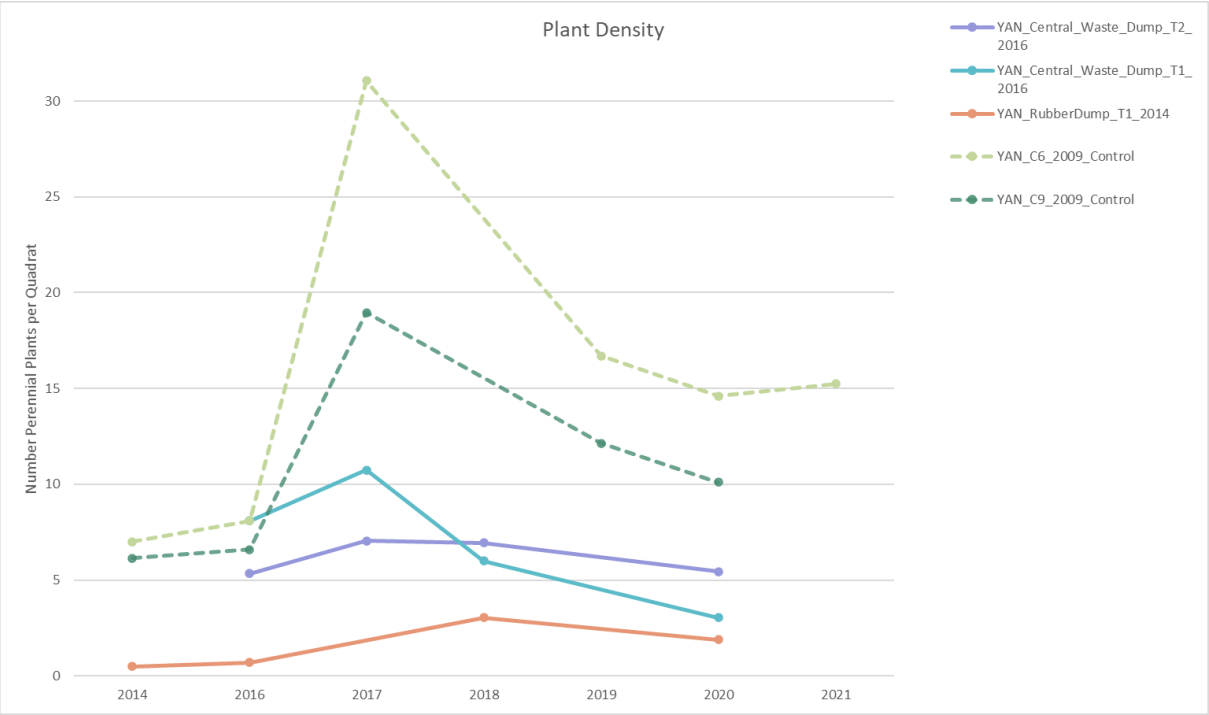

Figure 42: Native perennial plant density (plants/ quadrat) for the Central Waste Dump and Rubber Dump rehabilitation and reference sites over time (reference sites burnt post 2016 monitoring).

Native perennial plant cover

Native perennial plant cover decreased at the Central Waste Dump rehabilitation between 2018 and 2020, whilst remaining relatively constant at the Rubber Dump rehabilitation from 2016 onwards (Figure 43). Although declining trends from 2017 onwards occurred at the Central Waste Dump rehabilitation, the 49% cover recorded at CentralWD_T2 in 2020 is significantly higher than both reference sites. In contrast, 13% and 24% plant cover values were recorded in 2020 for CentralWD_T1 and RubberDump_T1 respectively, neither being significantly different to the reference site range.

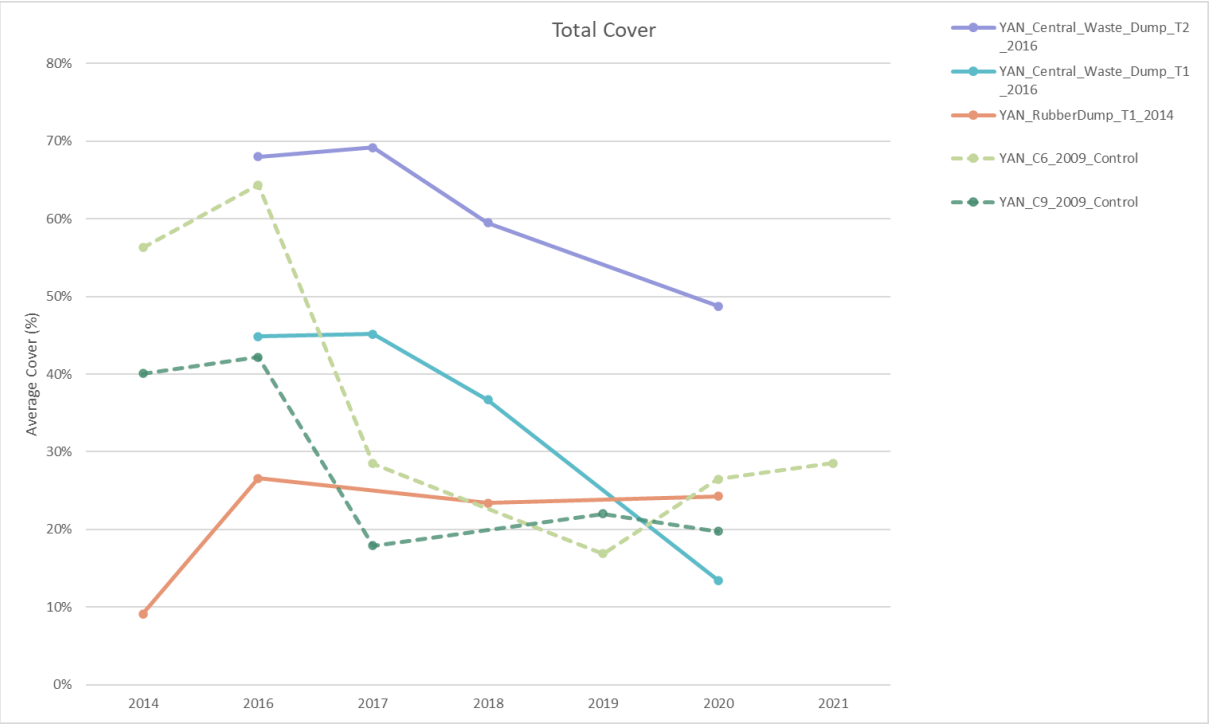

Figure 43: Native perennial total plant cover (%) for the Central Waste Dump and Rubber Dump rehabilitation and reference sites over time

West Angelas East and South waste dumps

Four transects were delineated at West Angelas' East and South Waste Dumps: EastWD_T1 on a flat area (categorised as "lower slope"), and EastWD_T2, SouthWD_T1 and SouthWD_T2 on mid-slopes. Rehabilitation works, which included reprofiling / dozing of waste dump slopes, seeding, contour ripping and topsoil application, were completed in 2012 with transects first monitored in 2013. Further information on the rehabilitation methodology for the East and South Waste Dumps is provided in Table 8.

Photographic evidence (Figure 44 to Figure 47) of the East and South Waste Dump rehabilitation indicates some successful outcomes, particularly regarding total plant cover. The highest quadrat values and trajectories most aligned with the relevant reference sites were observed at rehabilitation transect EastWD_T1 for all parameters.

The species density trajectories observed over the entire monitoring period are characteristic to the age of the rehabilitation, with early inclines reflecting successful establishment of colonising species, and the gradual declines occurring due to natural senescence of the short-lived colonisers. Corresponding steep declines in species density and plant density occurred between 2013 and 2014 at rehabilitation site SouthWD_T1, attributed to unusually high numbers of *Ptilotus nobilis* recorded in 2013.

Based on the 2019 monitoring quadrat values, the rehabilitation exhibited greatest success within total plant cover, an unusual outcome, as a high variation between rehabilitation and reference values is usually observed for this parameter. Upon further analysis, high variation was evident in the early monitoring years, and when the post-fire condition of the reference sites is accounted for, success in this parameter is mostly confined to EastWD_T1.

Figure 44: WA_EastWD_T1 (lower slope) (start) 2013 (one year after rehabilitation).

Figure 45: WA_EastWD_T1 (lower slope) (start) 2017 (five years after rehabilitation).

Figure 46: WA_SouthWD_T2 (end) 2013 (one year after rehabilitation

Figure 47: WA_SouthWD_T2 (end) 2013 (five years after rehabilitation

Native perennial species density and species richness

The East and South Waste Dump rehabilitation sites show mostly inclining trends in species density over the first three years of monitoring (2013 to 2015), with the only decline observed at SouthWD_T1

(Figure 48). There was no statistically significant variation between rehabilitation and reference species density values in 2015, indicating good establishment and early survival of native plant species. Establishment from seed was considered relatively effective, with thirteen of the twenty-two seeded species recorded in 2015 at one or more of the rehabilitated sites. Two transects, EastWD_T1 and SouthWD_T2 recorded higher numbers of species per quadrat than all five reference sites, with EastWD_T1 maintaining a trajectory above all references for the entire duration of monitoring.

Post 2015, the rehabilitation transects exhibit gradual declining trends in species density, with three of the four transects remaining within the relevant reference site range (C9 excluded for due to being heavily impacted by fire). However, rehabilitation transects EastWD_T2 and SouthWD_T1 fall outside the range if reference site C8 is also excluded. The observed species density trajectory at C8 suggests the site has not yet fully recovered (in this parameter) from the pre-2013 burn. Rather than informing vegetation parameter targets for rehabilitated sites, C8 data is more appropriate for establishing values that could be obtained in early rehabilitation.

From 2015 to 2019, the number of species per quadrat decreased at almost identical rates for EastWD_T1, SouthWD_T1 and SouthWD_T2, whilst EastWD_T2 remained relatively constant. Statistically, there were significant differences in species density between all eight sites in the last two monitoring years. However, the rehabilitated transects were comparable to at least one reference site. The greatest number of species per quadrat across all sites in 2019 was 4.4, observed at EastWD_T1 which also recorded the highest number of seeded species. Recording 0.9 species per quadrat, SouthWD_T1 had the lowest species density in 2019, decreasing by over half from 2017. Although species density at SouthWD_T1 was not significantly different to reference site C9, the low species density at the reference site was due to post-fire conditions, thus not reflective of the target vegetation community.

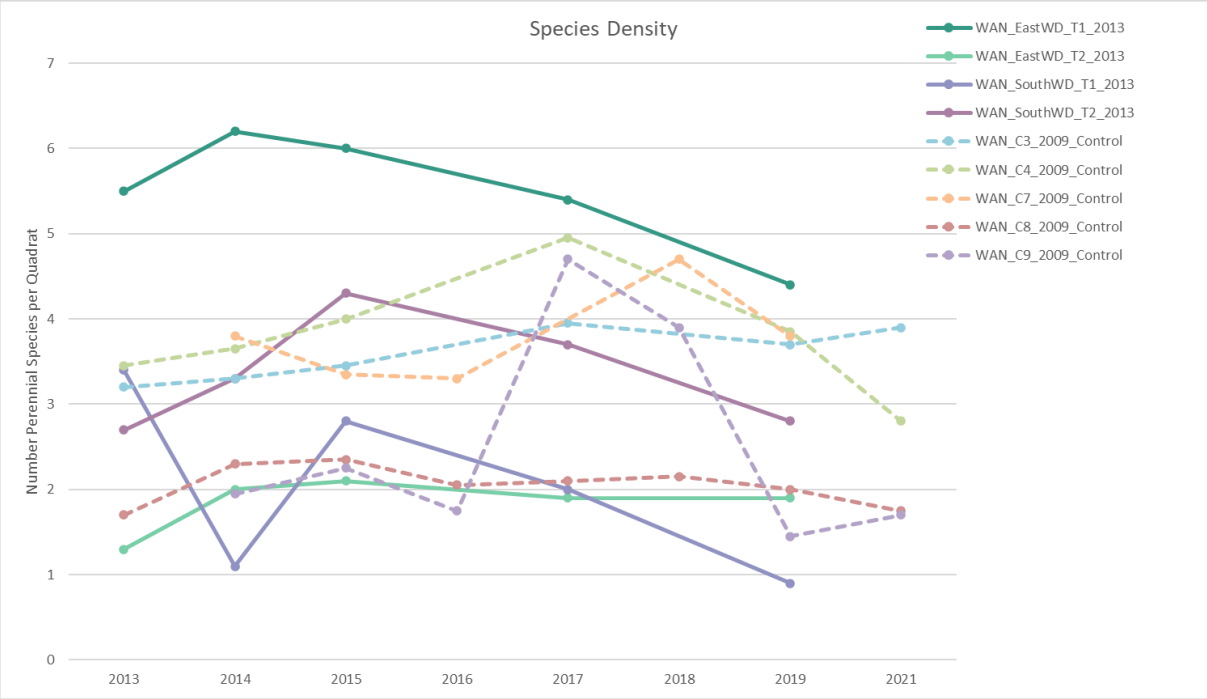

Figure 48: Native perennial total species density (species/quadrant) for the East and South Waste Dump transects and reference sites over time (EastWD_T1 represents a flat transect).

Native perennial plant density

Native perennial plant density at the rehabilitated transects remained relatively constant from 2013 to 2019, with the greatest fluctuations observed at SouthWD_T1 (Figure 49). The number of plants per quadrat recorded at SouthWD_T1 decreased substantially between the first two monitoring years, with

a gradual incline observed in the subsequent year. The high number of plants per quadrat recorded in 2013 at SouthWD_T1 was attributed to atypically high numbers of *Ptilotus nobilis*.

Significant variations between reference and rehabilitation plant density values exist for post-2016/17 data, mostly due to the considerably high post-fire values recorded at C3, C4 and C9. The greatest change in plant density in rehabilitated areas was observed at EastWD_T2, which increased from seven plants per quadrat in 2017 to 9.4 in 2019. Slightly higher plant densities were recorded at the East Waste Dump rehabilitation compared with the South Waste Dump rehabilitation, with SouthWD_T1 recording the lowest density of 1.2 plants per quadrat.

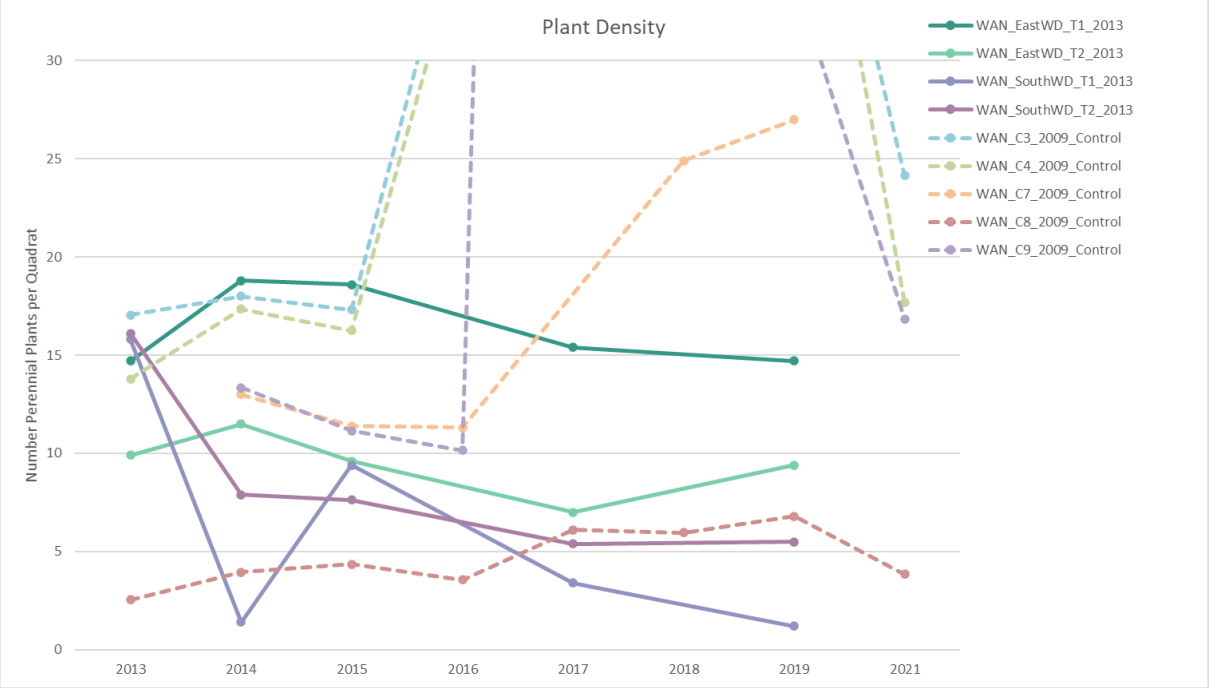

Figure 49: Native perennial plant density (plants/quadrant) for the East and South Waste Dump transects and reference sites over time[2]

Native perennial plant cover

Overall plant cover trajectories observed at the rehabilitation are roughly inverse to those observed at the post-fire reference transects – C3, C4 and C9 (Figure 50). Increasing trends were observed at all four rehabilitation transects between 2013 and 2014, with plant cover continuing to increase until 2015 at all transects except SouthWD_T2 which saw a steep decline in cover between 2014 and 2015. Rehabilitation cover begins to plateau post-2015 at both East Waste Dump transects, whilst cover at the South Waste Dump transects shows similar stabilising trends post-2017. This was least evident at SouthWD_T1 where a significant loss of cover occurred between 2015 and 2017, with the declining trend continuing but lessening in severity between 2017 and 2019. Despite this, cover at SouthWD_T1 at the time of the 2019 monitoring was notably higher than initial cover recorded in 2013. Although the 2019 monitoring report found some significant differences, plant cover at all rehabilitation transects was either within the reference site range (16% to 35% cover), or (at EastWD_T1) higher than the reference site range. The highest native perennial plant cover overall (57%) was recorded at rehabilitation transect EastWD_T1, where over 55% cover had been maintained since 2015, indicating an excellent rehabilitation outcome in this parameter.

[2] Full reference site data not presented on x-axis due to scale limitations. Full results available in Appendix 1.

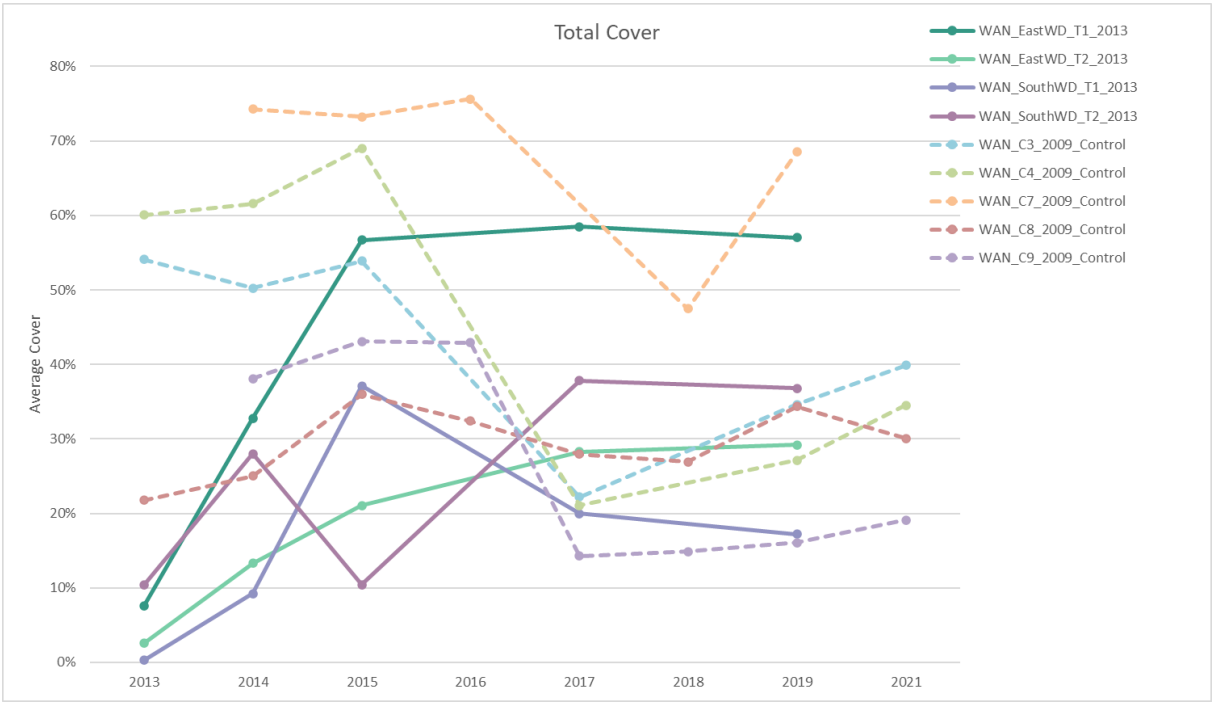

Figure 50: Native perennial total plant cover (%) for the East and South Waste Dump transects and reference sites over time.

5.4.6. Discussion

A comparative overview of the range of vegetation parameter values recorded during recent monitoring assessments for each closure domain is presented in Table 9. Higher species richness values were observed at the seeded sites, suggesting a potential correlation, especially if the low values recorded at HD1 Old Landfill are excluded on the basis that only half the area received seed. Similarly, higher numbers of flowering / fruiting species appear to be associated with the application of seed.

A wide range of total cover values were recorded for all closure domains, and no weeds were present at any site as of the last monitoring event. As expected, erosion gullies were only recorded at waste dump sites, which was the only closure domain where all transects had annuals present. Overall, the most satisfactory results in spinifex density and spinifex cover occurred at the borrow pit sites, although the highest value in spinifex cover was recorded at a waste dump site. Borrow pits scored the lowest in terms of annuals present and species richness, but exhibited good results in plant density, whilst seeded sites (waste dumps and landfill) performed poorly in this parameter.

Implications for rehabilitation methodology utilised within the HD2 Proposal area include the:

- Consideration of application of both topsoil and seed. Where available sites should be rehabilitated with both topsoil and seed applied.
- Additional erosion monitoring may be valuable to ensure successful outcomes at waste dump sites.
- Increasing the frequency of monitoring upon confirmation of a site being burnt may also be valuable, as compiling post-fire vegetation quadrat data will enable a more comprehensive understanding of post-fire recovery rates for Pilbara ecosystems. Considering the parallels observed between early rehabilitation and post-fire reference sites, this information could be utilised to predict the trajectory from rehabilitation to climax community, and thus the formulation of appropriate and achievable completion criteria.

Table 9 Rehabilitation monitoring overview for all sites

MONITORING	REHABILTATION SITE			
	HD4 Railway BPs and HD4 MAR, Camp and Mine BPS	**HD4 Dewatering Pipeline and HD4 Powerline**	**HD1 Old Landfill and YAN Landfill**	**YAN Central WD and Rubber Dump and WAN East and South WDs**

6. RESEARCH AND DEVELOPMENT

Rio Tinto undertakes research and development in order to increase its understanding of the local natural ecosystems, optimise its rehabilitation techniques and improve confidence in the ability to achieve closure outcomes. Research and development projects range from opportunistic on-ground trials to large-scale multi-partner funded research programmes. Trial monitoring data is reviewed regularly to identify opportunities to refine rehabilitation techniques, such as the germination rates of sown seed, for continual improvement.

Although some research and trial projects described below were not conducted specifically on the tenements covered by this report, the learnings can be applied to works conducted on these sites and indicate the scientific approach applied to strive for continual improvement. A selection of recent research and development projects are summarised below.

6.1. Eco-engineering solutions to improve mine site rehabilitation outcomes

Rio Tinto Iron Ore and BHP Western Australia Iron Ore are partners in a federally funded research program investigating the rapidly developing field of Restoration Engineering, with a particular focus on the mining-intensive Pilbara region of Western Australia. This 4-year Global Innovation Linkages (GIL) project is led by the Kings Park Science research team and has additional partners from The University of Western Australia (UWA), Greening Australia, University of California, Brigham Young University, the University of Nevada, and Natural Resource Conservation LLC (a private US-based consultancy). The Restoration Engineering approach partners ecological research, focused on best practice use of seeds from a recruitment biology point of view, with innovative ecologically guided engineering solutions focussed on the invention and modification of seeding equipment needed to deliver native seeds at scale.

This project has continued to test a range of custom-built precision seeding machines for use in sloped and rocky soils of the Pilbara. Firstly, a critical evaluation of the field limitations of current mechanised seeding techniques has been undertaken. Broadcasting seeds onto the soil surface is now known to be problematic and un-desirable. With this, new precision seed delivery machines have been designed, constructed, and field tested over the past three Pilbara summers in sites operated by both mining partners. Preliminary findings of this work have demonstrated that seeds are being incorporated in the upper soil layer more efficiently than previously achieved. Monitoring of these sites after significant rain events is suggesting seedling recruitment and rehabilitation performance of targeted genera such as Triodia is improving.

By experimentally comparing seed sowing depth (standard practice versus precision placement with the newly designed machinery) and manipulating the recruitment dynamics of seeds (standard ‘off-the-shelf’ seed treatments versus seeds treated to maximise recruitment potential – using treatment such as flash flaming or smoke-priming of seeds), the research group have shown that perennial grasses establishment of focal *Triodia* species can be increased to 35 seedlings per square metre (6-fold higher that standard, common seeding practices). These findings were observed after this trial site received suitable cyclonic rainfall (Figure 51). In the summer season of 2020/2021, replicated, multi-hectare trials have been installed across both mining partner sites (Rio Tinto Iron Ore and BHP) in over 30 hectares that are made up of different landforms and soil types. These repeat trials are critical to assess the performance of the precision seed delivery machinery and seed treatments across years and under varying conditions of rainfall.

Figure 51: Germination of grass seed following trial of precision seeding equipment.

6.2. Acceptable rates of erosion for rehabilitated mineral waste landforms

A major consideration for rehabilitation and closure of waste landforms on mine sites is long-term erosion stability. In Western Australia, regulators require that landforms will remain 'stable' for hundreds of years or in the 'long-term'. Therefore, assessment of a landform's potential long-term erosion stability requires the use of erosion and/or landform evolution models and defensible erosion thresholds below which rehabilitation landform designs are considered acceptably erosion resistant or 'stable'.

To date, definitions of acceptable long-term erosion rates used in mining settings have been based on limiting the initiation of key erosion processes for steeply sloping land (i.e., rill and gully erosion). These approaches have been observed to achieve suitable results but may be somewhat conservative. Importantly, the rates currently applied as acceptable in landform design were based on measurements of erosion during rehabilitation monitoring and on landform evolution modelling for a limited range of materials and climates. To address this, Rio Tinto, with three other member companies of the Pilbara Rehabilitation Group (PRG), BHP, Fortescue Metals Group and Roy Hill, initiated a project aimed at defining acceptable rates of erosion for rehabilitation landform design for the Pilbara region of Western Australia. Landloch Pty Ltd was selected to undertake the work for this project using information derived from PRG member sites, with the Western Australian Biodiversity Science Institute (WABSI) acting as the project facilitator.

As part of the project, a review of information relating to erosion rates on natural and man-made landforms was conducted. This review showed that a wide range of approaches has been used to define acceptable erosion rates, including a linking to rates of soil formation; maintenance of soil quality (which may include considerations of plant/crop productivity, effective soil depth and soil organic matter and nutrient stores); rates of natural erosion in adjoining areas; potential for gully formation; and water quality impacts. Based on this review, a guideline was developed to define acceptable erosion rates for use in the design of stable mine waste landforms in the Pilbara region. The guideline uses a risk-based approach, with erosion thresholds being linked to the physical properties of the waste material and the adverse environmental impacts that may result from landform failure. The first phase of this project was completed in 2018 and stakeholder engagement occurred to communicate key project findings. Further work is underway to define how to incorporate this guideline into Rio Tinto's landform design processes and to understand implications for the business.

6.3. Additional waste samples for batter selector

Rio Tinto is looking to build a more robust test work programme to determine erodibility data for waste types across Rio Tinto mine sites in the Pilbara. The key driver for the work is to ensure that key waste types across the various mine sites and lithologies are well understood and that detail is provided on the thresholds used to derive the Rio Tinto erodibility classifications of low, moderate, and high.

Rio Tinto utilise a Batter Selector Tool (BST), that is based on laboratory testing of individual waste types to optimise the final landform design by determining appropriate lift heights, slope angles, berm widths and berm back slope angles on an individual landform basis. The BST is based on the ongoing testing of waste material samples over a number of years; however, sampling has historically been biased towards some sites and some waste types more than others. This project seeks to address identified gaps and build greater certainty into the application of the BST.

Landloch undertook a gap analysis of the BST in 2018 and provided input on key wastes to consider in future revisions of the tool. Rio Tinto have developed a list of sampling priorities based on the gap analysis. The list provides detail on the site, geology, consolidated rock type and priority rating based on existing waste characterisation data completed by Landloch and presented within the BST. Test work will continue, facilitating advancements within waste type classification methodology, and the BST and landform design will continue evolve.

6.4. Channar scree slope trial

In 2014, as part of a preliminary closure study for the Channar mine, it was proposed to use rock armouring for a number of constructed legacy landforms, including land bridges and waste dumps, where access for standard rehabilitation earthworks purposes is constrained and/or too steep to safely bench and push down the slopes. Specific design criteria were developed based on modelling to meet acceptable erosion rate and long-term stability, including maximum batter heights, gradient, and rock size. The Department of Mines and Petroleum (now DMIRS) were consulted regarding this approach in May 2015 and indicated the requirement of further information and certainty before such an approach could be endorsed. In August 2019, DMIRS were advised that planning for a trial of the concept was underway. This project aimed to implement a scree slope (rock armouring) trial at the Channar mine on the CHE WD1 NE waste dump.

From October to late December 2020, contractors constructed a ~1m thick, rock armour on the CHE WD1 NE. This was achieved by screening various stockpiled or blasted material in Channar NE, to test for rocky material yield. This rocky material was then hauled to the tip head, where it was tipped short and pushed over. This process usually took 2 or 3 days for material to be built up enough to push over the tip head (Figure 52 and Figure 53). The trial demonstrated that sufficient rocky material to build the rock armour, is achievable through screening stockpiled/dumped (or blasted) material. However, productivity of the screening plant can be variable. Achieved Yield was lower in stockpiles. The trial indicated that, based on yield, the most suitable rock armour material would be a mix of banded iron

formation (BIF) and hard cap. The trial was able to demonstrate that the scree slope design could be achieved from a constructability perspective achieving a consistent 1m rock armour cap along the slope, with minor variation attributed to the pre-trial landform profile.

The scree slope trial will be monitored using high resolution UAV survey for a minimum of 5 years, to monitor the long-term stability of the scree slope rehabilitation strategy.

Figure 52: Pre-project slope.

Figure 53: Post-project slope.

6.5. Growth media trials

Throughout the Pilbara, there is an ongoing opportunity to utilise mineral waste as soil substitutes or supplements for rehabilitation activities. It is anticipated that alternative growth media (AGM) will provide a suitable growth medium in rehabilitation areas where topsoil and subsoil are unavailable or limited. Research is underway to determine if utilising various types of AGM in various situation will provide acceptable rehabilitation outcomes.

When a waste type is identified as potentially suitable as an AGM, testing for standard parameters occurs, and then stockpiling will occur with relevant location information recorded on mine site survey records. Alternative growth media material has been previously identified and tested at Marandoo, Tom Price, Western Turner Syncline and Channar. Stockpiling of suitable material has commenced, with

additional investigations to incorporate materials into the mine plans for future recovery also underway. During 2017 the MMW4 rehabilitation project at Tom Price utilised S652 Gravels with monitoring of the rehabilitation showing positive trends and vegetation establishment. Monitoring progress of this area continued into 2020, and the materials are proposed for use at a future rehabilitation project at the MMS waste dump, tentatively planned for 2022 completion.

During 2019 a rehabilitation project, at the Brockman DP4 waste dump, had different ages of topsoil, subsoil and no soil incorporated into the design (Figure 54). The aim of the trial was to evaluate the performance of the soil materials, and to consider modifying the seed mix to better reflect the growth media. The rehabilitation of this area was completed in early 2020 and monitoring of its performance will be undertaken to provide a comparison of revegetation performance using fresh topsoil, stockpiled topsoil or subsoil.

Figure 54: Soil and alternative growth media trial design at the Brockman 4 DP1 and DP4 projects.

6.6. Mycorrhizal fungi trials at Middle Robe legacy rehabilitation sites

In 2020, a rehabilitation project targeting legacy areas was undertaken, which provided an opportunity to investigate the use of mycorrhizal fungi on rehabilitation performance. Most native Australian flora have a relationship with mycorrhizal fungi, which are often eradicated during heavy disturbance events. There is evidence that inoculating soil with a variety of mycorrhizae fungi will improve plant survivability and germination (Koziol et al., 2018). There is also evidence that mycorrhizae fungi may assist some native species to establish that otherwise wouldn't through traditional rehabilitation methods (Jeffries et al., 2003).

In the Middle Robe project, seed was coated in powder form mycorrhizae fungi for several trial areas (Figure 55). The expectation is that when moisture is encountered, the mycorrhizae will propagate and expand into the surrounding soil, inhabiting the new plants roots and assisting with plant nutrient uptake. The trial areas were incorporated into the 2021 monitoring program and will therefore enable control and trial data to be collection and analysed through time.

Figure 55: Mycorrhizal fungi trial areas.

7. PLANNED STRATEGIC PROJECTS

The Rehabilitation and Closure team facilitates a quarterly regulator forum. It is intended that this forum is utilised for ongoing updates on the:

- Annual progressive rehabilitation program.
- Research and development.
- Strategic improvement projects.

7.1. Rehabilitation performance and completion criteria development

A Rehabilitation performance and improvement framework incorporating a plan, do, check and act (PDCA) cycle to centralise and improve the management and communication of rehabilitation performance status, learnings, remediation requirements, risks, knowledge gaps and associated actions is a planned initiative for 2022.

In association with this initiative, a strategic project to review both the current monitoring programme methodology and available rehabilitation monitoring data to develop a standardised method to develop suitable SMART completion criteria for all operations is also scheduled for development in 2022. The development of quantitative completion criteria will then follow with a prioritisation for those assets approaching closure.

This has already occurred at Eastern Range and Channar and the completion criteria have been submitted with the MCP to regulators. Pending regulator feedback will be utilised for the alignment of the development process.

An associated outcome of this strategic work will be a defined procedure for the determination of when and where remedial works are required for rehabilitated sites where performance is not tracking towards acceptable performance criteria.

7.2. Seed strategic plan

If seed is not of a sufficient quantity, type and/or quality, the rehabilitation performance of implemented works will not meet agreed completion criteria to the satisfaction of stakeholders. Therefore, a strategic project will be undertaken to ensure suitable seed species and volumes are available to meet increasing rehabilitation outputs through to 2027 and beyond. The integration of Traditional Owner businesses into the seed supply chain will also be investigated.

APPENDIX B: SUPPLEMENTARY REFERENCE SITE DATA

Species density, plant density and total cover over time at HD4 / HD1 reference sites

Discussion

Flat_C12 trajectories do not seem to align with the period of supposed burning (between 2016 and 2018 monitoring assessments). High densities are usually recorded in the year following fire, yet Flat_C12's highest plant and density values were recorded in 2015. Additionally, no loss of cover was recorded during the entire monitoring period, with the steepest rate of increase recorded between the 2016 and 2018 monitoring events (when transect was documented as burnt). A 2017 monitoring assessment may have provided further insights into the atypical trends observed post-fire in Flat_C12, for example, the occurrence of an immediate and short-term post-fire decrease in cover that was not evident in 2018 due to quick regrowth at the transect.

The trends observed in Flat_C6 better align with expected post-fire trajectories, evident by initial increases in density values succeeded by relatively inversely proportional declines, and a sharp decline preceding stabilisation of total cover 1-2 years post-burn. Notably, if only 2014 and 2016 Flat_C6 data is considered (likening it to Flat_C12's monitoring schedule) the resulting trajectories circumvent the originally observed density increases and successive decreases which are characteristic of post-fire vegetation communities.

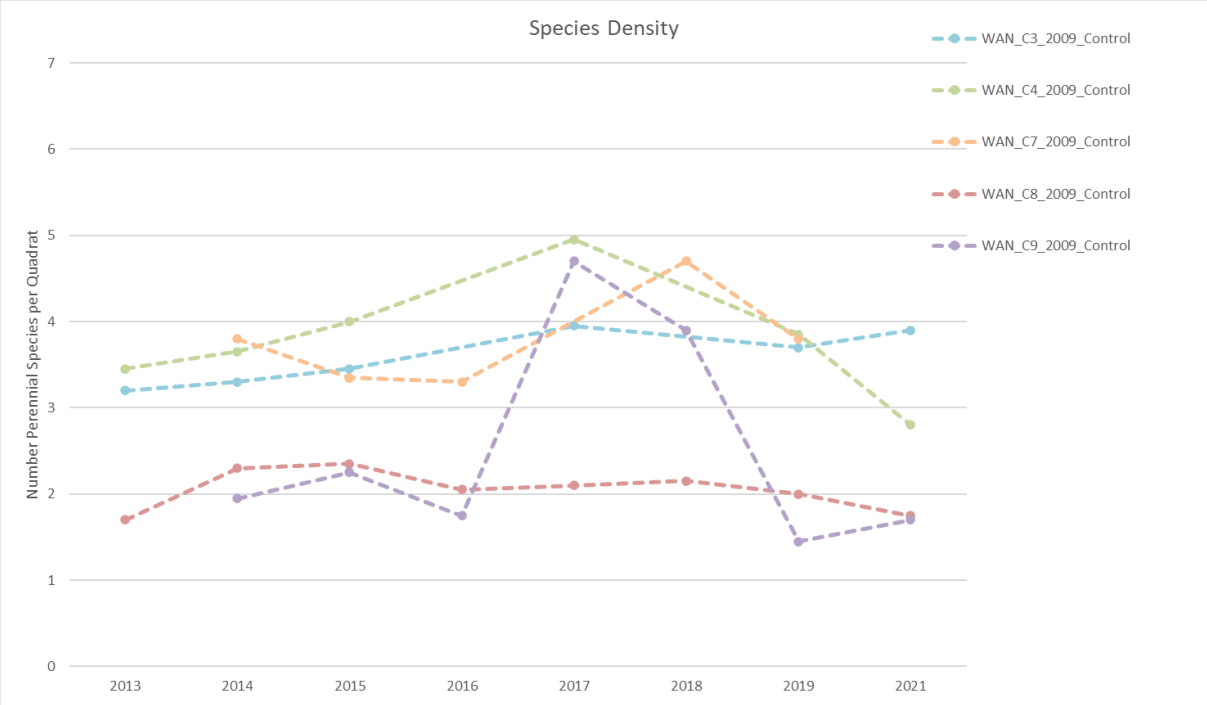
The high cover but low plant and species density values recorded over the duration of monitoring in Flat_C2 suggests a dominance of one or a few species, which is not a good target for rehabilitation due to less diversity and subsequently, less resilience. Although, consistently low values were recorded at the transect, the stable trajectory provides, to some extent, a base reference of minimal values for rehabilitation.

The linear trajectories observed for Flat_C5 are a result of only two monitoring events taking place at the transect and do not reflect how density and cover parameters behave over time (evident through comparison with consistently monitored transects).

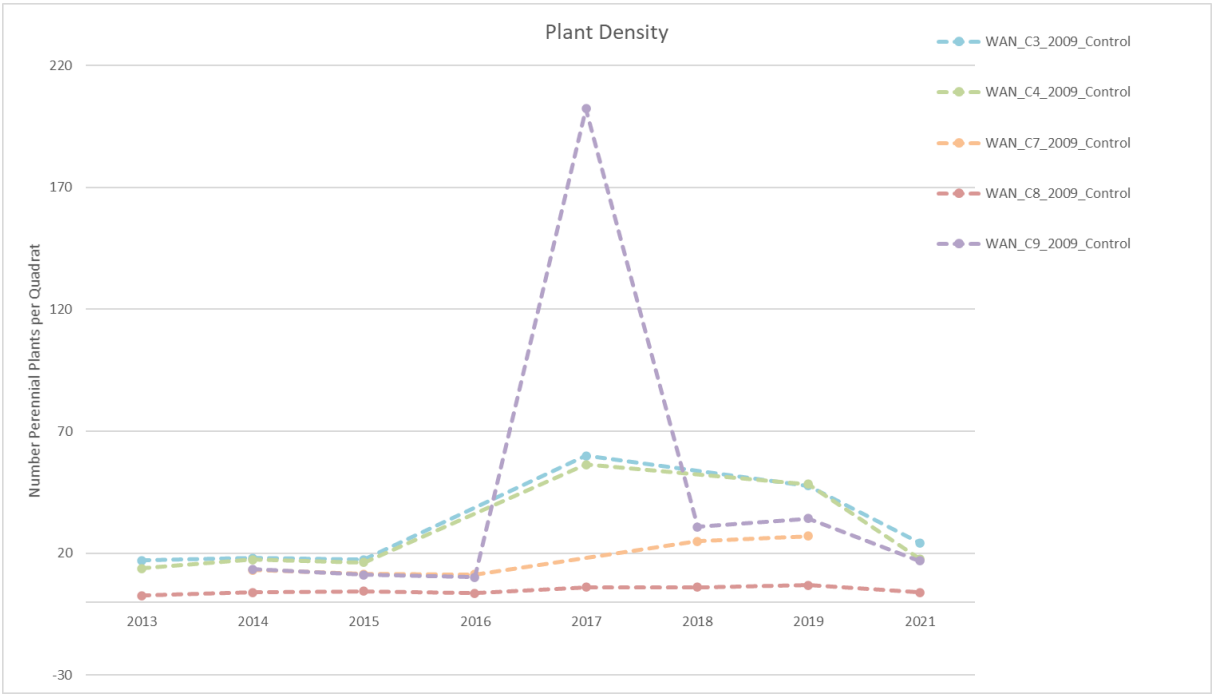
Selected HD1 and HD4 reference sites for this Summary

The most recent rehabilitation monitoring reports for Hope Downs 1 Old Landfill, Hope Downs 4 Railway and Powerline, Mine Access Road, Camp and Mine borrow pits, and the WFSF borrow pits use topographically flat reference sites Flat_C2 and Flat_C5 for comparative analyses. Flat_C5 was first monitored in 2013 and again in 2020 with significant differences observed for each vegetation parameter, resulting in linear trends that do not accurately reflect how vegetation parameters fluctuate or develop over time (see above for graphs which demonstrate this). Meaningful comparisons to the

rehabilitated sites cannot be made without intermediate data for Flat_C5. For this reason and the fact that it is categorised as 'inactive' within Rio's monitoring schedule, it has been excluded from comparative analyses. The initial Flat_C2 site (HD4_Flat_C2_2013_Control) was destroyed after the 2014 assessment, with a replacement site (HD4_Flat_C2_2015_Control) established in 2015 but not used until 2018. For the purposes of this Summary the abbreviated site name 'Flat_C2' refers only to the 2015 site.



Rehabilitation at the Dewatering Pipeline was compared to two reference sites on flat terrain, Flat_C11 and Flat_12, which were also used in 2015 and 2016 for the HD4 Railway and Powerline, and HD4 Mine Access Road Mine and Camp borrow pits (see table below for an overview of reference site selection at HD4 and HD1 for each monitoring year).



Given the poor suitability of Flat_C2 as a reference site, Flat_C11 and 12 have been included for comparative analyses of HD4 moderate impact disturbance sites. For rehabilitation preceding 2016 Flat_C6 is also used, as some comparative value is retained despite the site being burnt between the 2014 and 2015 assessments. Variations in vegetation parameters resulting from the impacts of fire were taken into consideration for all burnt reference sites. Further justification for inclusion of burnt reference sites is provided in the West Angelas reference sites discussion.

Species density, plant density and total cover over time at West Angelas reference sites

Discussion

The 2017 and 2019 monitoring reports compare rehabilitation on the East and South Waste Dumps to four reference sites: C3, C4, C8 and C9, with an additional reference site C7 used for the 2015 and 2014 assessments. Reference sites C3 and C4 were entirely burnt between the 2015 and 2017 monitoring surveys, while C9 was largely burnt (90% of quadrats) between the 2016 and 2017 monitoring surveys. Fire also impacted reference site C7 (between 2017 and 2018) and C8 had not been burnt since monitoring began in 2013 but was affected by fire in 2011/12. Photos depicting the effects of fire on the vegetation at each site are provided in Appendix C.

Monitoring reports refer to C8 as the “unburnt reference site”, using the observed trends (when significant variations between other reference sites exist) to confirm rehabilitation quadrat data is within the reference range. The use of C8 as an ‘unburnt reference’ lacks viability due to early reports recording

considerably low plant density and total cover, consistent with the site being burnt in 2011/12. Sites with low counts for native species and low total cover (relative to other reference sites) do not provide appropriate data for quantitative targets and may distort the accompanying analyses. This was recognized within the 2013 and 2014 monitoring reports, where the low plant density and low total cover recorded at C8 skewed the results of the significance of variance analysis. The site still holds comparative value, but not as an unburnt reference, and any parallel trends observed at the rehabilitation transects should be assessed in consideration of potential long-term post-fire alterations of vegetation parameters.

Yandicoogina reference sites overview

Yandicoogina Landfill rehabilitation was compared to two reference sites, YAN_C6 and YAN_C9, classified as mid slope and flat lower slope, respectively. YAN_C6 comprises hummock grassland of *Triodia basedowii* and *Triodia wiseana*, with *Eucalyptus gamophylla* and *Acacia* spp., present on mid slopes. The flat terrain of YAN_C9 also exhibits hummock grassland but comprises *Triodia pungens* with *Eucalyptus gamophylla*, *Eucalyptus xerothermica*, and *Acacia* spp.

Both sites were impacted by fire prior to the 2017 assessment and the subsequent alterations in vegetation structure and composition were taken into consideration for this Summary. Appendix C provides a visual example of post-fire secondary succession states at the Yandicoogina reference sites.

DRAFT

1 THE PROPOSAL AND CONDITION REQUIREMENTS

1.1 The Proposal

This Hope Downs 2 Impact Reconciliation Procedure (IRP) has been prepared in accordance with the Western Australian Department of Water and Environmental Regulation's (DWER) requirements relating to offset reconciliation for the Hope Downs 2 Proposal (the Proposal). The Proposal is currently subject to assessment under Part IV of the *Environmental Protection Act 1986* (EP Act) Assessment Number 2316, and the *Environment Protection and Biodiversity Conservation Act 1999* (EPBC Act) Assessment 2021/9035, as an accredited assessment.

This IRP addresses both State and Commonwealth offset requirements. Rio Tinto on behalf of Hamersley HMS Pty Ltd (the Proponent) intends to seek the Department of Climate Change, Energy, the Environment and Water's (DCCEEW) approval to utilise the WA Pilbara Environmental Offset Fund (PEOF), as the nominated 'Conservation Offset Fund', to meet EPBC Act Decision Notice offset requirements.

1.2 Ministerial Statement and Commonwealth approval condition requirements

Conditions from Ministerial Statement XXXX (State) and Decision Notice 2021/9035 (Commonwealth) relevant to offsets for the Proposal are included in Table A 1 and Table A 2 respectively of Appendix 1.

2 PROCEDURE

The methodology for determining the baseline and offset contributions to deliver an outcome that aligns with DWER's IRPs and Impact Reconciliation Reports (IRRs) is detailed below. Content of both IRPs and IRRs is outlined in Section 3.2.

2.1 Identification of environmental values requiring offsets

Ministerial Statement XXXX and Decision Notice 2021/9035 include conditions that require the Proponent to offset the residual significant impact of the Proposal including clearing of 'good to excellent' condition native vegetation and high local significance vegetation, moderate significance critical supporting (foraging and dispersal) habitat and high significance critical (roosting and breeding) habitat in the Hamersley Interim Biogeographic Regionalisation for Australia (IBRA) subregion.

Ministerial Statement XXXX and Decision Notice 2021/9035 specify the biodiversity values listed in Table 1 below and associated offset rates.

Table 1: Environmental Values Requiring Offsets for the Proposal

Biodiversity Value		Offset rate ($/ha)[1] (excl. GST)
State (WA) Ministerial Statement XXXX (Placeholder values subject to offset conditions		
[Cond #]	[condition]	$TBC
EPBC Decision Notice 2021/9035 (Placeholder values subject to offset conditions		
TBC	[TBC]	$TBC

2.1.1 Vegetation Condition

To support approval processes for the Proposal, baseline flora and vegetation surveys were conducted, identifying native vegetation types and condition in the proposed Development Envelope. Details of the surveys, including the time they were undertaken, are provided in Appendix 8. The 'CondDate' attribute in the

[1] Base rate provided in Ministerial Statement XXXX and Decision Notice 2021/9035, to be adjusted annually in accordance with the average percentage change in the Perth Consumer Price Index (CPI) applicable for the calendar year that disturbance occurred.

 © 2023 Rio Tinto

data standard reflects the date that the vegetation survey occurred. Where vegetation surveys occurred over a period of time, the most recent date has been used.

At the time of the surveys botanists recorded the condition of the vegetation based on Trudgen's (1991) Vegetation Condition Index[2]. This data was then digitised and logged in the Rio Tinto (the Company) central GIS system. Note that all clearing conducted (at the time of the IRP submission) prior to the Proposal's approval has been assigned a vegetation condition of 'Cleared' in the offset exempt footprints, completely degraded in vegetation condition data and has been removed from environmentally significant values area data. A reconciliation of offset exempt clearing conducted between submission of the IRP and commencement of the Proposal will be documented in the first IRR, as per Section 4.

Where fire has occurred, the vegetation condition was extrapolated from surrounding unburnt vegetation assuming that the area will regenerate over time.

2.1.2 Footprint Attribution

Aerial ortho or satellite imagery encompassing the proposed Development Envelope is taken as close to the Proposal's approval time as practicable and aligning with the Proponent's existing flyover schedules. Where required, ground survey and truthing practices may also be used to supplement the imagery.

Cleared areas are identified and digitised according to an internal data standard using the Company's GIS package. The 'CondDate' attribute in the data standard reflects the end of the reporting period as the vegetation was cleared, up to the date of commencement of action under the current Ministerial Statement (MS) or, if a prior MS was superseded during the report period, the date the prior MS was superseded.

Whilst IRRs are required to be submitted biennially (refer to Table 4 for timing), footprints for each environmental value and EPBC protected matters will be created annually.

2.2 Method to determine impacts

2.2.1 Footprint attribution

Aerial ortho or satellite imagery encompassing the proposed Development Envelope is taken as close to the end of the reporting period as practicable and aligning with the Company's existing flyover schedules. Where available, ground survey and truthing practices may also be used to supplement the imagery.

Although IRR's are submitted biennially (refer to Table 4 for timing), footprints for each environmental value and EPBC protected matters will be created annually.

The previous annual footprint, or baseline footprint if first reporting year, is overlaid on the report period image to identify new clearing and rehabilitation activities and/or changes in ground condition and land use. These areas are then digitised and attributed in a similar process to that outlined in Section 2.1.2 above, in the Company's GIS package, to the Company's relevant data standards.

2.2.2 Offset contribution determination

Once the cleared footprint has been updated and finalised, data from the Company's internal data standard is consolidated and translated into the required DWER data standards.

For MS: Footprints attributed to the current MS are overlaid against baseline layers for vegetation condition, type and areas of significant environment value that have been identified as requiring offset. The offset contribution is determined where the footprint and offset applicable areas intersect.

For EPBC Act Decision Notice: Footprints attributed to the EPBC Act approval, after impacts commenced, will incur offset requirements (footprints prior to impacts commencing under the EPBC Act approval will be attributed to a MS or other clearing mechanism).

For areas that are offset applicable under both the State and Commonwealth approvals, the offset will be paid once only, at the highest applicable rate (i.e., no overlap between MS and EPBC Act approval offset payable layers) (Refer to Table 2 and Table 3).

Data and supporting spatial files will be submitted biennially in the IRRs, refer to Section 3.2.2 and Table 4 for details of IRR content and reporting period and frequency of the IRRs.

[2] Trudgen, M.E. (1991) *Vegetation Condition Scale. In: National Trust (WA) 1993 Urban Bushland Policy*. National Trust of Australia (WA). Wildflower Society of Western Australia (Inc.) and the Tree Society (Inc.), Perth, Western Australia.

 © 2023 Rio Tinto

Where a previous and current MS (for the same Proposal) both have offset conditions over a common overlapping area, offset applicable clearing under both MS's will be subject to the requirements and rates of the newest MS, unless otherwise specified[3].

The increase in the amount to be paid per hectare cleared in respect of the year in which clearing occurred will be calculated by application of the Perth Consumer Price Index (CPI) and paid as specified in the approval conditions.

Following the determination of offset liability, the Company will source the appropriate funds annually, aligning with internal accounting processes. Following submission and approval of IRRs (biennial), DWER will issue an invoice, which the Company will pay by transferring the required funds into the prescribed fund. The Company will submit evidence of each payment made to the prescribed fund to DCCEEW within 10 business days of the date of making the payment.

To meet the requirements of the EPBC Act Offsets Policy, an initial contribution of 10% of the total calculated offset contribution for matters of national environmental significance (MNES) values is required to be paid into the PEOF prior to the commencement of the Action (see Table 3 for estimated contribution calculations). Since the initial payment is made prior to impacts commencing, this amount will be subtracted from the subsequent offsets payable prior to CPI adjustments being applied until the full 10% has been accounted for, with CPI then applied only to any remaining amount owing for that period.

DRAFT

[3] Noting, the Proposal is not subject to a previously approved Ministerial Statement so this requirement is not applicable in this instance however, due to overlap other Ministerial Statements (MSs), relevant offset rates will apply in line with the scope approved under each Proposal's MS.

Initial estimated contribution into the PEOF (Commonwealth requirement, 10% of the overall EPBC Act offset contribution)						**$474,281**

[5] Estimated offset rates calculated on the 2021/22 financial year (excluding GST). Real value of contributions will be maintained through indexation to the Perth Consumer Price Index (CPI), with the first adjustment to be applied to the first contribution

[6] No known records of Pilbara Olive Python have been identified within the Development Envelope. The Proponent has applied a conservative approach in limiting clearing of potential Critical habitat (i.e. Gorge/Gully and Breakaway habitat)

3 REPORTING

3.1 Frequency and timing

The reporting schedule for IRP and IRR submission for the first three periods is outlined below in Table 4. It will be extrapolated and implemented until the end of the period of effect of the approval or as otherwise agreed to by DWER and the Australian Government Minister for the Environment.

Table 4: Proposed reporting period and frequency of the Impact Reconciliation Reports

Biennial period	Action	Timing
	Ministerial Statement issued	DD Month Year
	Decision Notice issued	DD Month Year
	Proposal implementation commenced	[Year 1]
	Initial EPBC Act payment	Prior to or upon commencement of the Action
	Submit evidence of initial payment to the DCCEEW	Within 10 business days of receipt of payment
Period 1	First biennial reporting period	From the commencement of the action to 31 December [Year 2]
	Aerial survey/ground-truthing	As close to 31 December as practicable
	IRR submission	30 April [Year 3]
	Submit evidence of payment into PEOF account to the DCCEEW	Within 10 business days of receipt of payment
Period 2	Second biennial reporting period	1 January [Year 3] – 31 December [Year 4]
	IRR submission	30 April [Year 5]
	Submit evidence of payment into PEOF account to the DCCEEW	Within 10 business days of receipt of payment
Period 3	Third biennial reporting period	1 January [Year 5] – 31 December [Year 6]
	IRR submission	30 April [Year 7]
	Submit evidence of payment into PEOF account to the DCCEEW	Within 10 business days of receipt of payment
Final Period	Final reporting period	1 January [Year X] – 31 December [Year X]
	Final IRR submission	30 April of Year after final reporting period
	Submit evidence of payment into PEOF account to the DCCEEW	Within 10 business days of receipt of payment

3.2 Content

Commercially sensitive information within spatial data and aerial imagery in both Baseline and IRRs will be considered when completing required metadata and licensing statements (provided separately).

3.2.1 Baseline

The Baseline package will contain three components:

 © 2023 Rio Tinto

1. IRP – this document.
2. Aerial imagery clipped to the proposed Development Envelope boundary and taken as close to the commencement of the approval as practicable, with an index providing date of capture for each image compiling the full composite.
3. Spatial data to support the above procedure. At a minimum, spatial data will meet the following:

    - be topographically accurate and georeferenced;
    - use GDA2020 (datum) co-ordinate system and projected into the appropriate Map Grid of Australia zone (i.e., 50);
    - include closed polygons and clipped to the relevant approval boundaries (any topology errors rectified);
    - be supplied in ESRI geodatabase format or shapefile;
    - be aligned with and attributed according to DWER's GIS Data Standards;
    - polygons of similar 'purpose' shall not overlap (i.e., clearing polygons shall not overlap, vegetation type and condition polygons shall not overlap, and exemption polygons shall not overlap);
    - all clearing data will be supplied to two decimal places in attributable tables.

    Spatial data and layers shall include:

    - Spatial boundaries including:
        - Development Envelopes *(Current and overlapping Proponent MSs only, previous MSs not to be included)*;
        - Areas of Significance *(Environment Matters specified in MS and EPBC Act Decision Notice, prescribed in offset conditions) with areas already cleared at the time of IRP submission removed;*
    - Vegetation condition and type (1 consolidated polygon per condition and type), by IBRA region;
    - Offset exempt areas. Exemptions may include clearing associated with:
        - previous MS (1 consolidated polygon per MS) *(where areas are not subject to offsets);*[7]
        - overlapping MS where the proponent is a Rio Tinto Company (1 consolidated polygon per MS), by IBRA region;
        - MS-prescribed NVCPs (1 consolidated polygon) *(where MS prescribes NVCPs which contribute to the total Proposal clearing allocation),* by IBRA region;
        - other NVCP (1 consolidated polygon), all clearing attributed to NVCPs within the Proposal's Development Envelope, not prescribed by the MS, by IBRA region;
        - other clearing mechanism (1 consolidated polygon, by IBRA region) – may include:
            - Clearing authorised under an alternative approval mechanism (e.g., *Bush Fires Act 1954*, *Land Administration Act 1997*, Prescribed clearing under Regulation 5 of the *Environmental Protection (Clearing of Native Vegetation) Regulations 2004*). Note NVCP has been separated;
            - Clearing conduction prior to clearing legislation commencement;
            - Clearing not completed by the Proponent (where possible, information will be added within the notes section of the attribution table detailing the suspected cause of the impact).
        - Note: Exemptions related to clearing mechanisms applied at the Western Australian level do not apply to the EPBC Act approval, except for clearing not conducted by the Proponent.
    - Maps to support the above-mentioned spatial data.

[7] Noting, the Proposal is not subject to a previously approved Ministerial Statement, so this requirement is not applicable in this instance. However, due to overlap other Ministerial Statements (MSs), relevant offset rates will apply in line with the scope approved under each Proposal's MS.

 © 2023 Rio Tinto

3.2.2 Impact Reconciliation Reports

IRR's will contain three components:

1. A biennial report specifying the annual area cleared (in hectares), and base and CPI adjusted rates for each offset applicable requirement outlined in the MS and EPBC Act approval as well as estimates of projected clearing for subsequent biennial periods. The report structure and content will be in accordance with an internal template which will be reviewed biennially to ensure alignment and consistency with DWER issued templates and guidance material. A final IRR will be submitted in the year after the final reporting period that includes the offset attributable clearing footprint that has occurred over the life of the approval.
2. Aerial imagery clipped to the relevant approval boundaries and taken as close to the end of the annual reporting periods as practicable, with an index providing date of capture of each image compiling the full composite.
3. Spatial data to support the above report. Both IRR and Baseline spatial data shall be used to inform the overall requirement for offsets for the action. At a minimum, spatial data will meet the following:
    - be topographically accurate and georeferenced;
    - use GDA2020 (datum) co-ordinate system and projected into the appropriate Map Grid of Australia zone (i.e., 50);
    - include closed polygons and clipped to the relevant approval boundaries (any topology errors rectified);
    - be supplied in ESRI geodatabase format or shapefile;
    - be aligned with and attributed according to DWER's GIS Data Standards;
    - polygons of similar 'purpose' shall not overlap (i.e., clearing polygons shall not overlap, vegetation type and condition polygons shall not overlap, and exemption polygons shall not overlap);
    - all clearing data will be supplied to two decimal places in the attribute tables.

    Spatial data and layers for both the MS and EPBC Act approval shall include:

    - Clearing activity:
        - all clearing undertaken for each calendar year of each biennial reporting period (1 polygon per year, per mechanism, per IBRA region);
        - offset payable clearing undertaken for each calendar year of each biennial reporting period (1 polygon per year, per rate, per mechanism);
        - updates to offset exempt areas (1 polygon for each previously submitted layer indicating changes).
    - Maps to support the above-mentioned spatial data.
    - Updated spatial layers if a change is required (refer to Section 4).

4 MANAGEMENT OF CHANGE

The Proponent recognises that due to the timing of new submissions, approval complexity and continued process and technology improvements, changes to submitted data may be required. For the below listed known changes, the Proponent will supply any updated data and support spatial files in the next IRR submission. Note that only the changed information will be provided, rather than the re-supply of the entire layer:

- offset exempt areas acknowledging that clearing will continue to occur between submission of baseline as part of pre-approval conditions (where required) and Proposal approval; and
- updated exempt areas as a result of continued clearing or until the previously approved offset-exempt clearing allocation has been exhausted.

For unforeseen changes, the Proponent will conduct an assessment of materiality and will initiate discussions with DWER and DCCEEW to determine an appropriate resolution strategy.
