Environmental Impact Statement for South of Embley Project

This Environmental Impact Statement has been prepared to meet the assessment requirements for the Project under the *State Development and Public Works Organisation Act 1971* (Qld) and the *Environment Protection and Biodiversity Conservation Act 1999* (Cth).

Rio Tinto Alcan

RTA Weipa Pty Ltd

This Environmental Impact Statement (EIS) has been prepared to meet the environmental assessment requirements under both State and Commonwealth law.

Pursuant to the *State Development and Public Works Organisation Act 1971* (Qld), Queensland Coordinator-General has declared the South of Embley Project a "significant project" for which an EIS is required. This EIS is submitted in order to meet the Coordinator-General's assessment requirements as stated in the Terms of Reference for the Project.

Section 1.8 of this EIS contains more information on how to make a submission.

Pursuant to the *Environment Protection and Biodiversity Conservation Act 1999* (Cth), the Commonwealth Minister for Sustainability, Environment, Water, Population and Communities has decided that the South of the Embley Project is a "controlled action" for which an EIS is required. This EIS is submitted to meet the requirements of the tailored EIS guidelines for the Project. Section 1.8 of this EIS contains more information on how to make a submission.

VOLUME 1

EXECUTIVE SUMMARY

1 INTRODUCTION 1.1

1.1 Project Proponent 1.1
1.2 Project Description 1.4
1.3 Project Rationale 1.5
1.4 Relationship to Other Projects 1.8
1.5 Socio-economic Costs and Benefits 1.9
1.6 Project Alternatives 1.10
1.6.1 Beneficiation Plant Location 1.11
1.6.2 Port and Stockpile Location 1.11
1.6.3 Workforce Housing 1.12
1.6.4 Location of Barge and Ferry Terminals 1.12
1.6.5 Power Supply 1.13
1.6.6 Bauxite Beneficiation Technology 1.13
1.6.7 Water Demand Management 1.14
1.6.8 Water Supply 1.14
1.6.9 Initial Tailings Storage Facility Establishment 1.15
1.6.10 Volume of Dredged Material 1.15
1.6.11 Disposal of Dredged Material 1.16
1.7 Environmental Impact Assessment Process 1.17
1.7.1 Purpose of the EIS 1.17
1.7.2 Objectives of the EIS 1.17
1.7.3 EIS Process 1.18
1.7.4 Structure of the EIS 1.20
1.8 Public Consultation Process and Submissions 1.21
1.9 Legislative Framework and Project Approvals 1.22
1.9.1 State Development and Public Works Organisation Act 1971 (Qld) 1.23
1.9.2 Environment Protection and Biodiversity Conservation Act 1999 (Cwlth) 1.23
1.9.3 Environment Protection (Sea Dumping) Act 1981 (Cwlth) 1.24
1.9.4 Agreement Acts 1.24
1.9.5 Mineral Resources Act 1989 (Qld) 1.25
1.9.6 Environmental Protection Act 1994 (Qld) 1.25
1.9.7 Sustainable Planning Act 2009 (Qld) 1.26
1.9.8 Land Act 1994 (Qld) 1.26
1.9.9 Native Title Act 1993 (Cwlth) 1.26
1.9.10 Aboriginal Cultural Heritage Act 2003 (Qld) 1.26
1.9.11 Queensland Heritage Act 1992 (Qld) 1.27
1.9.12 Cape York Peninsula Heritage Act 2007 (Qld) 1.27
1.9.13 Water Act 2000 (Qld) 1.27
1.9.14 Water Supply (Safety and Reliability) Act 2008 (Qld) 1.27
1.9.15 Wild Rivers Act 2005 (Qld) 1.27
1.9.16 Fisheries Act 1994 (Qld) 1.28
1.9.17 Coastal Protection and Management Act 1995 (Qld) 1.28
1.9.18 Vegetation Management Act 1999 (Qld) 1.28
1.9.19 Nature Conservation Act 1992 (Qld) 1.28
1.9.20 Land Protection (Pest and Stock Route Management) Act 2002 (Qld) 1.28
1.9.21 Transport Infrastructure Act 1994 (Qld) 1.29
1.9.22 Transport Operations (Marine Pollution) Act 1995 (Qld) 1.29
1.9.23 Transport Operations (Marine Safety) Act 1994 (Qld) 1.29
1.9.24 Civil Aviation Regulations 1988 and Civil Aviation Safety Regulations 1988 (Qld) 1.29

2 PROJECT DESCRIPTION 2.1

2.1 Overview of the Project 2.1
2.2 Location and Tenure 2.1
2.3 Construction 2.5
2.3.1 15Mdptpa Production Capacity 2.5
2.3.2 30Mdptpa Production Capacity 2.13
2.3.3 50Mdptpa Production Capacity 2.13

Contents

2.4 Bauxite Mining 2.15
2.4.1 Ore Reserves 2.15
2.4.2 Mine Development and Schedule 2.15
2.4.3 Mining Equipment and Methods 2.15
2.4.4 Final Landform 2.15
2.5 Bauxite Processing (Beneficiation) 2.16
2.5.1 Beneficiation Plant 2.16
2.5.2 Tailings 2.17
2.5.3 Product Stockpiles 2.17
2.6 Port Facility and Shipping 2.18
2.6.1 Facility details 2.18
2.6.2 Shipping 2.18
2.7 Associated Infrastructure 2.20
2.7.1 Workforce and Accommodation 2.20
2.7.2 Transport 2.23
2.7.3 Water Supply and Management 2.25
2.7.4 Sewage 2.26
2.7.5 Power Generation and Supply 2.26
2.7.6 Mine Infrastructure Areas 2.27
2.7.7 Telecommunications 2.28
2.8 Decommissioning and Rehabilitation 2.28
2.8.1 Decommissioning 2.28
2.8.2 Mine Rehabilitation 2.28

3 LAND 3.1

3.1 Land Use 3.1
3.1.1 Existing Land Use 3.1
3.1.2 Impact on Existing Land Use 3.1
3.2 Geology 3.3
3.3 Topography 3.6
3.4 Soils 3.9
3.4.1 Previous Studies 3.9
3.4.2 Survey Methodology 3.9
3.4.3 Soil Types 3.11
3.4.4 Soil Mapping 3.12
3.4.5 Soil Descriptions 3.14
3.4.6 Soil Chemical and Physical Properties 3.18
3.4.7 Particle Size Distribution 3.19
3.5 Salinity Hazard 3.19
3.6 Erosion Potential and Control 3.19
3.6.1 Erosion Potential 3.19
3.6.2 Erosion and Sediment Control 3.20
3.6.3 Erosion Monitoring and Maintenance 3.21
3.7 Land Use Suitability 3.21
3.7.1 Pre-mine Land Use Suitability 3.21
3.7.2 Post-mine Land Use Suitability 3.24
3.8 Contaminated Land 3.26
3.8.1 Potential for Contamination from Existing and Past Uses 3.26
3.8.2 Contamination Prevention and Control 3.27
3.9 Acid Sulphate Soils 3.28
3.9.1 Humbug Barge Terminal 3.29
3.9.2 Hornibrook Ferry Terminal 3.33
3.9.3 Hey River Barge/Ferry Terminal 3.33
3.10 Rehabilitation 3.40
3.10.1 Post-Mining Land Use 3.40
3.10.2 Post-Mining Landform 3.40
3.10.3 Rehabilitation Strategy 3.41
3.10.4 Topsoil Management 3.41
3.10.5 Revegetation 3.41
3.10.6 Success Criteria 3.42

3.10.7 Maintenance....3.43

Environmental Impact Statement

for South of Embley Project

Executive Summary

EXECUTIVE SUMMARY

Project Overview

The proposed project, referred to as the South of Embley (SoE) Project (or "the Project"), consists of the construction and operation of a bauxite mine and associated processing facilities, barge and ferry terminals, and a port. The Project involves a staged increase in production up to 50 million dry product tonnes per annum (Mdptpa). The initial installed capacity is subject to ongoing feasibility studies but is likely to be either 15Mdptpa or 22.5Mdptpa. Actual production rates and the timing and size of capacity expansions would depend on market conditions. The EIS has been prepared to assess the impacts of several different levels of production along the expansion pathway: a minimum rate of 15Mdptpa, a maximum rate of 50Mdptpa, and a nominal intermediate rate of 30Mdptpa.

The Project is located near Boyd Point on the western Cape York Peninsula (refer **Figure A**). Boyd Point is approximately 40km south-west of Weipa and 40km north of Aurukun, with the closest mining areas being 4km from Napranum, 15km from Aurukun, and 50km from the nearest cattle station homesteads. The Project area would be predominantly located on a portion of ML7024 south of the Embley River, on ML6024, on certain Strategic Port Land with the Port of Weipa, and offshore dredging and disposal areas.

The main elements of the Project are:

- bauxite mining;
- bauxite processing and disposal of fine waste materials in tailings storage facilities;
- product bauxite stockpiles adjacent to the port facilities;
- construction and operation of port and ship-loading facilities between Boyd Point and Pera Head;
- dredging for the construction and maintenance of the port, and disposal of dredged spoil at an off-shore spoil ground;
- ancillary infrastructure including diesel-fuelled power station, workshops, warehouse, administration facilities, sewage treatment plants, general waste disposal and diesel storage;
- water infrastructure including a water supply dam on a freshwater tributary of Norman Creek (Dam C), a pump on the Ward River, pipeline, and up to 12 artesian bores;
- a temporary on-site camp for the construction phase – up to 630 beds; and
- dredging for the construction and operation of a new ferry terminal at Hornibrook Point, a roll on/roll off (RORO) barge facility at Humbug Point, and a new barge/ferry terminal on the western bank of the Hey River, and disposal of dredged spoil at the existing Albatross Bay spoil ground. The ferry and barge terminals would be used to transport workforce, materials and equipment between Weipa and the SoE Project.
- Modification of the east wharf at Lorim point to provide protected tug moorings.

The main infrastructure components are illustrated in **Figure B**. It is anticipated that construction would commence in early 2012, following receipt of relevant environmental approvals and Rio Tinto's internal project approvals. The initial construction phase is expected to take approximately three years. The estimated capital cost to establish 15Mdptpa capacity would be approximately $1,450 million. The final cost is subject to completion of feasibility studies. The Project has bauxite reserves capable of sustaining a mine life of approximately 40 years, depending on annual production rate.

The Project would deliver significant economic benefits to the local, regional, and state economies. Economic modelling predicts the following:

- The peak construction workforce is expected to be 630, with an average of 310 full-time equivalent jobs over the three years.
- Following commencement of production, the Project will generate direct employment for approximately 400 employees and 100 contractors (based on 15Mdptpa) and up to 1,020 employees and 255 contractors at maximum production (50Mdptpa).
- An estimated 1,170 jobs generated indirectly across other sectors of the Queensland economy, including approximately 790 jobs in the Far North Queensland (FNQ) region (based on a production rate of 15Mdptpa).
- A contribution to Queensland's economy of approximately $832 million per year (based on 15Mdptpa) and up to $3 billion per year at maximum production (50Mdptpa).
- Generation of approximately $123 million in taxes and royalties per year (based on 15Mdptpa) and up to $410 million in taxes and royalties per year at a maximum production rate (50Mdptpa).

The Proponent

The Project would be developed and operated by RTA Weipa Pty Ltd (RTA), which is wholly-owned subsidiary of Rio Tinto Aluminium Limited. These companies are in the Rio Tinto Alcan product group, which is one of five product groups operated by the global mining group, Rio Tinto.

Rio Tinto Alcan supplies bauxite, alumina and primary aluminium to Australia, New Zealand and export markets. About 37% of Australia's total production of bauxite, 36% of its alumina and 40% of its primary aluminium is provided by Rio Tinto Alcan.

Rio Tinto Alcan's Australian head office for bauxite and alumina is based in Brisbane. Bauxite and alumina interests in Queensland include the existing Weipa mine and the Yarwun and Queensland Alumina Limited alumina refineries in Gladstone. Rio Tinto Alcan also operates the Boyne Smelters Limited aluminium smelter in Gladstone.

RTA has a record of responsible environmental management during more than 40 years of mining bauxite in the Weipa region. RTA has not been the subject to any proceedings under a Commonwealth or State law for the protection of the environment. RTA has a Health, Safety and Environment Policy that includes commitments to minimise environmental impact and continually monitor and improve the way the company works.

The primary contact for the Project is detailed below:

Project Background and Need

RTA is currently mining the East Weipa and Andoom deposits located on ML7024 north of the Embley River. RTA is also mining from the adjacent Ely bauxite deposit (on ML7031) held by Alcan South Pacific Pty Ltd (acquired by Rio Tinto in 2007) under an agreement. Mined bauxite is trucked to one of two beneficiation plants located at Lorim Point and Andoom, on the northern bank of the Embley River. Product bauxite is railed from Andoom to Lorim Point and conveyed to RTA's stockpiles prior to shipment from the Port of Weipa.

The northern bauxite reserves are gradually depleting and with continuing demand for bauxite, RTA has undertaken extensive drilling programmes on ML7024. Significant bauxite reserves have been identified on the portion of ML7024 that lies south of the Embley River.

RTA plans to develop a new bauxite mine capable of producing a maximum of 50Mdptpa. The initial phase of mining operations would involve production to replace depleted East Weipa

production as well as developing third party markets. Production capacity would expand to replace Andoom production once those reserves are depleted. Production capacity would thereafter be expanded to 50Mdptpa when market conditions are suitable.

The option of not proceeding with the Project is not financially feasible as the bauxite reserves will be depleted in RTA's current mining areas leading to the progressive closure of the Weipa mine; without an alternative source, the Gladstone alumina refineries would lose a viable, ongoing source of bauxite and the town of Weipa would lose a major financial contributor.

Project Objectives

The key objectives of the SoE Project are to:

- extend the life of RTA's mining operations in Weipa beyond depletion of East Weipa and Andoom reserves;
- maintain continuity of bauxite supply to Gladstone refineries and third parties;
- enable increased bauxite production in the Weipa region in response to the rising world demand for this product and to enhance RTA's competitiveness as a bauxite producer;
- continue mining-related employment in the Western Cape region;
- maintain Weipa as the main residential and commercial support base for the Project;
- operate the mine in a manner that has an acceptable impact on surrounding communities and the environment;
- develop and operate the SoE Project in compliance with all relevant statutory requirements; and
- continue to maintain an open and honest relationship with stakeholders.

Project Alternatives

RTA has undertaken studies to optimise the Project design and a number of alternatives for various Project components have been considered but not adopted, including;

- beneficiation plant location – continued use of the Lorim Point beneficiation plant;
- port and stockpile location – use of existing facilities at Lorim Point;
- port vessel capacity – establishing a port capable of accepting bulk carrier vessels up to 90,000 dead weight tonnage (dwt);
- workforce housing and transport – establishing new workforce-only accommodation on-site with a drive-in drive-out and/or fly-in fly-out roster arrangement;
- barge and ferry terminal locations adjacent to existing Evans Landing Wharf;
- power supply – generating power at Weipa and installing a high voltage transmission line to the Project area;
- beneficiation plant technology – dry beneficiation;
- water demand management – use of thickened tailings;
- water supply – pumping water from Weipa via pipeline, desalinisation, two water supply dams and sole reliance on artesian water; and
- initial tailings storage facility establishment – locating a tailings storage facility on a non-mineralised area to the north of the Boyd beneficiation plant.

Approval Process

On 21 November 2008 the SoE Project was declared "a "significant project" for which an environmental impact statement (EIS) is required" under section 26(1)(a) of the *State Development and Public Works Organisation Act 1971* (Qld) (SDPWO Act), by the Queensland Coordinator-General.

RTA referred the Project to the Commonwealth Minister for Sustainability, Environment, Water, Population and Communities for a decision as to whether the Project constituted a controlled action under the provisions of the EPBC Act. On 2 October 2008, the Project was declared a "controlled action" under the *Environmental Protection and Biodiversity Conservation Act 1999* (Cwlth) (EPBC Act) (Referral No. 2008/4435). Following a change to the proposed port design to accommodate larger bulk carriers, RTA withdrew the referral and submitted a new referral for the revised Project. On 29 October 2010, the Project was declared a "controlled action" (Referral No. 2010/5642). In addition, the Minister also determined that an assessment under Part 8 of the EPBC Act is required before the consideration is given to issuing a permit under the *Environment Protection (Sea Dumping) Act 1981*. In accordance with the Commonwealth Minister's decision on the assessment approach, the Project will be assessed by way of an EIS under the EPBC Act (as well as an EIS under the SDPWO Act). One EIS document has been produced for assessment by the Commonwealth and the State and the EIS process shall meet the impact assessment requirements under both Commonwealth and State legislation. Approval under the Commonwealth *Environment Protection (Sea Dumping) Act 1981* (Sea Dumping Act) is required for the dredging and offshore disposal of dredged material. A sea dumping permit application was submitted to the Commonwealth Department of Sustainability, Water, Environment, Population and Communities on 1 October 2010. The EIS has also been scoped to meet the requirement of the Sea Dumping Act and includes information to support the application for a Sea Dumping Permit for dredging and disposal associated with Stage 1 capital dredging at the Port and capital dredging associated with the ferry and barge terminals.

Other key approvals required by the Project include:

- an amended environmental authority (mining lease);
- barge and ferry terminal development approvals; and
- amended licence to take artesian water.

Land

Lands within the Project area are not used for agriculture and are relatively undisturbed by development. Exploration activities have taken place throughout the Project area and are continuing. While overall there has been very little direct disturbance and the terrestrial environment is generally in good condition, some areas have been affected by camping, recreational vehicle use and rubbish dumping, and some areas have been significantly affected by frequent fires and damage from feral pigs. The Project would have no direct impact on agricultural land uses or management practices of surrounding land.

Areas to be disturbed during the 40-year mine plan comprise 27,290ha for mining areas; 700ha for a water supply dam; and approximately 1,400ha for other Project infrastructure established on non-mining areas. Generally, the area to be disturbed for mining contains Red Kandosol soils, which have low potential to develop accelerated erosion when cleared of vegetation. Yellow Kandosols and Redoxic Hydrosols occur along drainage lines, and these soil types would be disturbed for construction of dams and infrastructure. The Hydrosol soil types have a higher erosion potential. A range of erosion and sediment control measures would be employed, including restricting clearing to areas essential for mining, revegetating mined pits as soon as is practical, and completing vegetation clearing and mine development work during the dry season where possible. Vegetation buffers would be established, which provide "setback" distances of mining areas from sensitive riparian, wetland and estuarine vegetation types.

Most of the soils are only suitable for low intensity grazing of native pastures. There is no good quality agricultural land within the Project area. Overall, the post-mining land suitability for low intensity grazing is likely to be the same as the pre-mining suitability.

Soils at the Humbug barge terminal, the Hornibrook ferry terminal and the Hey River barge/ferry terminal sites would be disturbed by reclamation and cut and fill activities associated with construction. Soils at these locations were investigated for acid sulphate soil potential. The only soils that may require the addition of lime to manage acid generation are soils at the Hornibrook ferry terminal site.

Mine rehabilitation would be undertaken progressively during the life of the mine. RTA's objective for the rehabilitation of areas disturbed by SoE Project mining activities is to establish a self-sustaining vegetation community using appropriate local native tree, shrub and grass species. The final land use options would be developed and discussed with the Traditional Owners, as required under the Western Cape Communities Co-existence Agreement (WCCCA), and relevant government stakeholders. Approximately 60cm of soil would be stripped and then placed directly back on previously mined areas or stockpiled for future use in rehabilitation once a suitable area became available. Revegetation would be likely to include re-spreading of freshly stripped topsoil or stockpiled topsoil, ripping the mine floor to break up the compacted floor and increase water infiltration, and scarifying prior to seeding and fertilising. Native species seed mixes would be tailored to the anticipated post-mining conditions of the area to be rehabilitated. Preliminary rehabilitation success criteria for the Project area would be developed within three years of commencement of bauxite mining. Rehabilitation performance would be measured against the adopted criteria.

Climate

The Project area lies within the Australian Monsoon Zone and has a tropical climate with distinct wet and dry seasons. The mean annual rainfall at Weipa is 1,769mm falling on an average 109 days, with most occurring from December through to March. Key characteristics of the climate in this region are the occurrence of cyclones and wet season inundation of flood plains.

Cyclones, along with the associated storm surge and high winds, pose a risk to the safety of employees and the community, and may potentially damage infrastructure and revegetated areas. The risks to the safety of employees and the community would be managed by a detailed Business Resilience and Recovery (BRR) Plan and specific Cyclone Emergency Procedures. The heights of the port and barge/ferry terminals have been designed after taking into consideration maximum wave heights and storm surges resulting from cyclones. All plant and infrastructure would be designed and constructed to the relevant Australian Standards to reduce the risk of structural damage caused by high wind speeds.

Wet season inundation of flood plains and wetlands resulting from overtopping of main watercourse banks is a seasonal characteristic of the area. The main impact is restricted access for vehicles rather than flood damage. The design of land-based infrastructure (including dams) would incorporate appropriate flood design criteria for storms. The design of dams is based upon guidelines by the Australian Committee on Large Dams.

Surface Water

The main catchments within the Project footprint are the Norman Creek, Ina Creek and Ward River catchments. The surface waters of the Project area are used by Traditional Owners and visitors for fishing, camping and recreation.

The stream form within the Norman Creek catchment is diverse. Most streams are comprised of stable banks with a high sediment transport potential. Ongoing monitoring of geomorphic assessment sites in Norman Creek would be conducted.

The Project area freshwater streams are not unusual in terms of conductivity and hardness compared with streams in other bauxite areas. However, they have lower solute concentrations and lower hardness compared to other waters in northern Australia. The water quality characteristics of the Project area reflect the nature of water flowing through and within bauxite terraces, with the laterite layers acting as a physical and chemical filter resulting in very clear, almost salt-free surface waters. The Project area streams and tree swamps have naturally elevated dissolved aluminium concentrations.

Proposed mining activities may result in residual impacts on surface water quality, including potential impacts on sediment loads (sedimentation and turbidity/total suspended solids) and water chemistry (hydrocarbon contamination and altered metals concentrations). The water quality of natural surface drainage systems would be maintained by preserving riparian vegetation corridors, implementing mitigation strategies such as the proper handling and storage of dangerous goods and hazardous substances to prevent spills, and implementing sediment and erosion control measures. Analysis of crude ore from the Project, as well as tailings solids and liquid, tailings recovery slot water, and stockpile runoff from existing Andoom and East Weipa operations, indicates that runoff or leachate from crude ore and tailings are unlikely to be a significant contributor of aluminium to surface water and are not anticipated to have an adverse affect on surface or groundwaters. The process water ponds and tailings storage facilities are constructed as "turkeys' nests", and neither of these dams would contain contaminants in concentrations that are hazardous. Turbidity and a range of metals would be regularly monitored in surface waters to provide an early indicator of any potential water quality impacts.

Stormwater runoff generated within active mine areas would be predominantly contained within the internally draining mine pits and would then infiltrate through the pit floor and walls. In the event that the active pit or post-mining topography is not an internally draining pit, stormwater runoff would be directed via a sediment pond. Rainfall-runoff modelling showed that in undisturbed catchments within the Project area the proportion of surface runoff (<1% of rainfall) is unusually small and reflects the flat topography and the very high infiltration rates of the soils and lateritic strata. Given the low surface runoff rates and that mining pits retain overland flow, the risk of elevated sediment loads in catchment runoff during some stages of mine development is considered low.

The Project's principal water requirements are for process water, haul road watering, vehicle wash-down, dust suppression and potable supplies. The Project's water demands range from 16GL/year at 15Mdptpa to 64GL/year at 50Mdptpa. Water would be recycled from the tailings storage facilities, the mine industrial area drainage slots, heavy and light vehicle wash bays, stormwater runoff from product stockpiles and the wharf, treated effluent from the Boyd and Norman Creek sewage treatment plants, and used preferentially as process water. Water would be drawn in order of preference from tailings storage facilities, water recovered from slots adjacent to tailings storage facilities, water supply dam (Dam C), surface water stream (Ward River) and, lastly, artesian bores. Dam C would be constructed on a freshwater tributary of Norman Creek and would have a maximum storage capacity of 29GL and could be constructed in either in two stages or a single stage. The dam would be constructed in a single stage should expansion of production above 15Mdptpa be anticipated to occur quickly, or should an initial production capacity of 22.5Mdptpa be adopted. To maintain the reliability of the overall surface water supply from 30Mdptpa to 50Mdptpa production rates, some water would be pumped directly from the lower reaches of the Ward River. The artesian demand would therefore fluctuate depending on whether there is above or below average rainfall runoff into the dam.

The impact of Dam C on downstream flow was modelled. The key findings are:

- the effect of Dam C at 15Mdptpa, 30Mdptpa and 50Mdptpa production rates is to reduce mean annual flow immediately downstream in the Norman Creek tributary to 78.3%, 67.2% and 49.5% of original flow respectively; and
- considering the whole Norman Creek system catchment discharge (i.e. discharge into the estuary), the mean annual input into the estuary would be 93.5%, 90.2% and 84.9% of original flow respectively.

The presence of Dam C leads to an appreciable annual decline in flows immediately downstream on the particular branch of the Norman Creek on which it is built. However, when the catchment is considered as a whole, the overall decline (maximum 15%) is well within the range of normal year-to-year variation (the 10th percentile annual flow is 42% lower than the mean annual flow).

Dam C would be fitted with a low-level outlet pipe which would permit the controlled release of environmental flows when required. The spillways would be at a low gradient (<3%) and be designed to facilitate fish passage during spillway flow events.

The impact on the hydrological regime as a result of pumping from the Ward River was also modelled and found to be minor. The annual volume of water pumped from the Ward River would be capped at 1% of mean annual river flow at the pump station and the rate of pumping at all times would be less than 20% of the river flow rate.

The effect of mining on the discharge from catchments subject to mining was assessed using a rainfall–runoff model which showed that mining has a temporary impact on the partitioning of surface runoff and baseflow, and that as rehabilitation matures the overall hydrological regime at a catchment scale returns toward an "undisturbed" situation. The Ina Creek catchment has the largest proportion of area mined but the overall change to average annual discharge is very small (–1.4% at maximum impact; –2.2% post-closure). There are only very small changes to the discharge from the overall Norman Creek system (–1.0% at maximum impact; –1.8% post-closure) and overall Ward River system (–0.2% at maximum impact; –0.5% post-closure). The modelling indicates that the overall impact of mining on catchment discharge is very much less than the normal year-to-year variation driven by rainfall variation because surface runoff is extremely low and hence changes to surface drainage patterns have little impact on overall discharge into streams. The Project would not have any impact on the Watson River or Archer River and therefore the impact on discharge to the Archer Bay Aggregation would also be very minor, if any.

Groundwater

The groundwater resources in the area have been differentiated as shallow aquifer and artesian aquifer resources.

The bauxite layer (part of the Wyaaba beds) is highly permeable and is usually unsaturated. The bauxite overlies a kaolinite clay layer (part of the Bulimba Formation) which is generally of low permeability and typically contains macropores that allow preferential flow. The kaolinite layer is a transitional zone between the bauxite and the underlying sandstone Bulimba Formation. On the Weipa Peninsula north of the Embley River, the Bulimba Formation hosts a high yielding shallow aquifer which is used to supply existing RTA mining operations. However, the shallow aquifers in the Project area tend to be poorly developed and discontinuous. Generally, groundwater quality results are similar to that of surface waters with the exception of some higher concentrations of dissolved metals.

There is a large seasonal influence on the shallow aquifer water table which is separated from the artesian aquifers by the 500m thick mudstones of the Rolling Downs Group. The wet season water table level is generally below the base of the bauxite, rising within the bauxite only at the height of the wet season, if at all. The dry season water table level generally falls to 4 to 8m below the base of the bauxite, with the kaolinitic layer below the bauxite generally hosting the shallow aquifer during the dry season. Stream flow during the dry season tends to be maintained by baseflow originating predominantly from kaolinitic strata and is unlikely to originate from the bauxite. The removal of bauxite would only have the potential to change discharge from the shallow aquifer in situations where the bauxite is an appreciable source of baseflow.

Redirection of surface flow due to disturbance from mining does not greatly alter aquifer recharge characteristics because direct surface runoff from the bauxite plateau is a very small proportion of incident rainfall (<1%).

The artesian resources are hosted within the Gilbert River Formation and Garraway Beds. These are part of the Great Artesian Basin (GAB) aquifers, the main artesian groundwater resource in the region, and capable of supporting a large rate of abstraction. Typically, water bearing formations in the Project area are located at depths 750 to 1,000m below ground level. Artesian water quality is generally brackish (electrical conductivity ranging from 1,800µS/cm to 16,000µS/cm) with variable cation, anion and metals concentrations. The GAB aquifers are recharged primarily by direct infiltration of rainfall where the GAB sandstone outcrops along the

eastern margin of the region (the recharge area) – along the flanks of the Great Dividing Range, particularly along watercourses. Recharge springs are quite common in the recharge areas on Cape York Peninsula and result from overflow or the rejection of recharge from the overfilling of aquifers. These springs provide an important source of water for maintaining surface water flow during the dry season. Watercourse springs are also found on Cape York Peninsula and are the part of a watercourse where water enters the watercourse through its bed or banks to become baseflow in the watercourse.

The GAB Resource Operations Plan states that a decision associated with abstraction from a management unit connected to a spring is subject to the cumulative spring factor not exceeding 400mm head of water. The spring factors for the closest recharge and watercourse springs to the proposed borefield have been calculated and demonstrate that the cumulative spring factor limit of 400mm is not exceeded for any of the existing or proposed new bores.

RTA extracts artesian groundwater from borefields at both East Weipa and Andoom operations under an existing Water Licence which allows abstraction of up to 9GL per annum. There are no other large users of artesian groundwater on Cape York. RTA proposes to install an artesian borefield that accesses the Gilbert River Formation artesian aquifer as part of the Project and to apply to increase the artesian allocation to cover the fluctuations in artesian demand. It is proposed that a five-year moving average of 12GL per annum be established, with a peak abstraction of 15GL in any one year.

The potential impacts of artesian groundwater abstraction were modelled. The modelling results indicate that under the proposed licensed abstraction regime, the existing Water Licence condition relating to a 5m maximum relative drawdown would be met and that the aquifer could sustainably support abstraction rates greater than the proposed rate of 12GL per annum.

Discharge springs, which are defined as spring's supplied by underground water from the GAB, are not found in the Project area or Cape York. It is therefore unlikely that the threatened ecological community '*The community of native species dependent on natural discharge of groundwater from the Great Artesian Basin'* would occur in the Project area.

Marine

The marine impact assessment focused on the proposed port site, the spoil disposal ground offshore of Boyd Point, the existing Albatross Bay spoil ground and the proposed location for barge/ferry facilities, and impacts of sediment dredging, sea disposal of dredge spoil, and construction and operation of the port and barge/ferry terminals.

Initially, approximately 6,500,000m^3 of marine sediments would be dredged from the port site to establish the berth pockets and departure areas over a period of about 300 days. Dredged spoil would be transported to the new offshore spoil disposal ground. Initially annual maintenance dredging of approximately 890,000m^3 is expected to be required to maintain under keel clearance for ships. When the wharf is extended in a second stage to expand its capacity to at least 50Mdptpa, a further 2,400,000m^3 of dredged spoil would be generated and disposed of at the same offshore spoil ground and annual maintenance dredging would increase by 280,000m^3 per annum to a total of approximately 1,170,000m^3 per annum.

Minor volumes of material would be dredged at Hornibrook ferry terminal (18,680m^3), Humbug barge/ferry terminal (10,670m^3) and Hey River barge/ferry terminal (17,300 m^3) to obtain sufficient draft for project support vessels. Dredge spoil would be disposed of at the existing Albatross Bay spoil ground. At each of the barge/ferry terminal facilities dredging is likely to take only one to two weeks. Annual maintenance dredging of these areas would increase the annual dredge volume conducted by North Queensland Bulk Ports by approximately 7,000m^3.

Assessment of the chemical and physical characteristics of material to be dredged from the proposed port area and the barge/ferry terminals, using the framework of the *National Assessment Guidelines for Dredging* (NAGD), indicates that all dredge spoil is suitable for sea disposal and did not identify any constituents present at levels of environmental concern that would persist in the water column during dredging or sea disposal.

Water quality at the proposed port, new spoil ground, and proposed ferry and barge facilities all exhibit significant natural fluctuations in suspended sediment and turbidity. The extent of this natural variation buffers water quality impacts associated with dredging, disposal, construction and operation to some extent. Generally, these habitats may be described as being more resilient to short-term water quality changes.

Near shore fringing reef communities in the vicinity of the proposed port area occur at Boyd Point, Pera Head and between Pera Head and Thud Point. These comprise both reefs containing hard corals and low profile reefs containing soft coral-sponge assemblages. The importance of these reef systems (Boyd Point to Thud Point) in a regional context is considered to be high as they support resources that are of conservation, cultural, commercial and recreational importance. In particular, the near shore sponge and soft coral reefs provide a food resource for a range of turtle species in the area. Nine Mile Reef is accessed frequently by recreational fishers. No reefs need to be removed for dredging or wharf construction purposes.

At the proposed port site, a turbid plume would eventuate as material is released to the water column during the operation of the dredgers. The migration and dispersion of turbid plumes during capital dredging at the proposed port area and disposal at the proposed new spoil ground has been predicted through modelling. Model outputs identify that the turbid plume generated by port area capital dredging extends parallel, along the coast. During flood tides the plume extends from the dredge location to beyond Pera Head. During the ebb tide the dredge plume extends from Pera Head to Boyd Point. Under ambient conditions, Boyd Point and Pera Head reef areas demonstrate a high variation in turbidity, driven primarily by local wind and associated wave events. Median dredge-derived plume concentrations remain below event-based ambient ranges reported from reef habitats and the duration of peak dredge-derived plume periods are similar to natural event durations.

Modelling of turbid plumes generated by spoil disposal at the proposed new spoil ground identified a median TSS concentration of less than 1mg/L above background. The disposal plumes at the new spoil disposal ground tend to disperse along a southerly trajectory due to tidal currents and do not reach the Nine Mile Reef, which is located approximately 6km south-west of the spoil disposal ground. No impact to recreational or guided fishing over that area is predicted.

Sediment deposition modelling was used to predict sediment deposition rates over key reef habitat areas for seven different dredging periods representing different dredging activities. Based on modelled sedimentation predictions, reef systems between Boyd Point and Thud Point may experience impacts from increased sediment deposition.. The mean annual sediment deposition concentration recommended to guard against excessive coral recruit mortality is 3mg/cm^2/day. Daily deposition rates at Pera Head Reef, and reef systems south of Pera Head to Thud point, during the peak plume period, are predicted to be higher than 3mg/cm^2/day. The total rate of deposition during the peak plume period may represent a potential risk of mortality to coral recruits. However, the predicted sediment concentrations remain much lower than the recommended daily maximum sediment concentration. Corals already established on the reef are likely to be more resilient than recruits, as demonstrated by colony survival following natural events where deposition rates would be significantly higher than the recommended daily maximum sediment concentration.

The creation of a turbidity plume from dredging and subsequent deposition and re-suspension of fine sediments may adversely affect hard corals, which require sunlight for photosynthesis. Three light regimes related to coral sustainability were developed based on the relationship between TSS and light: "favourable", "light limited" and "unsustainable". Using TSS values from plume dispersion modelling and reef habitat depth profiles, a prediction of impact based on benthic light availability was made for reef habitats of the study area between Boyd Point and Thud Point during inshore and offshore dredging.

Modelling indicates that 86-89% of the hard coral reef habitat area mapped around Boyd Point, Pera Head and Thud Point would maintain a "favourable" light regime throughout the dredging program and is not considered to be at risk. The remaining reefs, during the peak plume period, would experience periods of reduced light availability for durations similar to ambient light

reduction events recorded at Boyd Point during field investigations. However, the predicted plume TSS concentrations remain well below reported maximum ambient concentrations. Whilst the change in light availability is not considered sufficient to initiate an acute response, the rate at which these corals can acclimatise is not well defined, and they remain at risk of developing sub-lethal responses to reduced light regimes. Modelling results indicate that, following the peak plume period, the receiving habitats enter a period of respite, where TSS reductions result in substantial improvements to the light climate. Given the relatively short duration of light attenuation, and general respite provided to coral reef systems after the peak plume period, these predicted light reductions are not thought to be a driver of acute impact associated with the dredging process. The analysis did not identify any coral habitats entering "unsustainable" light regimes.

The development of a reactive environmental monitoring program would be an important part of the dredging program. Monitoring of turbidity, deposition and photosynthetically active radiation is proposed to be undertaken at Boyd Point, Pera Head and Thud Point reef areas. The objective of this monitoring is to assist in identifying extended periods of high turbidity/low light availability which can lead to coral stress. Should signs of unacceptable coral stress become apparent, then dredging operations would be located to offshore in the departure channel to allow corals a period of respite and return to more favourable light conditions.

Seagrass habitats in the Albatross Bay area provide nursery habitat for fish and macroinvertebrates and species of conservation significance (e.g. dugongs and green turtles). Seagrass and mangroves are not present in the immediate vicinity of the proposed port development. Seagrass habitat was not identified in recent surveys of the dredge footprints of the Hornibrook ferry terminal or the Hey River terminal; however, patches of seagrass may occur in the vicinity. Isolated patches of seagrass have been identified within or immediately adjacent to the proposed dredge footprint at the Humbug barge terminal. The area of seagrass within the dredge area is conservatively estimated to be 1250m^2, which represents about 0.003% of the seagrass meadows within the Weipa region. Given the minor scale and short duration of dredging for the barge and ferry terminals, it is unlikely that sediment loads would approach critical levels for the seagrass.

The development footprints for all marine infrastructure components of the SoE Project (port area, proposed spoil ground, Albatross Bay spoil ground, Hornibrook ferry terminal, Humbug barge terminal and Hey River barge/ferry terminal) have been confirmed by field inspection as consisting primarily of soft sediment habitats that contain sparse epifauna typical of soft sediments, such as seapens and tube-dwelling anemones, soft-corals or sponges. These areas can also contain diverse and abundant assemblages of macrobenthic infauna. Physical disturbance from dredging, spoil disposal and marine infrastructure construction, as well as the turbidity plume caused by dredging, may potentially have a significant local impact on the infauna assemblage at the site of the proposed port facility, the new spoil ground, the barge/ferry terminals and the Albatross Bay spoil ground. However, the soft sediment habitats of the Gulf of Carpentaria are not considered to be sensitive marine habitats. The areas proposed to be impacted by dredging, spoil disposal and construction of marine infrastructure would be extremely small relative to the area of soft sediment habitats in the region, therefore, these impacts pose a low risk on a regional scale. Macrobenthic infaunal assemblages can recover over time from the impacts of dredging and spoil disposal. Monitoring of infauna is proposed be undertaken at the new spoil ground location and at the proposed port to identify the extent of smothering impact, spoil migration and recovery over time. Monitoring is also proposed for the ongoing maintenance dredging campaigns at a frequency of five years, or as required by the conditions of future sea dumping permits.

The most effective control strategy to minimise negative effects of dredging on adjacent habitats is to minimise dredging time, allowing sensitive receptors to enter a recovery phase as quickly as possible. It is anticipated the port area would be dredged over a period of up to 10 months; however, there would be periods of respite as the dredging operations move between inshore and offshore locations. Dredging at barge/ferry terminals should take only one to two weeks each.

Dugongs (listed as "Vulnerable" under the *Nature Conservation Act 1992* (Qld) and as a "migratory species" under the EPBC Act) occur in low densities in Albatross Bay and graze on the seagrass beds in the Embley estuary. The absence of seagrass within the footprints of marine infrastructure, except for a very small area within the Humbug barge terminal footprint, ensures that there would not be a significant impact on Dugong foraging habitat. The operation of the ferry is predicted to pose a moderate risk of boat strike to dugong in the Embley estuary. Transit lanes that follow the deepest water and avoid significant meadows of seagrasses would be implemented to help reduce the risk of boat strike.

Three 'threatened' (EPBC Act) sea turtle species are known to nest on the beaches in the vicinity of the Project area and forage in the surrounding waters. Another three 'threatened' (EPBC Act) sea turtle species use the Project area waters for foraging. Sea turtle populations are currently adversely impacted by feral pigs (predation of nests) and becoming entrapped in ghost nets.

Approximately 71ha of sponge/soft coral habitat occurs between Boyd Point and Pera Head (inclusive). It is predicted that sediment deposition from port area capital dredging would be at its greatest between these two locations and may locally affect feeding preferences in marine turtles. It is estimated that 117ha of similar habitat occurs between Pera Head and Thud Point, with more likely to occur at inshore reef areas south of Thud Point and north of Boyd Point, therefore regional impacts to feeding habitats are not predicted.

Changes to the above-water, night-time lighting regime can affect sea turtle hatchlings' attempts to find water; therefore, lighting from construction and operation of the port may affect sea turtles. RTA has developed and would implement a lighting plan at the port to mitigate the potential effects of lighting on sea turtle hatchlings. Measures to reduce feral pig numbers in the Pera Head to Boyd Point area and assistance with marine turtle research programs would be developed and implemented in liaison with RTA, Traditional Owners and the Queensland Department of Environment and Resource Management (DERM). Overall, without mitigation, a changed light regime is predicted to pose a high risk to marine turtles. However, proposed programs designed to reduce the primary threats (feral pigs and ghost nets) would minimise overall impacts on local marine turtle nesting activity and increase hatchling emergence. Turtle exclusion devices would be fitted to dredges to minimise entrainment of turtles. The risk of turtle deaths due to boat strike is low.

Three species of sawfish of conservation significance are likely to occur in Albatross Bay. Although fish species are able to move away from any local areas affected by a disturbance (e.g. dredging and dredge spoil deposition), physical disturbance to the dredge sites, deposition of spoil, and the re-suspension of disturbed and deposited sediment may have impacts of minor magnitude on sharks and rays, including sawfishes, and bony fishes at the proposed port facility, the proposed new spoil ground, and the ferry/barge terminals.

The Project area is included in the area where the Northern Prawn Fishery (NPF), the Gulf of Carpentaria Commercial Inshore Finfish Fishery and the Gulf of Carpentaria Commercial Line Fishery operate. Recreational fishers and guided fishing tour operators also utilise the Project area. There may be localised impacts on these fishing activities from turbid plume generation and spoil deposition as well as restricted access due to construction and operation of the port and barge/ferry terminals. However, the areas where these fisheries and recreational fishers operate is large and there is considerable area where they can still operate unimpeded.

To minimise the risk of introducing marine pests through ships' ballast water or hull fouling, all vessels owned and contracted by Rio Tinto would manage ballast water through a Ballast Water Management Plan which would comply with Australian mandatory requirements and the *International Convention for the Control and Management of Ships' Ballast Water and Sediments*. Ship hulls would not be cleaned at the proposed port. RTA would undertake regular mussel trap monitoring in the vicinity of the new port when overseas ships are utilised to provide a means of early detection of pest introduction.

To manage the risk of introducing pollutants to the marine environment, no fuel or chemicals would be unloaded at the proposed port facilities. Product spillage into the marine environment

could occur from routine loading operations. Bauxite is non-hazardous and the risk of impact to marine ecology is considered to be low. RTA proposes to adopt engineered designs that minimise the risk of dust generation and product spillage.

The construction of the proposed port, tug berths and the ferry/barge terminals would involve pile driving activities. Pile driving may cause underwater acoustic impacts such as avoidance behaviour on marine fauna (including EPBC Act threatened species) in the vicinity of this activity. To minimise these potential underwater noise impacts on marine fauna, RTA proposes that an exclusion zone be established and monitored prior to and during normal pile driving activities, a soft start approach be undertaken prior to normal pile driving and normal pile driving would not be conducted while threatened marine fauna species are indentified within the nominated exclusion zone. The proposed mitigation measures should ensure that any impacts associated with underwater noise from pile driving (predominantly avoidance behaviour) on marine fauna remain low. The extent of the exclusion zone would be defined based on further literature review and quantitative analysis of the potential underwater noise impacts from pile driving relating to threatened marine fauna. The final extent of the exclusion zone would be defined in consultation with DSEWPaC.

Terrestrial Flora and Fauna

The Project area is relatively homogenous in vegetation and landform, and is characterised by large areas of Darwin Stringybark (*Eucalyptus tetrodonta*) open forests or woodlands, dissected by smaller areas of riparian vegetation, vine thicket patches and paperbark swamps. There are no Protected areas within or near the Project area.

Of the 27 Regional Ecosystems (REs) occurring in the Project area three are listed under the *Vegetation Management Act 1999* (Qld) as "Of concern" (none are "endangered"). RE 3.5.2 (*Eucalyptus tetrodonta*, *Corymbia nesophila* tall woodland on deeply weathered plateaus and remnants) is the most widespread RE within the Project area, and is listed as "Least concern". It comprises approximately 87,500ha or 86% of the REs mapped in Project area, and occurs almost exclusively upon the bauxite plateau areas (which is the area where mining is proposed).

Disturbance to REs within the Project area would comprise approximately 27,300ha within mining areas; 700ha within the footprint of the water supply dam; and 1,400ha within the footprint of Project infrastructure established on non-mining areas. The aggregate area of 29,400ha of remnant vegetation to be disturbed is comprised entirely of "Least concern" REs, apart from approximately 0.3ha of "of concern" RE 3.2.6a (*Casuarina equisetifolia* woodland on foredunes) which would be disturbed for the ship loading facility. Approximately 28,970ha of RE 3.5.2 would be disturbed, representing 4.3% and 3.7% respectively of its subregional and bioregional distribution.

The disturbance of other REs would be much less than 10% of their total extent in the Project area, apart from RE 3.3.5 (evergreen notophyll vine forest on alluvia on major watercourses) (28.8%). The total area of RE 3.3.5 within the Project area is small (28.5ha) but 8.2ha occurs within the footprint of Dam C and associated infrastructure. However, in the sub-regional and bioregional context, the disturbance to RE 3.3.5 would be negligible (<0.1%).

No EPBC Act listed "endangered ecological communities" are present in the Project area.

Two "threatened" orchid species listed under the EPBC Act are widely distributed in the Project area. Cooktown Orchid is located in coastal and non-coastal vine forest, and mangrove edges. It was found within the proposed footprint of Dam C, and in the vicinity of a proposed access road crossing of an upper Norman Creek tributary. Chocolate Tea Tree Orchid is located in riparian gallery forest and Melaleuca dominated swamps particularly along major drainage lines and associated tributaries. It was found within the infrastructure corridor downstream of Dam C, and in the vicinity of proposed access road crossings of Winda Winda Creek and an upper Norman Creek tributary. The disturbance associated with the dam and other infrastructure represents a minor proportion of the habitat for these two orchids.

The threatened flora species are likely to be encountered in non-*Eucalyptus tetrodonta* vegetation communities which would not be directly affected by bauxite mining operations. The disturbance of sensitive non-*Eucalyptus tetrodonta* vegetation by mining would be avoided by the development of an environmental buffer system and the exclusion of mining from within the designated buffers and the non-*Eucalyptus tetrodonta* communities themselves.

Direct impacts on fauna habitats are linked to removal of vegetation to accommodate mining and Project infrastructure. Eight threatened fauna species (either EPBC Act listed or *Nature Conservation Act 1992* listed) have been confirmed as present in the Project area. Of these, two species are found within the proposed dam footprint. There is likely to be a short term impact on the breeding success of some pairs of Palm Cockatoos during construction of Dam C. However, other habitats are likely to support suitable nesting trees, and foraging habitat occurs elsewhere throughout the Project area. The loss of habitat for the Rufus Owl within the Dam C footprint is not insignificant in terms of habitat availability and other areas of suitable habitat occur throughout the Project area.

The Estuarine Crocodile (listed as "Vulnerable" under the *Nature Conservation Act 1992* and as a "migratory" species under the EPBC Act) is commonly encountered in the Weipa area including the freshwater swamps and creek systems within the Weipa mining leases. The tributaries that collectively form the Port Musgrave system and the Albatross Bay system surrounding Weipa (including the Embley and Hey estuaries adjacent to the Project area), have been identified as the two most significant Estuarine Crocodile habitats in Queensland. Overall the species is widespread in the Project area. One nest has been found within the footprint of Dam C on a freshwater tributary of Norman Creek. The Project is not expected to interfere with the total breeding effort of the species in the Project area.

Forty-four migratory bird species listed under the EPBC Act were identified as present or potentially present within the Project area. The majority of these species predominantly utilise habitats that would be located within environmental buffers and are not directly affected by mining. There are not anticipated to be any significant impacts on migratory birds resulting from the Project.

Impacts of habitat removal on the overall habitat landscape for fauna, and in particular faunal movement patterns, would be mitigated by retention of the environmental buffers, in particular a coastal margin vegetation buffer and by the retention of remnant vegetation.

Given the limited disturbance by infrastructure of non-*Eucalyptus tetrodonta* vegetation, the proposed environmental buffer system together with the retention of remnant vegetation, significant impacts on threatened flora and fauna species are unlikely.

RTA would implement fire, weed and feral animal management programs which would benefit threatened fauna in undisturbed areas by enhancing current habitat values.

Aquatic Ecology

The Project area sheds runoff from a centrally-located topographic high in all directions via numerous creeks and smaller, less defined drainage depressions. Aquatic ecosystems within the Project area also include swamps, lagoons, channels, lakes and estuaries. The systems are a mix of perennial and seasonal systems, some of which are interconnected with the groundwater system and have environmental values of national, state and regional significance.

There are three relatively large wetland aggregations partly or wholly contained within the Project area, including the lower Ward River. The lower Ward River within the Project area is included within the Archer Bay Aggregation which is a nationally significant wetland area listed in the Directory of Important Wetlands (DIWA).

These wetland systems provide areas of wetland habitat, productivity (carbon biomass), fish nursery, fisheries, nesting/feeding for migratory birds, aquatic refugia, habitat for threatened species and cultural significance.

The two main aquatic vegetation community types are riparian overstorey and aquatic macrophytes. Macrophytes are not common in the Project area due to shading by closed

riparian forests, nutrient poor water and leaf litter dominated substrates, and high discharge rates.

A total of 45 species of fish were recorded in the Project area during two field surveys. Six species of crustacean were recorded and locally populations were dense. A species of freshwater crab, *Austrothelphursa* sp., was recorded and assessed by the Queensland Museum as possibly a new species. One specimen of Mysid (Shrimp) crustacean belonging to the family Lepidomysida, a stygofauna, was identified by Queensland Museum staff and has not previously been recorded in Australia.

No "endangered", "vulnerable" or "near threatened" aquatic species listed under the *Nature Conservation Act 1992* or the EPBC Act were confirmed as present within the Project area.

Other than Dam C on a freshwater tributary of Norman Creek, the direct disturbance footprint of proposed mining and infrastructure development occurs primarily within terrestrial ecosystems. Implementation of an environmental buffer system would ensure riparian, wetland and estuarine habitats were buffered from direct impacts associated with vegetation clearing other than where they occur within narrow linear infrastructure crossing drainage lines, or within the proposed dam impoundment.

The primary impact on aquatic ecology arises from Dam C. Dam C may act as a fish barrier to those species that need to traverse upstream and downstream of the dam. Downstream of Dam C there is potential for changes to stream geomorphology, greater seasonal variability in channel hosted lagoons/pools, decreased abundance of freshwater macrophytes, altered timing of flow, potential water quality impacts if dam seepage occurs, and salinity changes at the estuary interface. Any such changes would be confined to the downstream reach of the Norman Creek freshwater tributary on which Dam C would be located.

Mitigation and monitoring measures to manage potential Project impacts include the following:

- Environmental flows would be released from Dam C to match the timing of inflows. Flow rates would be monitored upstream and downstream.
- Post-mining drainage paths would be reconfigured as far as practicable to match that of pre-mining. Hydrological monitoring would be undertaken in representative sub-catchments affected by mining.
- Drainage would be managed during mining operations to minimise sedimentation.
- Vegetation buffers would be established.
- A fishway structure of an appropriate size to allow those species that need to traverse between upstream and downstream of Dam C would be incorporated into the spillway to provide habitat connectivity.
- Seasonal salinity regimes in upper estuarine reaches and their relationship to surface base flows, groundwater inflows and reach habitats would be monitored.
- Water quality in receiving reaches and their relationship to ambient dissolved oxygen levels, soluble aluminium, iron and manganese concentrations would be monitored.
- Representative vegetation ecotonal boundaries would be mapped from aerial photography to detect any long-term (decadal) shift, and surface water would be monitored for salinity at monitoring points located in each of the major estuaries.
- Aquatic faunal communities in receiving reaches would be monitored periodically.

Air Quality

The Project area is undeveloped and remote. Potential sources of particulate emissions from the environment surrounding the proposed mine primarily comprise unsealed roads, smoke from bushfires, existing RTA mining activity north of the Embley River, and cattle station activities.

Air dispersion modelling was conducted to predict the ground level concentrations of particulates, nitrogen dioxide (NO_2), sulphur dioxide (SO_2) and concentrations of deposited dust at sensitive receptors close to the SoE Project area (Weipa, Napranum and Aurukun). The predicted concentrations at the nearest sensitive receptors all comply with the air quality objectives for particulates, NO_2 and SO_2 described in the *Environmental Protection (Air) Policy 2008* (Qld) (EPP (Air)). Predicted deposited dust concentrations were less than the maximum dust concentrations described in the DERM Guideline *Preparing an Environmental Management Overview Strategy (EMOS) for Non-standard Mining Projects.*

The predicted particulate levels (inclusive of background) at sensitive receptors were up to 27$\mu g/m^3$ for the 24-hour PM_{10} (respirable particulates less than 10 micrometres in diameter), compared to the proposed criterion of 50$\mu g/m^3$. Predicted fine particulate levels (inclusive of background) were up to 10$\mu g/m^3$ for the 24-hour $PM_{2.5}$ (respirable particulates less than 2.5 micrometres in diameter), compared to the proposed criterion of 25$\mu g/m^3$ and up to 2$\mu g/m^3$ for the annual $PM_{2.5}$ (compared to the proposed criterion of 8$\mu g/m^3$). Annual average total suspended particulate (TSP) levels were predicted to be up to 23$\mu g/m^3$ (compared to the proposed criterion of 90$\mu g/m^3$). Dust deposition levels were predicted to be up to 52mg/m^2/day (compared to the proposed criterion of 120mg/m^2/day).

Apart from conventional haul road watering and dust suppression sprays (e.g. truck dump chutes), no special mitigation measures are required.

Predicted NO_2 levels (inclusive of background levels) at sensitive receptors were up to 52 parts per billion (ppb) for the 1-hour NO_2 (compared to the proposed criterion of 120ppb) and up to 6ppb for the annual average NO_2 (compared to the proposed criterion of 30ppb). Predicted SO_2 levels (inclusive of background levels) were up to 3ppb for the 1-day SO_2 (compared to the proposed criterion of 80ppb) and up to 1.5ppb for the annual average SO_2 (compared to the proposed criterion of 20ppb).

An inventory of project greenhouse gas (GHG) emissions was prepared for the Project. The primary sources of GHG emissions include the on-site diesel-fired power station, heavy vehicle transport, and vegetation clearing prior to mining. The estimated total GHG emissions at 15Mdptpa, 30Mdptpa and 50Mdptpa production rates are 182kt CO_2-e (carbon dioxide equivalents), 319kt CO_2-e and 508kt CO_2-e per annum respectively. The estimated GHG emission intensity of the Project at the 15Mdptpa production rate is 0.0121t CO_2-e/t bauxite. This estimate includes the GHG emissions that would be generated as a result of the initial vegetation clearing for infrastructure. At higher mining rates there would be greater operational efficiency and the intensity declines to 0.0106t CO_2-e/t bauxite at 30Mdptpa, and to 0.0102t CO_2-e/t bauxite at 50Mdptpa. For comparative purposes, between 2007 and 2009 the GHG emission intensity of the current Andoom and East Weipa operations averaged 0.026t CO_2-e/t bauxite. Rio Tinto aims to progressively reduce the greenhouse gas emission intensity of its' operations and increase energy efficiency through efficient design considerations, GHG awareness training, efficient operation and maintenance of equipment, and regular auditing of energy efficiency.

Noise/Vibration

The residential areas along the Embley River, namely Napranum and the accommodation areas in Evans Landing, would be the nearest sensitive receptors to the Project area. The median current background ($L_{A90(1\ hour)}$) noise levels at the nearest sensitive receptors were found to be 41dB(A) during the day and 38dB(A) during the evening and night. The existing mining operations north of the Embley River contribute to the noise environment in Evans Landing and Napranum.

During the construction phase of the Project the most significant noise sources would be the construction of the proposed port, mine industrial area and the ferry and barge terminals. It is unlikely there would be significant impacts to sensitive human receptors from these activities due to the distance of these activities from residential receptors. For example, Napranum, Nanum and Weipa are approximately 4km from the closest mining areas and 40km from the Boyd infrastructure area and proposed port; Aurukun is approximately 15km from the closest mining areas and 35km from the Norman Creek infrastructure area. However, underwater noise generated by piling has the potential to affect marine animals. It is anticipated that the marine construction activity would temporarily deter most turtles and marine mammals from the immediate area. For precautionary purposes, it is proposed that an exclusion zone be established and monitored by an observer around pile driving activities and that a soft start approach be undertaken prior to normal pile driving. Normal pile driving would not be conducted while threatened marine fauna species are indentified within the nominated exclusion zone. The extent of the exclusion zone would be defined based on further literature review and quantitative analysis of the potential underwater noise impacts from pile driving relating to threatened marine fauna. The final extent of the exclusion zone would be defined in consultation with DSEWPaC.

The proposed noise level criteria for the Project have been derived taking into consideration the acoustic quality objectives for health and wellbeing as well as the control of background creep, described in the *Environmental Protection (Noise) Policy 2008* (Qld) (EPP (Noise)). Noise modelling was conducted for the 50Mdptpa production rate (which is likely to produce the highest noise levels) for typically adverse meteorological conditions. The modelling demonstrated that operational noise levels from mining and barge/ferry operations, including low frequency noise levels, at 50Mdptpa, are expected to comply with all proposed noise level objectives and criteria in Weipa, Napranum and Aurukun during the day, evening, night and night with wind.

The manufacturer's sound power level specifications for major equipment items would be considered when purchasing equipment. A noise monitoring campaign would be conducted after operation commences to validate the noise model. If actual noise levels exceed applicable noise limits, action would be taken to reduce noise levels.

Blasting is not proposed, therefore there would be no impact from blasting noise, ground vibration, or flyrock.

Cultural Heritage

The WCCCA is a registered Indigenous Land Use Agreement (ILUA) (QIA2001/002) under the *Native Title Act 1993* (Cwlth) between RTA, the State of Queensland and relevant Indigenous parties. The *Aboriginal Cultural Heritage Act 2003* (Qld) recognises ILUAs as a mechanism for managing cultural heritage as long as cultural heritage is included in the ILUA (as it is in the WCCCA). The WCCCA provides for a system of cultural heritage management over the Project area. This agreed process for identifying, assessing and managing places of cultural heritage significance satisfies the requirement of the *Aboriginal Cultural Heritage Act 2003* and meets Queensland legislative requirements for any new permits or approvals required for Project development works. The WCCCA requires RTA and Traditional Owners to establish mutually agreed plans for each commercial activity (including mining) that may have an impact upon Indigenous cultural heritage.

Under the auspices of the WCCCA, six cultural heritage surveys have been completed in the Project area. The areas surveyed included, but were not limited to, the proposed port, Boyd

and Norman Creek mine infrastructure areas and tailings storage facilities, the proposed barge/ferry terminal at Hey Point, the infrastructure corridor and Dam C. The surveys to date have documented archaeological sites totalling 538 scarred trees, 23 surface stone artefact scatters (with a total of 43 artefacts), and 111 shell middens. Previous anthropological fieldwork, undertaken prior to the six cultural heritage surveys, has identified 15 places of cultural significance to Traditional Owners (ethnographic sites). Many of the flora and fauna species in the area have significant cultural heritage value for Traditional Owners. These values have been discussed with Traditional Owners and documented in cultural heritage survey reports.

Results of archaeological surveys indicate that 82.5% of scarred trees, 88.4% of stone artefacts and 100% of shell middens and ethnographic sites are located outside of the infrastructure footprint and would not be affected by the Project. The remaining sites inside the footprint may be affected during construction of the Project. The results of archaeological surveys suggest that scarred trees are the site type mostly likely to be impacted by the proposed Project. Recorded shell middens are located outside of the areas for proposed facilities and future mining. Other site types are typically found in the riparian vegetation zone around watercourses, the coastline and significant vegetation such as thickets of vine forest. The majority of Project facilities are situated outside of this riparian vegetation zone. Measures to mitigate impacts on cultural heritage sites would be developed in consultation with Traditional Owners.

The majority of known places of cultural heritage significance are outside future mining areas, although access to some of these places may be affected by mine development. RTA would initiate discussions with the Western Cape Communities Coordinating Committee (WCCCC) and the Traditional Owners to establish separate heritage action plans for each location and incorporate these into the Community, Heritage and Environment Management Plan (CHEMP).

RTA would work with Traditional Owners and the relevant WCCCC sub-committee for the selection and appointment of consultants and development of the scope of ethno-botanical and ethno-faunal studies of the Project area. Information from such studies would be incorporated into management arrangements for the Project area. RTA would also evaluate options to work collaboratively to develop a knowledge database of flora and fauna species of cultural significance in the region.

Further management work would be undertaken, in consultation with Traditional Owners and in accordance with the WCCCA process, to fully assess the impact of the proposed Project on Indigenous cultural heritage and develop mitigation strategies where required. This would include progressive detailed surveys of all areas identified for future development.

Through consultation with Traditional Owners and the WCCCC SoE Sub-Committee, a scope and agreed timeframe for the development of a CHEMP is being prepared. The CHEMP would provide a long-term strategy for the management of land access, fire, flora and fauna, signage, weeds, environmental monitoring and further documentation of places of cultural heritage significance.

Searches of local government, state and national heritage registers and lists found there are no registered non-Indigenous heritage sites located within the Project area. Archaeological surveys have identified seven non-Indigenous heritage sites. The majority of these sites appear to be associated with early exploration drilling for bauxite, extending back to the 1950s and 1960s. The sites include a disused airstrip, sawn log crossings of creeks and remnants of drilling camps, and all have low local significance. The Project area as a whole has been assessed as being of moderate local significance, based on both the social significance of the landscape to the local Indigenous people (being part of the original Weipa Aboriginal Reserve), and the historic significance of the area to non-Indigenous and Indigenous people alike. Some house stumps from a small satellite Aboriginal mission near Hey Point were located in the 1990s but could not be relocated during a recent survey. This area is not with the Project area.

Neither the identified non-Indigenous heritage sites, nor the Project area as a whole, are assessed as being of state or national significance, or as being of sufficient significance to warrant protection or the constraint or restriction of any proposed activities.

In the event that previously unidentified cultural heritage sites were located within the Project area during the course of mining activity, a six-step unanticipated discovery process would be implemented.

Visual Values

The Project area is predominantly a homogenous, relatively-flat bauxite plateau landform covered by 25 to 35m high Darwin Stringybark woodlands and is mostly undisturbed, apart from vehicle tracks and lines cleared for exploration drilling. Bauxite cliffs from 7 to 20m high occur along various parts of the coastline and form an aesthetically prominent landscape.

The Project area is situated in a remote location and is not easily accessible from surrounding communities. There are no gazetted public roads that traverse the Project area south of the Embley River and hence no viewpoints accessible from gazetted public roads. There are no permanent residences in the Project area and the nearest communities are located away from the main Project components. Major Project components (e.g. the proposed port) are not visible from Traditional Owner outstations; however they may be visible while travelling en route to these areas.

The primary viewpoint of the Project is from coastal and estuarine waters. The Gulf of Carpentaria waters adjoining the Project area, and estuaries within the Project area, are used by professional, recreational and tour-guided fishing groups. Although the proposed port infrastructure would be directly visible from vessels using Gulf of Carpentaria waters the visual impacts are anticipated to be low, owing to the height of the natural cliffs and vegetation and the transitory nature of visits to the area.

Visual impacts of the stockpile and plant areas, as well as topographic changes associated with mining, are considered to be low due the setback distance from the coastline, the retainment of vegetation buffers and the lack of visual receptors.

Waste Management

The major sources of waste from the Project are:

- green waste from clearing of vegetation ahead of mining;
- dredged material from port and barge/ferry terminals;
- tailings from the beneficiation plant;
- general waste such as food scraps, paper, plastic, rags, cans and glass;
- regulated waste such as hydrocarbon waste, detergents, solvents, batteries and tyres;
- scrap metal;
- sewage effluent and sludge;
- ballast water; and
- ship waste.

The adopted waste strategy incorporates the waste minimisation hierarchy and would ensure appropriate waste monitoring, tracking and reporting.

Consideration would be given to the selective extraction of structural grade timber prior to mining, where practicable and where the timber can be beneficially used. Green waste would be pushed into windrows and burnt.

Tailings would be stored in tailings storage facilities constructed on mined areas near the Boyd and Norman Creek beneficiation plants. Geochemical analysis indicates the tailings are not hazardous. The tailings storage facility design is based upon the *Guidelines on Tailings Dam Design, Construction and Operations* by the Australian National Committee on Large Dams.

Colour-coded and labelled bins and storage areas would be used to segregate and collect general waste, recyclables and regulated waste. General waste would be collected regularly and transported for disposal at the licensed Weipa Waste Management Facility at Evans Landing (also known as the Evans Landing landfill). Regulated waste would be removed from site for appropriate treatment and/or disposal by a licensed regulated waste contractor.

The sewage treatment plants (STPs) would be designed and operated to treat water to meet Class A Recycled Water quality, as defined in Schedule 3D of the *Public Health Regulation 2005* (Qld). Treated effluent would be recycled on-site for process water, dust suppression, landscape watering or other uses that are appropriate for the quality of water produced. Sewage sludge drying pits would be capped and remediated at the end of the Project life.

All vessels owned and contracted by Rio Tinto would manage ballast water through a Ballast Water Management Plan which would comply with the Australian mandatory requirements and the *International Convention for the Control and Management of Ships' Ballast Water and Sediments*. RTA would complete baseline monitoring followed by three-monthly mussel larval monitoring in the vicinity the new port when overseas ships are utilised.

Ships would not generate substantial volumes of wastes at the site as most ships visiting the proposed port would have onboard incinerators. Waste from Australian vessels would be managed with the site's operational waste management system. Cans, bottles, ash from the incinerator, and any other inert waste may be removed from an overseas ship following inspection by AQIS officers and then disposed of at Evans Landing landfill. Most ships visiting the proposed port would have onboard STPs. Ships' sewage would be managed in accordance with the *Transport Operations (Marine Pollution) Act 1995* (Qld) and *Regulation 1995* which regulates the discharge of sewage in coastal waters. Where required, facilities would be provided to allow sewage to be pumped out for treatment. Ships would either be required to retain any oil-contaminated slops and washings on board or facilities would be provided to remove and treat oil-contaminated water.

A Dredge Management Plan, which would be developed and approved as part of a sea dumping permit, would be implemented to manage spoil disposal from dredging operations associated with the construction of the port and ferry/barge terminals.

Transport

Road access to the Weipa area is currently by way of the Peninsula Developmental Road (PDR). The road network in the vicinity of the Project is largely undeveloped, with vehicle access restricted to minor vehicular tracks. Current road access to the site is from the PDR via Aurukun Road, Beagle Camp Access Road, Pera Head Access Road, and Amban Access Road. The PDR is largely unsealed. The unsealed sections can be rough and corrugated, and during the wet season, the road is prone to closure. Aurukun Road connects the township of Aurukun with the PDR. It is largely unsealed and is subject to the same safety hazards as the PDR. Between Napranum and Weipa, the PDR is also known as Kerr Point Road and John Evans Drive and is a sealed two lane road. It is the main thoroughfare for employees travelling from Weipa to work at RTA's East Weipa operations.

Prior to construction of the barge and ferry terminals and new Mine Access Road, the main access to the site, including deliveries of aggregate from the Archer River Quarry, would be from the Peninsula Developmental Road (PDR) via Aurukun Road, Beagle Camp Access Road, Pera Head Access Road, and the Amban Access Road,. The predicted impact on the PDR and Kennedy Highway during this time is negligible. However, increases in traffic volume are predicted for roads with lower background levels, including a predicted 23% increase for the Aurukun Road. While this increase may seem significant, in absolute terms the total daily traffic, including that generated by the Project, is considered to remain at very low levels.

Once the new barge/ferry terminals and Mine Access Road are established, primary access to the site would be via the proposed barge/ferry terminals on the Embley and Hey Rivers. Once construction is completed and production commences, there would be limited pavement impact on the Aurukun Road, the PDR, and Kennedy Highway as it is unlikely that heavy vehicles would be using roads external to the site.

The following roads would experience an increase in pavement impacts of more than 5% during some stages of the Project:

- the PDR between the Archer River Quarry and the Aurukun Road turnoff during the delivery of aggregate;
- the PDR between Weipa and the Aurukun Road turnoff prior to construction of the barge/ferry terminals and Mine Access Road;
- Kerr point Road and John Evans Drive prior to construction of the barge/ferry terminals and Mine Access Road, and during operations at 50Mdptpa; and
- Aurukun Road between the PDR and the Access Road turnoff during the construction phase.

RTA proposes that the intersections for entry to the Hornibrook ferry terminal and Humbug barge terminal be upgraded prior to the commencement of operations.

Materials would be brought in via the Aurukun Road only when the road is declared open by the Police and Department of Transport (i.e. not during wet season closures). Heavy vehicle usage along the PDR to Weipa would also largely occur only during the dry season. RTA would repair any damage caused by Project-related traffic on these roads.

Bauxite shipments would commence from the proposed port once the Boyd beneficiation plant is commissioned. The shipment of bauxite through the Port of Weipa would reduce when mining operations cease at East Weipa. Deliveries of cargo and fuel would continue to the Port of Weipa. The volume of cargo and fuel deliveries are expected to increase 20% during the construction phase and more than double at 50Mdptpa, compared to the current volume of deliveries for the existing Weipa operations.

The proposed mooring area for ships is in an area of the Northern Prawn Fishery utilised by the commercial trawlers. The area is also utilised for recreational fishing. Fishing vessels are permitted to operate within mooring areas. Only a small proportion of available fishing ground would be temporarily unavailable while vessels are anchored in the area.

The Project would not require changes to airport or rail infrastructure at Weipa.

Consultation

The following groups and individuals were identified as stakeholders in this Project and were provided with the opportunity to participate in the consultation process:

- Federal, state and local government agencies and services providers including the Weipa Town Authority (WTA);
- Non-government organisations and local community groups;
- Traditional Owners and other Aboriginal groups;
- Industry, local business and service providers operating throughout the Western Cape region;
- Recreational and professional fishing groups;
- General public and residents of local communities in Aurukun, Napranum, Weipa and Mapoon;
- Regional pastoral lease holders and managers; and
- RTA and local contractor employees based on the Western Cape.

The following consultation tools were used:

- Project DVD for use during, and as follow-up to, individual and group briefings and during public displays;
- Project newsletters and feedback forms;

- Free-call number answered in Brisbane by SoE Project staff;
- Direct stakeholder contact (including telephone calls and face-to-face meetings);
- A webpage on the Rio Tinto Alcan website which provided information on the Project;
- RTA employee communications;
- Public information sessions and displays; and
- Advertisements to solicit public comment on the Draft Terms of Reference for the EIS.

The feedback provided during the consultation process was considered in the Project's social impact assessment (SIA) and the key issues raised during the consultation were considered during Project planning and design.

Across all stakeholder groups the issues and opportunities of greatest significance were:

- traffic/transport on the proposed new access road to the Project;
- land and sea management;
- community consultation and engagement;
- employment, training and educational opportunities;
- breakdown in community cohesion;
- water supply dam construction;
- opportunities for business development; and
- workforce arrangements.

In addition, there are a number of other issues which, while not key issues for local stakeholder groups as identified during the consultation meetings, are issues of importance to indirectly affected stakeholders such as State and Commonwealth government departments and agencies. These other issues of relevance to government stakeholders are:

- demographic changes;
- economic impacts on the local economy;
- housing and property values; and
- cumulative impacts.

These concerns have been addressed in the relevant EIS sections.

The EIS consultation and engagement program will continue throughout the EIS process. Prior to the commencement of construction a comprehensive stakeholder engagement plan for ongoing consultation and engagement will be developed. Interaction with stakeholders who have already been consulted as part of the Project planning phase will continue over the remainder of the EIS process and throughout the construction and operational phases. The WCCCC SoE Sub-Committee and the WCCCC will continue to provide the consultative mechanism for ongoing consultation and engagement with Traditional Owners.

Social Impact Assessment

The local communities that could be affected by the Project include the Aurukun, Mapoon, Napranum and Weipa communities. Extensive community consultation was undertaken as part of this EIS and this information provided the basis for the SIA. Mitigation and management strategies were developed for all issues identified during the SIA consultation.

The most significant concerns expressed were regarding the Mine Access Road (Hey River barge/ferry terminal to the Boyd infrastructure area) and the location of the barge/ferry terminal on the Hey River. The majority of stakeholder groups consulted were concerned about the disadvantages of public access to the Mine Access Road including issues of safety, unauthorised access to traditional lands south of the Embley River, the increased potential for

illegal alcohol transportation, and potential for environmental damage. RTA proposes to restrict access to the barge, ferry and Mine Access Road to persons and vehicles entering the Project area for the purpose of authorised mine-related business. Security measures would be implemented at each terminal.

Daily access and transport from Aurukun to the Project area by road, boat and/or air was raised as an opportunity to improve employment and business opportunities for residents of Aurukun. RTA is committed to facilitate the provision of access and transport for Traditional Owners living in Aurukun and working in the mine. RTA would work with the WCCCC Employment and Training Sub-Committee to identify opportunities for training and employment for residents of Aurukun and ways to provide appropriate access to the mine site. Traditional Owners indicated they would like to see opportunities exist for residents of Aurukun to be employed during both construction and operational phases.

Access to areas on ML7024 and ML6024 with cultural heritage and recreational significance, the protection of coastal and riparian landscapes, and management of land and sea areas were raised by the majority of stakeholders and were considered a high priority. RTA would continue to manage access for Traditional Owners to specific areas, including the three outstations in the Project area at Amban (False Pera Head), Waterfall (near Ina Creek) and Six Ti-Tree (just south of Waterfall). Amban, Waterfall and Six Ti-Tree are generally utilised in the dry season for varying periods. Access would be managed in accordance with RTA's obligations outlined within the WCCCA. This would be monitored on a regular basis in line with the mine plan development, safety requirements during construction and operational phases, and the needs of Traditional Owners of the Project area. RTA would cause as little disturbance as possible to Traditional Owner access and would work collaboratively with Traditional Owners and the relevant WCCCC sub-committee to develop a land access strategy. The strategy would aim to provide access for Traditional Owners both during active and non-active mining periods for areas including Hey Point, Boyd Bay, Pera Head, Amban/Norman Creek and Waterfall/Six Ti-Tree/Ina Creek. RTA is committed to working with Traditional Owners, WCCT and other key stakeholders to establish a program to support caring for land and sea, including assistance with the development and implementation of a ranger program and a permit system for the Project area to protect significant cultural heritage sites and environmental values, and allow controlled access for recreational purposes to the Project area.

RTA remains committed to the existing obligations under the WCCCA with regard to land and coastal management. In response to the issues raised by Traditional Owners, RTA recognises and supports the need for the joint development of a comprehensive CHEMP for the area of the mining lease south of the Embley River. A CHEMP would provide the framework for RTA and Traditional Owners to work together to manage the community, heritage and environmental values of the area covered by the mining lease south of the Embley River in the context of the WCCCA. Such a plan would aim to address, but not be limited to, land access, fire, flora, and fauna, signage, weeds, environmental monitoring and further documentation of places of cultural heritage significance. To address issues related to sea access, RTA would designate a safe passage underneath the proposed jetty for small recreational and charter boat users to prevent the need to travel around the wharf and jetty, in accordance with Maritime Safety Queensland requirements. Access to moorings at Boyd Bay would not be restricted.

Almost all stakeholder groups requested additional information and/or follow-up meetings and indicated the need for ongoing consultation by the Project team during studies and the construction phase. A comprehensive plan for ongoing consultation and engagement would be developed prior to the commencement of construction. This would ensure continuity of engagement with key stakeholders, including Traditional Owners and Western Cape communities, and provide mechanisms to seek further information, provide feedback and raise concerns related to the Project.

Mining is the principal driver of the Weipa economy and the mining workforce is the principal driver of Weipa's population. Based on 2006 census data, mine-related employees and contractors constituted 43% of the total employed workforce in Weipa and about 29% of the town's population of 3,096.

Throughout the consultation process, employment and training was raised by almost all stakeholder groups as an opportunity for the people of the region arising from the Project. Employment was a key consideration for Traditional Owners in particular. RTA would continue to work with the local communities to invest in employment and training to create a locally-based labour pool with the appropriate skill sets and knowledge to meet the particular employment needs of the Project. RTA would continue initiatives targeting pre-work development, employment and training for local Indigenous people. As part of the Project RTA would:

- continue to actively participate as a member of the Regional Partnership Heads of Agreement (RPA) Steering Committee, WCCCC and Ely Coordinating Committee to develop and implement pre-employment and job-readiness programs to support local Indigenous employment across the Western Cape region;
- develop and implement culturally-appropriate recruitment practices for positions at all levels and across various disciplines within the operations;
- develop and implement programs and services to support the retention of Indigenous employees including mentoring and employee and family support strategies that aim to address the root causes of socio-economic disadvantage;
- develop and implement long-term career planning strategies, including professional development and leadership programs for local Indigenous employees;
- in collaboration with Traditional Owners, continue to deliver cross-cultural awareness programs for all employees and contractors, including curriculum with specific reference with Wik and Wik Way traditional culture and values;
- proactively consider tenders for Project contracts that involve local Indigenous people and/or local Indigenous enterprises. This may include joint ventures, direct employment, training opportunities, equipment usage or cooperative arrangements with local Indigenous people and enterprises; and
- provide a supportive career development pathway for local Indigenous people and youth, including traineeships and apprenticeships across a range of disciplines during the construction and operational phases of the Project.

RTA also proposes to address any potential skills shortages and labour impacts in the region by working collaboratively with various State and Commonwealth Government agencies, regional stakeholders (including TAFE and other training and education providers) and job network provider to build a locally based skilled labour pool for construction and operational phases of the Project.

Law and order and alcohol and substance abuse were key issues raised during consultation meetings with a range of stakeholders. A number of mitigation strategies would be implemented to address these issues. A range of control measures to restrict unauthorised access to the mining lease would be implemented. RTA would implement strict policies for employees and contractors in relation to fitness for work, including alcohol and other drugs, with strict pre-employment medical programs and an ongoing random drug and alcohol testing regime. RTA would also continue to support the implementation of alcohol management plans for each community, with inclusion of this information in employee and contractor induction programs. Strategies to ensure an effective response to incidents and to raise awareness of regional law and order and alcohol management initiatives would be developed in consultation with RTA, the Queensland Police Service and other government agencies.

There was concern expressed by both Indigenous and non-Indigenous stakeholders that the construction of dams would potentially have a negative impact on sensitive environmental areas, areas of cultural heritage significance, and recreational fishing. RTA would consult with Traditional Owners to explore ways for ongoing involvement in environmental monitoring, biological surveys and management of Dam C during operations, and ongoing consultation with Traditional Owners would be undertaken to investigate potential post-mining land uses associated with Dam C. To minimise effects on fish populations RTA proposes to design the

dam spillway to allow fish passage in times of overflow, and environmental releases would occur from the dam to ensure the timing of flow downstream matches natural timing. It is not expected that there would be a significant impact on the downstream environment.

Wik and Wik Way Traditional Owners, shire councils, local businesses and service providers expressed strongly their view that they wish to take advantage of potential business opportunities available through the Project. In order to continue supporting the development of Indigenous businesses in the Western Cape, particularly as it relates to the Project, RTA would:

- continue to work collaboratively with key regional stakeholders, including the WCCT, Western Cape Chamber of Commerce and the Regional Partnership Steering Committee to identify and support the ongoing development of Indigenous businesses through the region;
- examine applicable contracts for local and Indigenous business opportunities, including the breakdown of larger contracts into smaller jobs to increase the potential opportunities for awarding contracts to local providers of goods and services;
- work collaboratively with the WCCT and Traditional Owners to identify and pursue all social, commercial and economic development opportunities associated with the Project;
- provide updates to the WCCT on the status of Indigenous business spending across the Weipa operations in line with RTA's existing reporting requirements for employment and training; and
- in collaboration with key local and regional stakeholders, identify opportunities to support and implement a range of business development programs and support services.

RTA, through its membership of the Chamber of Commerce, would continue to monitor the impact of its activities on local businesses and work with businesses to address concerns, where possible. Local businesses would be provided with relevant information on future opportunities that arise from RTA's proposed development activities.

A number of stakeholders were concerned about the construction camp having a "wet" mess (i.e. serving alcohol) and that, unless the canteen is tightly regulated, the illegal transport of alcohol into communities with alcohol bans could escalate. There was also concern workers may leave the camp and access areas with environmental and cultural significance and potentially cause damage to these locations. The wet mess would be licensed for the responsible service of alcohol to camp occupants only. The consumption of alcohol would be regulated and confined to the wet mess and designated areas within the camp. Any activities outside the camp would be controlled via a permit system developed in collaboration with Traditional Owners in order to minimise any potentially adverse impacts on the places of environmental and cultural heritage significance.

The Project's construction workforce would be accommodated in an on-site camp and negligible effect on the local housing market is expected. The population projections indicate that when production commences at SoE, Weipa would have a population of 3,500, marginally smaller than populations in 2007–2008 (4,000). At a SoE production rate of 30Mdptpa, when Andoom production is likely to have ceased, the overall operational workforce would decrease because the SoE Project has thicker bauxite reserves and shorter average haul distances and hence higher labour productivity than Andoom. At a SoE production rate of 30Mdptpa the Weipa population is projected to be about 3,300, slightly higher than it was in 2006. Future demands on infrastructure and government services are expected to be no higher than in recent years.

At 50Mdptpa, the population of Weipa is projected to be approximately 400 above the peak of 2007–2008. Such a population rise would require development of more residential land and housing, industrial land, and provision of expanded government services. RTA would work with Weipa Town Authority (WTA) to develop additional subdivisions as required to allow for the

construction of additional houses. RTA would assist WTA with industrial lot developments if required.

Economic Environment

Based on the results of economic modelling, the potential range of annual economic impacts during the construction and operation phases is estimated to be:

Construction Phase (for 15Mdptpa production capacity)

- Direct employment averages more than 300 per annum over three years;
- Indirect employment of approximately 179 in the local area, 395 in the FNQ region, 632 state-wide and 705 nationally;
- Direct financial contribution of $264 million locally, $527.9 million in the FNQ region, $989.9 million in Queensland and $1,319.8 million nationally;
- Indirect financial contribution of $201.7 million locally, $612.2 million in the FNQ region, $1,829.3 million in Queensland and $2,828.2 million nationally.

Operations Phase – 15Mdptpa production scenario

- Direct employment (including contractors) of approximately 500 in local region;
- Indirect employment of approximately 390 locally, 788 in the FNQ region, 1,170 state-wide and 1,771 nationally;
- Direct annual financial contribution of $575 million across the local, regional, Queensland and national economies;
- Indirect annual financial contribution of $96 million locally, $182 million in the FNQ region, $257 million in Queensland and $423 million nationally.

In addition to direct employment, opportunities are likely to arise as a result of the Project supporting existing local businesses and providing opportunities for new business development. A number of indigenous and non-indigenous business development, training and employment opportunities and mitigation strategies relating to strategies for local participation were identified through the SIA.

RTA is a party to the Regional Partnership Heads of Agreement, which includes a statement of intent by the parties to improve opportunities for business development employment and training of Indigenous people in the Western Cape region. RTA would continue to fulfil these commitments and monitor and evaluate progress of the various projects and activities and their impact on the local social-economic environment.

The WCCCA provides a range of benefits, including employment and training, and RTA's current obligations under the WCCCA related to the Weipa operations would also apply to the Project.

The disruption to the local economy by the construction and operation of the Project is likely to be minimal. Operations at the Project are purely a continuation of the mining practices currently being undertaken, and should have a negligible impact.

There has been no cattle production/agriculture in the Project area for many years and, as such, there would be no direct impact on agricultural land uses within the Project area. No adverse impacts are expected on surrounding land uses.

Health and Safety

Health and safety risks associated with the SoE Project have been identified through the use of a preliminary Project hazard analysis and risk assessment, and controls identified to manage these risks. The control strategies address legislative and Australian Standard requirements where applicable.

The risk profile for the proposed facilities is generally "low" or "moderate".

RTA would implement the existing CLASSIC Health Safety and Environment (HSE) Management System for the Project and the existing MarineSafe system at the proposed port. Both systems incorporate occupational health and safety standards that are currently in use at all Rio Tinto operations, and provide the basis for effective management of employee and contractor health and safety.

Hazard and Risk

The Project would utilise a number of substances (e.g. fuel and oils) that are regulated by the Australian Code for the Transport of Dangerous Goods by Road and Rail and are considered hazardous. The storage, handling and use of these substances would be in accordance with current Australian Standards and industry codes of practice.

The RTA risk management system has been developed in accordance with the Australian Standard for Risk Management (AS/NZS 4360:2004). The preliminary Project HSE risk register was compiled by Rio Tinto to identify potential hazards, accidents, spillages and abnormal events occurring during the Project. There were 13 "high", 54 "moderate", and 11 "low" risk scenarios identified. There were no critical risks.

Further detail on the "high" risk scenarios has been incorporated into the relevant sections of the EIS, including proposed prevention or mitigation measures.

There are no sensitive receptors, such as kindergartens, schools, hospitals, aged care facilities, residences, or commercial places close to the mining, processing or port areas. As such, there are no hazards identified for the Project that could impact public health values in the short or long term.

The existing Weipa operations maintain and implement, as required, a detailed Business Resilience and Recovery (BRR) Plan. The BRR Plan would be updated to include the Project area and updated regularly throughout each stage of the Project.

Cyclones are one of the highest risks to the Project, due to the frequency of their occurrence in the Gulf area and their potential severity. RTA's current Cyclone Emergency Procedure, which aims to minimise personal injury and damage to property, would be adapted to include the SoE Project.

Cumulative Impacts

Cumulative impacts are impacts that arise from the interrelationship of residual Project impacts and impacts of the SoE Project in combination with other current proposed mining projects.

In March 2007 the State of Queensland entered into a development agreement with the Aluminium Corporation of China Limited (Chalco) to develop the Aurukun Bauxite Project. Chalco was granted mineral development licence MDL 378 located immediately to the east of RTA's ML7024 (refer **Figure A**). A bauxite mine producing 6.5Mdptpa was proposed, with product to be transported by conveyor across ML 7024 for shipment from a new port located close to Boyd Point. The proponent proposed to accommodate a fly-in fly-out workforce on-site. In June 2010 the Queensland government announced that the development agreement had come to an end and there is currently uncertainty about the future development of the Aurukun Bauxite Project.

RTA liaised with Chalco during the planning phase for their proposed project to discuss any potential for co-location and/or sharing of certain infrastructure. Where possible, and subject to commercial agreement, RTA will seek to minimise environmental and property impacts in the

event that the Aurukun lease is developed in the future. Some impacts could potentially be mitigated by the following:

- establishment of a common infrastructure corridor for RTA's water pipeline, transmission line and overland conveyor (from the Norman Creek plant) and the Aurukun Bauxite Project's overland conveyor to the port; and
- co-location of port and stockpile facilities.

Cape Alumina Pty Ltd holds two Exploration Permit – Minerals (EPMs) over the Pisolite Hills resource area (EPM 14547 and EPM 15278 situated 50km north-east of Weipa), with an additional EPM to cover a barge loading facility (EPM 15984) (refer **Figure A**). The Pisolite Hills Project as originally proposed in 2008 would have nominally produced approximately five to seven Mdptpa of bauxite for 10 to 15 years. Product would have been trucked across ML 7024 to a barge-loading facility on the coast. RTA does not currently conduct mining activity or have infrastructure in the vicinity of the proposed haul road. A fly-in fly-out workforce was proposed, with accommodation to be provided in a camp on-site. In July 2010 Cape Alumina announced that the proposed Pisolite Hills Project was no longer viable due to the declaration of the Wenlock River Basin as a Wild River area.

Oresome Australia Pty Ltd is the proponent for the Urquhart Point Mineral Sands Project. The proposed project area is within mining lease application MLA 20669, north west of the SoE Project's Hey Point mining area (refer **Figure A**). The Urquhart Point Mineral Sands Project is located outside of the catchments affected by the SoE Project area. The proposed project would involve excavating sand ridges using slot mining, processing 700,000 to 800,000t of sand per annum to produce heavy mineral sands, and shipping approximately 50,000t of heavy mineral sands product per annum. The project life would be four to six years with a target commencement date of 2012.

There is potential for cumulative impacts to arise from residual impacts of the SoE Project in combination with impacts of other current possible future mining projects, in relation to surface water, groundwater, marine ecosystems, flora, aquatic ecosystems, roads, shipping and social impacts.

The proposed 6.5Mdptpa Aurukun Bauxite Project is within the catchment of the Ward River estuary. While there are uncertainties as to whether this project would proceed, the operation of both projects simultaneously could give rise to a cumulative impact on Ward River flows and catchment hydrology in the Ward River catchment. If the Aurukun Bauxite Project surface water demands were met from a dam on a tributary of the Ward River, the cumulative overall decline in mean annual discharge to the Ward River estuary would be very minor (<1%) and well within natural seasonal variation. Also, mining disturbance in the Ward River catchment would have a very minor change on the annual discharge from the overall Ward system (-0.6% at maximum mining impact; -1.2% post-closure).

Given the proposed mitigation strategies, in particular the environmental buffer system, there are unlikely to be significant cumulative impacts on aquatic ecosystems from impacts on catchment hydrology and river flows in the Ward River catchment.

Cumulative impacts on surface water quality in the lower Ward River system arising from activities associated with the Aurukun Bauxite Project and the SoE Project occurring simultaneously are expected to be low.

Abstraction of groundwater from the Gilbert River Formation and Garraway Beds artesian aquifers is to be investigated as a potential water supply source for the Aurukun Bauxite Project, which has the potential to cause cumulative impact on artesian aquifers in the region. Modelling results for the SoE Project indicate that abstraction rates could be increased by nearly 6GL above the proposed abstraction rate and still comply with RTA's current Water Licence conditions in relation to maximum relative drawdown.

The area of Darwin Stringybark (RE 3.5.2) that would be cleared by the Pisolite Hills Project and the Aurukun Bauxite Project is not publicly available but has been estimated. If all existing and proposed projects were fully developed, the subregional extent of RE 3.5.2 would be reduced to

approximately 89% of its former known distribution. The total clearing would not cause RE 3.5.2 to become regarded as "of concern" or "endangered" under the *Vegetation Management Act 1999*.

The reduction in spatial extent of non-Darwin Stringybark vegetation types within the Project area and the subsequent impacts on threatened flora occurring within these vegetation types, as a component of a possible larger cumulative reduction across the Cape York Bioregion (from other possible future projects), is anticipated to be minimal.

The PDR and a part of the Aurukun Road may receive a cumulative impact from both the SoE Project and the Aurukun Bauxite Project, if the Aurukun Bauxite Project were to proceed and both projects were to operate simultaneously. However, this is likely to occur only if the Aurukun Bauxite Project is in the construction or operational phase during the initial construction phase of the SoE Project. Cumulative impacts would be mitigated through repair or upgrade of the relevant part of the Aurukun Road.

If the Aurukun Bauxite Project constructed and operated an additional port facility near the proposed SoE Project port, the operation of two ports may result in cumulative impacts in terms of bulk carrier interactions and vessel interactions with commercial and recreational fishing vessels. The construction and operation of two ports may also have potential cumulative impacts on corals at Boyd Point, marine turtle nesting and the off-shore marine environment (depending on where the Aurukun Bauxite Project dredged spoil was disposed). Capacity may be provided at the SoE Project port for third parties, following agreement on suitable commercial terms. Such an arrangement would simplify the management of vessel movements compared to operating two ports and reduce cumulative impacts.

One matter raised consistently by stakeholders, in relation to cumulative impacts that would arise should more than one project proceed, was concern about the potential for the establishment of a road connection between the Project's Mine Access Road and the Aurukun Bauxite Project, thus facilitating the transport of illegal alcohol. A small number of stakeholders identified this as an opportunity for residents in Aurukun to obtain easier access to Weipa-based goods and services. There are also significant non-Project related cumulative impacts associated with current government services and programs currently being implemented in Aurukun. RTA would, by liaising with any other adjacent project proponents, endeavour to identify cumulative impacts and opportunities associated with employment, training and business development for the local communities. RTA would also seek to co-ordinate its' programs with others, including government programs and services currently being implemented in the region, and, where appropriate, would partner with the relevant Government agencies.

Environmental Management and Monitoring

Environmental protection commitments and proposed environmental authority conditions have been included in the relevant sections of the Environmental Management Plan (EM Plan).

The environmental monitoring for the SoE Project would include air quality, stream flow, surface water and groundwater quality, groundwater levels, noise, rehabilitation success, erosion, weeds, waste volume and type, sewage treatment plant water quality, community complaint records and cultural heritage assessments. The EM Plan outlines the Project's environmental monitoring program including monitoring sites, parameters and their frequency of measurement, and monitoring procedures and records.

Environmental Impact Statement

for South of Embley Project

Section 1
Introduction

1 INTRODUCTION

RTA Weipa Pty Ltd (RTA) and its parent company Rio Tinto Aluminium Limited (formerly named Comalco Aluminium Limited) have collectively mined and shipped bauxite from the existing Weipa operation since 1963. Weipa is located on the western side of Cape York on the Gulf of Carpentaria in northern Queensland, approximately 600km north-west of Cairns (refer **Figure 1-1**). RTA holds mining lease (ML) 7024 (granted 1 January 1958) pursuant to the *Commonwealth Aluminium Corporation Limited Agreement Act 1957* (Qld) (Comalco Agreement Act), a Queensland "Special Agreement Act" and ML6024 (granted 25 July 1985) pursuant to the Comalco Agreement Act and *Mineral Resources Act 1989* (Qld).

RTA is currently mining the East Weipa and Andoom deposits located on ML7024 north of the Embley River. RTA is also mining from the adjacent Ely bauxite deposit (on ML7031) held by Alcan South Pacific Pty Ltd (acquired by Rio Tinto in 2007) under an agreement. Mined bauxite is trucked to one of two beneficiation plants located at Lorim Point and Andoom, respectively. Product bauxite is railed from Andoom to Lorim Point and conveyed to RTA's stockpiles prior to shipment from the Port of Weipa (refer **Figure 1-2**).

The northern bauxite reserves are gradually depleting, and with continuing demand for bauxite RTA has undertaken extensive drilling programs on ML7024. Significant bauxite reserves have been identified on the portion of ML7024 that lies south of the Embley River which could sustain a mining operation for about 40 years, depending on annual production rate.

Due to the Embley River estuary, development of the reserves south of the Embley River poses logistical challenges to the continued use of existing Weipa infrastructure. The proposed Project, referred to as the South of Embley (SoE) Project (or "the Project"), consists of the construction and operation of a bauxite mine and associated processing facilities, barge and ferry terminals and a port. The Project involves a staged increase in production up to 50 million dry product tonnes per annum (Mdptpa). The initial installed capacity is subject to ongoing feasibility studies but is likely to be either 15Mdptpa or 22.5Mdptpa. Actual production rates and the timing and size of capacity expansions would depend on market conditions.

This Environmental Impact Statement (EIS) has been prepared to identify potential environmental and social issues associated with the Project and set out proposed management measures.

1.1 Project Proponent

The Project would be developed and operated by RTA Weipa Pty Ltd, which is a wholly-owned subsidiary of Rio Tinto Aluminium Limited. Both companies are in the Rio Tinto Alcan product group. Rio Tinto Alcan is one of five product groups operated by the global mining group, Rio Tinto. Rio Tinto Alcan supplies bauxite, alumina and primary aluminium to Australia, New Zealand and export markets. About 37% of Australia's total production of bauxite, 36% of its alumina and 40% of its primary aluminium is produced by Rio Tinto Alcan.

Rio Tinto Alcan's Australian head office for bauxite and alumina is based in Brisbane. Bauxite and alumina interests in Queensland include the existing Weipa mine and the Yarwun and Queensland Alumina Limited alumina refineries in Gladstone. In Queensland, Rio Tinto Alcan also operates the Boyne Smelters Limited aluminium smelter in Gladstone.

RTA Weipa Pty Ltd was registered under the *Corporations Act 2001* (Cth) in 2009 and the bauxite mining assets within ML 7024 and ML 6024 and some ancillary assets were transferred to RTA Weipa Pty Ltd from Rio Tinto Aluminium Limited effective 1 March 2011. The restructure is to replicate the position which exists through the vast majority of the Rio Tinto group (and resources companies generally) where, to provide for corporate and financial flexibility, separate operations are generally held in a special purpose vehicle.

A record of responsible environmental management has been exhibited during more than 40 years of mining bauxite in the Weipa region. Whilst improvement of environmental performance

and outcomes continues, due enquiry indicates that RTA Weipa Pty Ltd, Rio Tinto Aluminium Limited and their Executive Officers have not been the subject of any proceedings under a Commonwealth or State law for the protection of the environment.

RTA has a Health, Safety and Environment Policy that includes commitments to minimise environmental impact and continually monitor and improve the way the company works (refer **Appendix 1A**). As described in **Section 1.9.6**, mining and mining-related activities on ML7024 at Weipa have transitional authorisation under section 616B of the *Environmental Protection Act 1994* (Qld) (EP Act) relating to "Special Agreement Act" mines. RTA has commenced the process to transition to an environmental authority (mining activities) (EA) under the EP Act with respect to ML7024 and ML6024, by way of an application and Environmental Management Plan submitted in February 2010. The grant of application of the EA is pending, however it is anticipated that the conditions are likely to require the current RTA Weipa operations to prepare or significantly revise and submit the following management plans as a minimum:

- Land Use Management Plan;
- Rehabilitation Management Plan;
- Erosion and Sediment Control Plan;
- Water Management Plan; and
- Waste Management Plan.

Following the Coordinator General's assessment of the SoE Project EIS, an application would be made to amend the EA in respect to any requirements particular to the SoE Project, such that the Department of Environment and Resource Management (DERM) may issue the required amended EA under the EP Act for operations on ML7024 and ML6024. Subsequently, the required management plans would be either reviewed to ensure adequacy for the SoE Project or new management plans developed and implemented for the SoE Project, incorporating any relevant conditions of consent.

1.2 Project Description

The Project involves the construction and operation of a bauxite mine and associated processing and port facilities to be located near Boyd Point on the western side of Cape York Peninsula. Boyd Point is approximately 40km south-west of Weipa and 40km north of Aurukun, with the closest mining areas being 4km from Napranum, 15km from Aurukun, and 50km from the nearest cattle station homesteads. The Project area would be predominantly located on a portion of ML7024 south of the Embley River, on ML6024, on certain Strategic Port Land within the Port of Weipa, and offshore dredging and disposal areas (refer **Figure 1-1**).

The Project consists of the following components:

- **bauxite mining** – involving the clearing, salvage of topsoil, stripping of overburden, extraction of up to 50Mdptpa of bauxite, replacement of topsoil and revegetation. Mined areas would be progressively rehabilitated. Refer to **Section 2.4** for a detailed description;
- **bauxite processing** – crude bauxite would be transported using a network of internal haul roads to one of two beneficiation plants (Boyd beneficiation plant, followed by a second plant at Norman Creek). A beneficiation plant separates the bauxite and waste materials through screening, crushing, washing and dewatering. Chemicals are not

used in the process, only water. Fine waste materials would be discharged to tailings storage facilities. Refer to **Section 2.5** for a detailed description;

- **product bauxite stockpiles** – product stockpiles and a stacker-reclaimer would be established adjacent to the port facilities (refer to **Section 2.5.3**);

- **port and ship-loading facilities** – involving the construction and operation of a new port, ship-loading and tug mooring facilities between Boyd Point and Pera Head. Works would include a jetty, berths, ship-loader and dredging of berth pockets and departure areas. Protected moorings for tugs to use during inclement weather would also be constructed alongside the existing Lorim Point east wharf. The initial phase of the new port would have a capacity of 30Mdptpa, increasing to a maximum design capacity of 63Mdptpa when demand requires. The design capacity allows for third parties following agreement on suitable commercial terms. The construction of these facilities will result in the disposal of approximately 6,500,000m^3 of dredged material to sea for the initial phase of the port. Refer to **Section 2.6** for a detailed description;
- **ancillary infrastructure** – involving the construction and operation of a diesel-fuelled power station, workshops, warehouse, administration facilities, package sewage treatment plant, general waste disposal and diesel storage facilities. Refer to **Section 2.7** for a detailed description;
- **water infrastructure** – involving the construction of a water supply dam on a freshwater tributary of Norman Creek (Dam C), with the later construction of a water pumping station on the Ward River, plus pipelines and up to 12 artesian bores. Refer to **Section 2.7.3** for a detailed description;
- **temporary on-site camp for the construction phase** – involving the construction of a facility with up to 630 beds. The existing Evans Landing camp (located on ML7024) would also be used during the construction phase as required. During the operations phase employees would be housed in the existing Weipa community and commute to site on a daily basis via ferry and a new mine access road. Refer to **Section 2.7.1** for a detailed description; and
- **barge and ferry facilities** – involving the construction and operation of a new ferry terminal at Hornibrook Point, a roll on/roll off (RORO) barge facility at Humbug Wharf, and a new barge/ferry terminal on the western bank of the Hey River. These would be used to transport workforce, materials and equipment between Weipa and the Project. Dredged material derived from the construction of these facilities would also be disposed at sea. Refer to **Section 2.7.2** for a detailed description.

The main infrastructure components are illustrated in **Figure 1-3** and **Figure 1-4** and a detailed project description is set out in **Section 2**. The land parcels and tenure within the Project area, including Strategic Port Land, are summarised in **Table 2-1** and shown in **Figure 2-1**.

1.3 Project Rationale

RTA plans to develop a new bauxite mine capable of producing up to 50Mdptpa along an incremental expansion pathway. The EIS has been prepared to assess the impacts of several different levels of production along this pathway: a minimum rate of 15Mdptpa, a maximum rate of 50Mdptpa, and a nominal intermediate rate of 30Mdptpa. However, the actual rates and the timing of production increases are subject to market conditions. The initial production rate is subject to ongoing feasibility studies but is likely to be either 15Mdptpa or 22.5Mdptpa.

The initial phase of mining operations would involve production to substitute depleted East Weipa economic reserves as well as developing third party markets. Production capacity would expand to replace Andoom production once those economic reserves are depleted. Production capacity would thereafter be expanded to 50Mdptpa when market conditions are suitable. The

Project has bauxite reserves capable of sustaining a mine life of approximately 40 years, depending on annual production rate. The indicative production schedule used in the EIS is presented in Table 1-1, however, it should be noted that the timing and size of production increases are subject to market conditions.

Table 1-1 Indicative Production Scenario for EIS

	SoE Production					
	Construction			Minimum rate	Intermediate rate	Maximum rate
Mining Centre / Year*	-1#	-2	-3	1-13	14+	Subject to market
East Weipa (production)	✓			x	x	x
Andoom (production)	✓			✓	x	x
SoE (Mdptpa)	x			15	30	50

* Years and production rates are nominal and subject to change due to market conditions, construction timetables and available economic reserves.

Nominal start date for construction in early 2012, subject to receipt of relevant environmental approvals and Rio Tinto's internal project approvals.

The key objectives of the Project are to:

- extend the life of RTA's mining operations in Weipa beyond depletion of East Weipa and Andoom reserves;
- maintain continuity of bauxite supply to Gladstone refineries and third parties;
- enable increased bauxite production in the Weipa region in response to the rising world demand for this product and to enhance RTA's competitiveness as a bauxite producer;
- continue mining-related employment in the Western Cape region;
- maintain Weipa as the main residential and commercial support base for the Project;
- operate the mine in a manner that has an acceptable impact on surrounding communities and the environment;
- develop and operate the Project in compliance with all relevant statutory requirements; and
- continue to maintain an open and honest relationship with stakeholders.

Extensive resource definition investigations and environmental surveys have taken place in the Project area. It is anticipated that construction would commence in early 2012, following receipt of relevant environmental approvals and Rio Tinto's internal project approvals. The initial construction phase is expected to take approximately three years. The estimated capital cost to establish 15Mdptpa capacity would be approximately $1,450 million. The final cost is subject to completion of feasibility studies.

1.4 Relationship to Other Projects

In March 2007 the State of Queensland entered into a development agreement with the Aluminium Corporation of China Limited (Chalco) to develop the Aurukun Bauxite Project. Chalco was granted mineral development licence (MDL) 378 located immediately to the east of RTA's ML7024 (refer **Figure 1-1**). A bauxite mine producing 6.5Mdptpa was proposed, with product transported by conveyor across ML7024 for shipment from a new port located close to Boyd Point. The proponent proposed to accommodate a fly-in fly-out workforce on-site. In June 2010 the Queensland Government announced that the development agreement had come to an end and there is currently some uncertainty about the future development of the Aurukun Bauxite Project.

RTA liaised with Chalco during the planning phase for their proposed project to discuss any potential for co-location and/or sharing of certain infrastructure. Where possible, and subject to commercial agreement, RTA will seek to minimise environmental and property impacts in the event that the Aurukun lease is developed in the future. Some impacts could potentially be mitigated by the following:

- establishment of a common infrastructure corridor for RTA's water pipeline, transmission line and overland conveyor (from the Norman Creek plant) and the Aurukun Project's overland conveyor to the port (refer **Figure 1-3**); and
- co-location of port and stockpile facilities.

The SoE Project's water supply and power supply are designed to be independent of any other project.

Cape Alumina Pty Ltd holds two granted Exploration Permit – Minerals (EPMs) over the Pisolite Hills resource area (EPM14547 and EPM15278 situated 50km north-east of Weipa), with an additional EPM to cover a barge loading facility (EPM15984) (refer **Figure 1-1**). The Pisolite Hills project as originally proposed in 2008 would have nominally produced five to seven Mdptpa of bauxite for 10 to 15 years. Product would have been trucked across ML7024 to a barge-loading facility on the coast. RTA does not currently have mining activity or infrastructure in the vicinity of the proposed haul road. A fly-in fly-out workforce was proposed, with accommodation to be provided in a camp on-site. In July 2010 Cape Alumina announced the proposed Pisolite Hills project was no longer viable due to the declaration of the Wenlock River Basin as a Wild River area.

The potential cumulative impact from bauxite mining of clearing of regional ecosystems is assessed in **Section 7.9.1**. The potential cumulative impact from water supply infrastructure and potential cumulative impacts to catchment hydrology from bauxite mining is assessed in **Section 5.2.3** and **Section 5.2.4** respectively.

The Project is not expected to give rise to any consequential impacts that require assessment under the *Environmental Protection and Biodiversity Conservation Act 1999* (Cwlth) (EPBC Act).

1.5 Socio-economic Costs and Benefits

The Project is located in the Western Cape Region, which includes the Aurukun, Mapoon, Napranum and Weipa communities. Extensive community consultation was undertaken as part of this EIS and this information provided the basis for the social impact assessment.

Mining is the principal driver of the Weipa economy and the mining workforce is the principal driver of Weipa's population. Based on 2006 census data mine-related employees and contractors constituted 43% of the total employed workforce in Weipa and about 29% of the town's population of 3,096.

The Project's construction workforce would be accommodated in an on-site camp and negligible affects on the local housing market are expected (refer **Section 17.4.9**).

At a Project production rate of 15Mdptpa, RTA's overall workforce (including Andoom) would be marginally smaller than in 2007–2008 and Weipa would have a population of about 3,500, down from just over 4,000 reached in 2007–2008 (refer **Section 16.2.1**). At a production rate of 30Mdptpa, the overall workforce would reduce slightly (due to greater productivity in SoE operations compared to Andoom operations) and Weipa's population is projected to be about 3,330. Future demands on infrastructure and government services are expected to be no higher than in recent years.

SoE mine production would be capable of increasing above 50Mdptpa when market conditions are suitable. Under the 50Mdptpa production scenario, the population of Weipa is projected to be approximately 400 above the peak of 2007–2008. Such a population rise would require development of more residential land and housing, and provision of expanded government services.

The area south of the Embley River is primarily the traditional lands of the Wik and Wik Way people. RTA's existing operations are relatively remote from this area and from Aurukun, the nearest community. The Project would bring development activities much closer to the Traditional Owners and their country. RTA would continue to work with Traditional Owners to facilitate access to country, subject to mine safety requirements. RTA would also continue existing employment, training and business development programs and tailor them to the needs of the Project and community. The potential social impacts of the Project, both adverse and beneficial, and proposed mitigation measures are discussed in **Section 16.**

The economic impacts of the Project are evaluated in **Section 17** and summarised below:

Construction Phase (for 15Mdptpa production capacity)

- Direct employment averages more than 300 people per annum over three years;
- Indirect employment of approximately 179 people in the local area, 395 people in the Far North Queensland (FNQ) region, 632 people state-wide and 705 people nationally;
- Direct financial contribution of $264 million locally, $527.9 million in the FNQ region, $989.9 million in Queensland and $1,319.8 million nationally;
- Indirect financial contribution of $201.7 million locally, $612.2 million in the FNQ region, $1,829.3 million in Queensland and $2,828.2 million nationally.

Operations Phase – 15Mdpta production scenario

- Direct employment (including contractors) of approximately 500 people in local region;
- Indirect employment of approximately 390 people locally, 788 people in the FNQ region, 1,170 people state-wide and 1,771 people nationally;
- Direct annual financial contribution of $575 million across the local, regional, Queensland and national economies;
- Indirect annual financial contribution of $96 million locally, $182 million in the FNQ region, $257 million in Queensland and $423 million nationally.

1.6 Project Alternatives

RTA has been undertaking studies to optimise the Project design. A number of options have been considered, including:

- beneficiation plant location;
- port and stockpile location;
- workforce housing;
- barge and ferry terminal locations;
- power supply;
- beneficiation plant technology
- water demand management;
- water supply;
- initial tailings storage facility establishment; and
- disposal of dredged material.

The option of not proceeding with the Project is not financially feasible as the bauxite reserves will be depleted in RTA's current mining areas leading to the progressive closure of the Weipa mine. Without an alternative source, the Gladstone alumina refineries will lose a viable, ongoing source of bauxite and the town of Weipa will lose a major financial contributor.

The Project is not sterilising other resource opportunities nor displacing existing agricultural or forestry enterprises. **Section 3.7.1** discusses pre-mine land use suitability.

The alternatives considered for major project components are described below.

1.6.1 Beneficiation Plant Location

The continued use of the Lorim Point beneficiation plant (refer Figure 1-2) to process ore mined from the SoE orebodies was evaluated. This option would require the crude ore to be transported on average more than 50km by conveyor or rail to the existing Lorim Point beneficiation plant, including over a 3.5km bridge spanning the Embley River estuary. Irrespective of the transport method selected, the cost of this system, including bridging the Embley River, proved to be cost prohibitive.

1.6.2 Port and Stockpile Location

The port and stockpile alternatives evaluated were:

- use of existing facilities at Lorim Point (northern bank of Embley River, refer **Figure 1-2**); and
- establishment of a new port between Boyd Point and Pera Head (refer **Figure 1-3**).

The use of the existing Lorim Point stockpiles and ship-loader would require all crude ore or product bauxite to be transported on average more than 50km by conveyor or rail to the existing Lorim Point beneficiation plant, over a 3.5km bridge spanning the Embley River estuary.

Irrespective of the transport method selected, or whether the ore was beneficiated at a new SoE-located plant or the existing Lorim Point plant, the cost of this approach (including bridging the Embley River) proved to be cost prohibitive. It should be noted that the new port has been designed to accommodate vessels of up to 185,000 deadweight tonnage (dwt). Dredging of berth pockets and departure areas and sea disposal of dredge material would be required to accommodate these vessels at the new port. The existing Port of Weipa facilities are limited to smaller ships up to 255m in length, 12.3m draft, and 85,000dwt (PCQ 2010). If the existing port were to be upgraded to accommodate the larger vessels, then dredging in the Embley estuary and subsequent disposal of dredged material would also be required.

The proposed new port would be much closer to the centroid of bauxite reserves (refer **Figure 1-3**) and hence would reduce energy usage as it minimises the overall land transportation distance of crude ore and product.

The location of the proposed Port between Pera Head and Boyd point has the closest access to deep water along the coastline south of the Embley River and therefore minimises the required dredge volume.

Two port vessel capacity options were evaluated – a port capable of accepting bulk carrier vessels up to: (a) 185,000dwt and 18.1m draft; and (b) 90,000 dwt and 12.8m draft. The larger vessel capacity option has been selected in order to maximise access to markets. For the purposes of evaluation studies, it has conservatively been assumed that vessel departures are unrestricted by tides and hence the depth of dredging required has been matched to this assumption.

The 185,000dwt vessel option, compared to the smaller vessel option, would require an increased dredge footprint (1,460,062m^2 compared to 135,000m^2), dredge depth, dredge volume (6,500,000m^3 compared to 250,000m^3) and dredging duration. The 185,000dwt vessel option would be likely to have the potential for greater impact on threatened and migratory marine fauna and the Commonwealth marine environment, as a result of the increased dredging. However, the use of larger vessels means that there would be fewer vessel movements during operations and more energy efficient transport of ore (i.e. less diesel used and emissions of greenhouse gases by ships). Neither vessel option would be likely to have a significant impact on threatened and migratory marine fauna and the Commonwealth marine environment.

1.6.3 Workforce Housing

The alternatives evaluated for the operation's workforce accommodation were:

- use existing residences in Weipa/Napranum (refer **Figure 1-2**) and commute daily to the Project site; and
- establish new workforce-only accommodation on-site with a drive-in drive-out and/or fly-in fly-out roster arrangement.

The continued use of Weipa/Napranum was selected as it maximised the use of the existing housing stock and community facilities and services, and minimised change to the social fabric of these communities. The mine's operational workforce would be bussed to and from work daily (refer to **Section 2.7.2**).

The construction workforce would be largely accommodated in a temporary construction camp located on ML7024 near Boyd Bay (refer **Figure 1-3**). This workforce would be predominantly sourced from eastern Australia and would fly-in and fly-out of Weipa when not on roster. The proposed temporary construction camp has been located in a mineralised area that would be later mined. There would be insufficient existing housing in Weipa/Napranum to accommodate the full construction workforce, therefore, additional temporary accommodation would need to be constructed in Weipa/Napranum which may also result in disturbance of existing flora and fauna habitat. Overall, the construction of temporary accommodation near Boyd Bay compared to Weipa/Napranum, would be likely to have similar potential impacts on threatened and migratory fauna and threatened flora. However, the provision of temporary worker-only accommodation on-site would minimise daily travel times and avoid locating a temporary construction workforce within an established township. Neither option would be likely to have a significant impact on threatened and migratory fauna and threatened flora.

The transport infrastructure options evaluated for the movement of personnel to and from site were:

- sealed road from Weipa to the Project site via the Peninsula Developmental Road (PDR) and the Amban Access Road;
- bridge over the Embley River to link Weipa to the Mine Access Road;
- barge carrying both passengers and vehicles to link to the Mine Access Road; and
- passenger ferry to link to the Mine Access Road.

The first option was not feasible due to excessive daily commute travel times. The second option is the least economically feasible due to the high cost of bridging the 3.5km wide Embley River estuary. The passenger ferry was selected in preference to the barge as it minimises travel time and hence reduces the risk of fatigue.

The barge and ferry terminals would be likely to have less potential impact on threatened and migratory fauna and threatened flora compared to the bridge, which would require additional vegetation clearing and piling. None of the options would be likely to have a significant impact on threatened and migratory marine fauna and the Commonwealth marine environment.

1.6.4 Location of Barge and Ferry Terminals

The operational workforce would commute to the site daily by driving to the Hornibrook ferry terminal on the north side of the Embley River, where they would leave their vehicles and catch a ferry to the Hey River barge/ferry terminal, from where they would be bussed to site. Freight and equipment would be transported via barge from the Humbug barge terminal on the north side of the Embley River to the Hey River barge/ferry terminal (refer **Figure 1-3**). The trucks would then drive off the barge and travel by the sealed on-lease Mine Access Road to the site.

Three locations for barge and ferry terminals were considered on the northern side of the Embley River. These included an area adjacent to the existing Evans Landing wharf, an area adjacent to the existing Humbug Wharf, and Hornibrook Point. The location at Evans Landing

was unsuitable due to the potential for significant interference with existing commercial and recreational boating and also to increased ferry travel time.

The Humbug barge terminal would be located adjacent to the existing Humbug Wharf, which is where the regular barge service from Cairns docks. Large machinery and supplies arriving by barge from Cairns can be transported to the Project without traversing public roads. Use of public roads would be required if the barge terminal was located at Hornibrook Point.

It is proposed to locate the ferry terminal at Hornibrook Point as this has the shortest route and hence the shortest travel time to the Hey River barge/ferry terminal. This location also has the advantage of reducing interactions with vessels that support the existing operation.

The potential impacts on threatened and migratory marine and estuarine fauna would be similar for all terminal locations. None of the options are likely to have a significant impact on threatened and migratory marine fauna and the Commonwealth marine environment.

1.6.5 Power Supply

The following power supply alternatives were evaluated:

- generate power at Weipa by expanding the existing diesel-fired station and installing a high voltage transmission line to the Boyd infrastructure area; and
- generate power on-site using diesel-fired generators.

The first alternative is the least reliable and least feasible, in part because the 3.5km wide Embley River estuary would have to be traversed by a high voltage line. In addition to the higher capital cost, line losses along the length of the 50km overhead power line would result in a less efficient operating system. As a result, on-site generation is proposed.

Alternative energy supplies such as biomass, wind, solar and wave were considered. Wave power was not technically viable. Wind and solar sources were not able to supply guaranteed minimum base load power. Biomass was not technically viable for low base load demand situations (e.g. beneficiation plant not running, ship loaders not running).

The option of installing a 50km overhead power line is likely to have a greater potential impact on flora and fauna habitat, compared to generating power on site, because additional vegetation clearing would be required. Neither of the options would be likely to have a significant impact on threatened and migratory fauna and threatened flora.

1.6.6 Bauxite Beneficiation Technology

Geological characterisation of the SoE orebody has shown that the greatest economic benefit can be obtained from the crude bauxite if the high-silica fine material (nominally <0.6mm) associated with the crude ore is removed. The silica in fines consumes caustic soda at the alumina refinery and caustic consumption is the primary cost driver in the bauxite and alumina production chain.

The following bauxite beneficiation (processing) technologies for removing fines were evaluated:

- dry beneficiation; and
- wet beneficiation.

Crude bauxite in the ground is a mixture of bauxite bearing pisolites (pea-shaped particles) locked in a matrix of finer materials including fine bauxite and clay. Energy is needed to break up the crude ore into pisolites and fine matrix material. A dry screening process would break up some of the large lumps but would not remove fine material adhering to pisolites. A substantial quantity of pisolites would also remain trapped in the matrix material and be rejected as oversize material by a dry screening plant, further eroding the value of the ore body. Comalco (now RTA) has previously investigated mobile in-pit dry beneficiation but found the plant was burdened with many technical problems which could not be effectively solved.

In a wet beneficiation plant the crude bauxite is soaked with water to break-up lumps and this "pre-conditioned" ore is then washed over a screen to remove the fines. The amount of water needed to wash the fines from the bauxite pisolites varies depending on the quantity and type of fines. A "high dispersion energy" plant uses more water than a "low dispersion energy" plant.

Wet beneficiation is an efficient and reliable technology that has been proven throughout the world and it has been adopted for the Project. As much crude ore as is practicable would be beneficiated in "low dispersion energy" plants. This would reduce overall water usage. Some ore from the Norman Creek mining area would need to be beneficiated in a "high dispersion energy" plant. Mining of this ore would be delayed until a "high dispersion energy" unit is added to the initial "low dispersion energy" plant at Norman Creek (refer **Section 2.5.1**).

1.6.7 Water Demand Management

The options evaluated for reducing and stabilising water demand for operations were:

- type of beneficiation plant;
- staging of significant plant expansions;
- product yield assumptions; and
- recycling of water within the beneficiation plant.

The design of the "low dispersion energy" beneficiation plants has incorporated materials handling and layout features that enable as much crude ore as is practicable to be beneficiated in these plants, thus reducing overall water usage. The plant design enables water in the circuit to be reused throughout the plant.

Tailings water recycling (refer **Section 2.7.3**) is crucial to reduce the proportion of water required from alternative sources. The recycling of water from tailings storage facilities commences once the floor of the tailings storage facility has been sealed through the deposition of fine tailings particles. The sealing takes two to three years during which time alternate water sources are required. The planned significant lifts in bauxite production rate are staged to follow the establishment of the recycled tailings water stream in order to eliminate high peaks in water demand.

The beneficiation process separates crude ore into product, oversized waste and tailings. Due to the characteristics of the ore body, these proportions would constantly vary and consequently the product yield would also vary. The Boyd beneficiation plant water usage is determined by the proportion coming from tailings recycling. The overall water demand has been based on the average yield of the ore body rather than minimum yield. In order to stabilise water demand, short term mine plans may need to be varied so that high or low yielding ore is mined to meet overall production plans.

The use of thickened tailings was also evaluated but not adopted. The same amount of water is used within the bauxite processing circuit regardless of whether there is a thickened or an unthickened tailings system. With a thickened tailings system, water is removed from the tailings stream for recycling before tailings are pumped in paste form to the tailings storage facility; it is difficult to recover additional water reliably from a thickened tailings storage facility. With an unthickened tailings system, all the recycled water is recovered from the tailings disposal facility. Overall, the effective water recovery is similar for both types of tailings systems; however, a thickened tailings system also requires the use of chemical flocculants and greatly increases the energy needed to pump the thickened tailings to the disposal area.

1.6.8 Water Supply

A wide range of options were considered to meet the forecast demands for water over the anticipated range of production rates up to 50Mdptpa.

Following a preliminary evaluation, the following supply options were not adopted on the basis of a combination of cost, sustainability, reliability and technical considerations:

- pumping water via pipeline from Weipa;

- desalinisation; and
- sole reliance on an artesian borefield.

Unlike the Weipa Peninsula, the Project area does not have a high-yielding shallow aquifer. The principal sources of supply are therefore restricted to recycled water from tailings storage facilities, surface water from streams, and deep artesian groundwater. The wide range of supply combinations utilising various proportions of these sources was investigated. Surface water supply options encompassed both dams and direct pumping from flowing streams. Nine dam site options in the Norman Creek catchment were evaluated, along with two in the Ina Creek catchment and four in the Ward River catchment. Following consideration of cost, sustainability, reliability, local community concerns, and the environment, the following principal supply sources have been adopted:

- Production rate less than 30Mdptpa – tailings water recycle, water supply dam (Dam C), and artesian; and
- Production rate 30Mdptpa to 50Mdptpa – tailings water recycle, water supply dam (Dam C), direct pumping from the Ward River, and artesian.

The water supply dam (Dam C) would have a maximum storage capacity of 29GL and could be constructed in either in two stages or a single stage (refer **Figure 1-3** for location). The dam would be constructed in a single stage should expansion of production above 15Mdptpa be anticipated to occur quickly, or should an initial production capacity of 22.5Mdptpa be adopted. This is the subject of ongoing feasibility studies. This EIS has assessed the impact of the dam at minimum, intermediate and maximum production rates of 15, 30 and 50Mdptpa respectively.

One water supply sub-option considered involved constructing a smaller single stage of Dam C only and constructing a second dam on the Ward River. This sub-option involved a greater total area of disturbance and was not the preferred approach of Traditional Owners and has not been adopted.

The various water supply sources are quantified in **Section 5.2.1**.

The selected option of constructing one dam is likely to have less potential impact on threatened and migratory fauna and threatened flora, compared to the sub-option of constructing two dams, because one dam would require less vegetation clearing.

1.6.9 Initial Tailings Storage Facility Establishment

Two locations were considered for the construction of an initial tailings storage facility to serve the Boyd beneficiation plant. The first was located on a non-mineralised area to the north of the plant and the second on a mineralised area to the south. The first dam alternative would be simpler and quicker to establish since the second would require pre-mining and crude ore stockpiling if ore was not to be sterilised. However, the second location to the south (refer **Figure 1-3**) was selected in order to reduce the overall out-of-pit footprint of disturbance by about 200ha.

Construction of the initial tailings storage facility to the south of the Boyd beneficiation plant is likely to have less potential impact on threatened and migratory fauna and threatened flora.

1.6.10 Volume of Dredged Material

Two key design factors influence the volume of marine sediment required to be dredged:

- the length of the jetty and wharf structure; and
- limitation of vessel departure times.

The length of the port jetty and dredge channel has been optimised taking into consideration the trade-off between increasing the jetty length versus dredging volumes. In the case of the proposed port, constructing a longer jetty would not substantially reduce the dredging volumes. The depth increases rapidly over the first 500m from shore (between the shore and the berth pocket) and then increases more gradually (refer **Figure 6-39**). For example if the jetty length was to increase by 40% then the dredge volume would only decrease by approximately 10%.

As designed, the approach jetty is 568m (from the top of the cliffs), and dredging commences at the berth pocket (refer **Figure 2-6**). Constructing a longer jetty would significantly increase the cost of construction without significantly reducing environmental impact.

Similarly, at the ferry and barge terminals, a sheet pile structure is proposed to optimise access to deeper water at the Hey River terminal, which minimises disturbance to mangroves in this area.

The high cost of dredging provides a financial incentive to reduce dredge volumes as much as possible. Dredge volumes at the Port could be reduced through limiting vessel departure times to high tide so that ships require less than -20.2m draft from lowest astronomical tide (LAT). However, this would limit the port capacity. A feasibility study is currently being undertaken to determine the economic feasibility of limiting vessel departure time. For the purposes of the environmental impact statement, it has conservatively been assumed that vessel departures are unrestricted by tides and hence the depth of dredging and associated impact assessment has been matched to this assumption (-20.2m LAT).

Dredge volumes have also been minimised at the ferry and barge terminals as much as practicable. The passenger ferry would be required to operate on all tides in order to transport workers at shift change. However, the volume of dredging for the ferry and barge terminals has been optimised by taking into consideration vessels with the lowest draft practical for the service conditions and optimising the approach and departure paths for the vessels.

1.6.11 Disposal of Dredged Material

Several alternatives for disposal of sediments from dredging were considered. The following alternatives were not adopted based primarily on environmental, material suitability, construction needs and economic viability:

- re-use for beach nourishment and land creation;
- off-site recycling;
- removal of hazardous constituents for beneficial re-use;
- disposal on land;
- placement of the material from the port area at the existing Albatross Bay Spoil Ground.

The re-use of material for beach nourishment is not considered appropriate given that the beach area is a known nesting area for marine turtles. Placement of dredged material on the beach would impact turtles' ability to nest and may reduce viability of nests through constant inundation of water through dewatering. Peer-reviewed literature documents negative impacts on turtles from beach nourishment activities. Using the material for land creation is considered inconsistent with the use of the area by turtles for nesting. There is no need to create more land for the development of the SoE Project.

The material to be dredged is not suitable for construction material. The material from the Port area is comprised of a relatively thin layer of sandy silts on at the surface overlying stiff clays and underlying siltstone, whilst the material from the barge and ferry terminals is comprised primarily of silty-clays. Material beneficial for offsite recycling typically requires relatively clean sands.

There are no hazardous constituents to be removed because the material is clean. Further, beneficial re-use opportunities do not exist.

If the material was pumped ashore, the dewatering process could adversely affect a shallow, low-yield aquifer via infiltration of saline seepage through the porous coastal soils. The shallow aquifer currently sustains baseflow in surface streams in the area. This water has very low salinity levels. Saline seepage from the marine sediment could adversely impact water quality. The disposal of dredged spoil to land would require construction of a containment facility to store the material. At the Hey River location, the construction of such a facility would require the removal of coastal vegetation. At Humbug Wharf and Hornibrook Point, the construction of

a containment facility would sterilise the site for a prohibitive period prior to development of the onshore terminal infrastructure, further the silty-clay dominated sediments would not be suitable for engineered use, especially in supporting heavy machinery. Awaiting construction of the containment facility would prevent commencement of dredging activities for some months, subsequently delaying the construction of the port, barge and ferry facilities. These facilities are on the critical path for construction of the Project. The revegetation of an elevated emplacement of marine sediments would pose difficulties and would be likely to require long-term maintenance.

Placement of the spoil from the port area at the Albatross Bay spoil ground would require the material to be barged about twice the distance than to the proposed new spoil ground. This would require at least three hopper dump barges and contractors' dredging spreads do not typically extend to that number of barges, particularly in such a remote area. If a suitable contractor was found then the costs would be significantly greater. If three hopper dump barges could not be secured, the dredging and sea disposal timeline would increase, potentially extending persistence of turbid conditions.

Ocean disposal of marine sediments in a marine environment provides a lower environmental risk than land disposal, due to:

- using the material for beach nourishment or land disposal is inconsistent with the use of the area by marine turtles;
- disposal on land could adversely affect water quality in the shallow aquifer; and
- revegetation of marine sediments would pose difficulties.

Both land and sea disposal have negligible risk to human health.

Sea dumping of the dredge material is being proposed based on the lack of suitable alternatives for the volume of material to be disposed and the clean nature of the material.

1.7 Environmental Impact Assessment Process

1.7.1 Purpose of the EIS

This Environmental Impact Statement has been prepared to meet the assessment requirements for the Project under the *State Development and Public Works Organisation Act 1971* (Qld) (SDPWO Act), the *Environment Protection and Biodiversity Conservation Act 1999* (Cth) (EPBC Act) and the *Environment Protection (Sea Dumping) Act 1981* (Cth) (Sea Dumping Act).

The EIS has been prepared to inform decision-makers, affected parties, interest groups and the public about potential environmental and social issues relating to the development and operation of the Project, and how these issues would be managed. The content of the EIS reflects the Terms of Reference (ToR) issued by the Queensland Coordinator-General (CG) and the EIS Guidelines issued by the Commonwealth Minister for Sustainability, Environment, Water, Population and Communities (the Minister).

This document will be made publicly available for comment and submissions will be sought from individuals and organisations. The EIS process allows for community consultation and ensures environmental protection by comprehensive consideration of potential impacts and management strategies. The Department of Employment, Economic Development and Innovation (DEEDI) is responsible for coordinating the impact assessment process under the auspices of the CG. The Department of Sustainability, Environment, Water, Population and Communities (DSEWPaC) fulfils a similar role for the Minister.

1.7.2 Objectives of the EIS

The objective of the EIS process is to ensure all impacts, direct and indirect – in particular environmental, social and economic impacts – are fully examined and addressed. The EIS aims to be a comprehensive document that provides:

- public information regarding the project, alternatives and preferred solutions; the existing environment and values that it would affect both on and off the site; the impacts that may occur; and the measures to be taken to mitigate all adverse impacts; and
- a definitive statement of measures or actions to be undertaken to mitigate any adverse impacts occurring during construction, operation and following decommissioning of the project. This is achieved by the inclusion of a draft Environmental Management Plan (EM Plan) (refer **Section 21**) in the EIS, which describes acceptable impacts and environmental management strategies designed to meet specific performance criteria.

The EIS relates to the entire life of the Project including construction, operation and decommissioning. The EIS enables reasonable economic and technically achievable conditions to be developed to ensure the impact of the Project is within acceptable levels. The level of analysis and detail in this document reflects the level of significance of particular impacts.

1.7.3 EIS Process

Summary of Parallel EIS Processes

The Project is to be assessed under two separate but parallel EIS processes under State and Federal environmental law. Further detail on the relevant processes is provided below.

The EIS addresses both the State Terms of Reference (**Appendix 1B**) and Commonwealth Tailored Guidelines (**Appendix 1C**) and it will be advertised for public and advisory agency comment:

- as a final EIS for the purposes of section 33(1) of the SDPWO Act; and
- as a draft EIS for the purposes of section 103(1)(c) of the EPBC Act.

For administrative and public convenience, all submissions on the EIS are to be lodged with DEEDI (for State EIS purposes and on behalf of the project proponent for Commonwealth EIS purposes). All submissions will then be copied and forwarded to RTA and DSEWPaC to meet requirements under the SDWPO Act and the EPBC Act. Further detail on the public submission process is provided in **Section 1.8**.

Additions to this EIS which are required as a result of public submissions will be made as appendices so that all relevant matters relating to both EIS assessment processes are contained within the one document.

Queensland EIS Process

On 13 June 2008, RTA lodged an Initial Advice Statement (IAS) and a request for "significant project" declaration with the CG. The IAS provides an outline of the proposed project, including the project rationale and its potential impacts. The IAS was subsequently updated on 3 November 2008.

The Project was declared a "significant project" for which an EIS is required pursuant to section 26(1)(a) of the *State Development and Public Works Organisation Act 1971* (Qld) (SDPWO Act) on 21 November 2008, by the CG. The declaration initiates the statutory environmental impact assessment procedure under Part 4 of the SDPWO Act

Matters considered by the CG in making this declaration included information contained in the IAS, relevant planning schemes and policy frameworks, infrastructure impacts, employment opportunities, environmental effects, complexity of local, State and Commonwealth Government requirements, level of investment and the project's strategic significance.

Draft Terms of Reference (ToR) were prepared and advertised for public and advisory agency comment on 16 January 2009. The CG was required to have regard to all comments received before issuing a final ToR in April 2009 (refer **Appendix 1B**). This EIS was prepared in response to the final ToR and applies to the whole of the Project. A table providing cross-references from the ToR to the EIS is presented in **Appendix 1D**.

If the CG is satisfied that the EIS responds to the ToR, this EIS may be advertised for public comment. The CG must consider all properly made submissions and any other submissions that he accepts about the EIS and any other material the CG considers is relevant to the Project.

If further information is requested by the CG, a "Supplementary EIS" will be prepared by RTA to cover outstanding matters. A final decision on the overall acceptability of the Project will be made on the basis of the information provided in the EIS and the Supplementary EIS.

At the completion of the EIS phase, the CG must prepare a report evaluating the EIS (CG's Report). The CG Report will evaluate the environmental effects of the project and any associated mitigation measures. The CG's Report will be publicly available.

The CG's Report does not authorise the commencement of work associated with the Project. Instead it sets the framework within which other State approvals are to be sought and the conditions that are to be granted. Of significance for the Project:

- the CG Report may state conditions for any draft environmental authority (mining lease) under the EP Act; and
- if the Project involves development requiring an application for a development approval under the *Sustainable Planning Act 2009* (Qld) (SP Act), the CG Report may, under section 39 of SDPWO Act, state for the assessment manager one or more of the following:
    - the conditions that must attach to the development approval;
    - that the development approval must be for part only of the development; and/or
    - that the approval must be preliminary approval only.

Alternatively, the report must state for the assessment manager:

- that there are no conditions or requirements for the project; or
- that the application for development approval be refused.

There is no legislative requirement for the CG's Report to be provided to the Minister to assist in his assessment of the Project under the EPBC Act, as the Bilateral Agreement between the State of Queensland and the Commonwealth does not apply.

Commonwealth EIS Process

RTA referred the Project to the Minister for a decision as to whether the project constituted a controlled action under the provisions of the EPBC Act. On 2 October 2008, the Project was declared a "controlled action" (Referral No. 2008/4435) and was to be assessed under the Bilateral Agreement with Queensland using the EIS Process under Part 4 of the SDPWO Act.

However, following a change to the proposed port design to accommodate larger bulk carriers, RTA withdrew Referral No. 2008/4435 and submitted a new referral to the Minister. On 29 October 2010, the Project was declared a "controlled action" for which an EIS was required (Referral No. 2010/5642), and the relevant controlling provisions were:

- listed threatened species and communities (sections 18 and 18A of the EPBC Act);
- listed migratory species (sections 20 and 20A of the EPBC Act); and
- Commonwealth marine areas (sections 23 and 24A of the EPBC Act).

The change to the Project and the inclusion of Commonwealth marine areas as a controlling provision meant that the Bilateral Agreement could no longer apply. Instead, the relevant EIS process is under Part 8 of the EPBC Act. As such, the Project will be subject to two different and separate EIS processes.

Tailored Guidelines were issued by the Minister to RTA (refer **Appendix 1C**), and these set the framework for how the EIS is to address the potential significant impacts of the Project on Matters of National Environmental Significance (MNES). A stand-alone report addressing these matters is

provided as **Section 22** of this EIS. A table providing cross-references to the Tailored Guidelines is provided in **Section 22 Table 38**.

If the Minister is satisfied that the draft EIS responds to the Tailored Guidelines, this EIS may be advertised for public comment as a "draft EIS". At the end of the submission period, RTA will finalise the "draft EIS", taking account of and summarising comments received within the submission period, and stating how such comments are addressed in the "final EIS". As soon as practicable after finalising the "draft EIS", RTA is to provide the finalised EIS to the Minister and will cause the finalised EIS to be published.

The Secretary of the Commonwealth Department of Sustainability, Environment, Water, Population and Communities, will review the EIS material on behalf of the Minister. The Secretary must then prepare and give to the Minister a Recommendation Report relating to the action, which states whether the taking of the action should be approved, and if so, the conditions that should be attached to the approval.

The Minister then has period of 40 business days (beginning on the first business day after the Minister receives the finalised EIS), in which to decide whether the Project should be approved.

The final approval decision of the Minister and associated conditions would be publicly notified by placing it on the DSEWPaC website.

1.7.4 Structure of the EIS

The EIS is structured as follows:

- **Executive Summary** – a comprehensive restatement of the Project's purpose, scope, methods, results, conclusions, findings and recommendations, i.e. a consolidation of the principal points of the EIS;
- **Section 1** provides an introduction to the Project and summarises applicable legislation, approvals and objectives for the Project;
- **Section 2** provides a detailed Project Description;
- **Section 3 to Section 19** covers the various elements of the environment, describing the existing environment and addressing the potential impacts of the Project and the mitigation strategies proposed to limit the impacts to acceptable levels;
- **Section 20** describes potential cumulative environmental impacts that may arise from construction and operation of the SoE Project, including those that arise from the interrelationship of residual Project impacts and in combination with other proposed mining projects;
- **Section 21** presents a draft EM Plan for the mine that describes management strategies to achieve acceptable environmental conditions and makes commitments about how impacts would be managed;
- **Section 22** presents a stand-alone EPBC Assessment Report to present MNES and a table of cross references showing where the various EIS Guidelines requirements are addressed in the EIS are presented in Table 38 of that report;
- additional parts of the EIS contain References, a Glossary, Abbreviations and Units, and Appendices;
- a copy of the Queensland ToR and the Commonwealth EIS Guidelines are presented in **Appendix 1B** and **Appendix 1C** respectively. A table of cross references showing where the various Queensland ToR requirements are addressed in the EIS are presented in **Appendix 1D**;
- details of the EIS study team are provided in **Appendix 1E**; and
- a summary of the proponent commitments is provided in **Appendix 1F**.

1.8 Public Consultation Process and Submissions

Prior to the commencement of consultation, a scoping study was undertaken to identify the key stakeholders who may be directly or indirectly affected by the Project (refer **Section 15.1.1**). A range of consultation tools have been utilised to facilitate engagement with the general public and specific stakeholders (refer **Section 15.1.2**).

Throughout the preparation of the EIS document members of the public and other interested parties have been encouraged to participate in the process by providing their input into public consultation programs. Newsletters providing information about the Project and promoting communication with the EIS team have been widely circulated in the Weipa region. A wide range of stakeholder meetings has been held. Responses from all parties have been considered in the design of environmental and social plans and strategies. The community consultation process and issues raised are described in **Section 15.2.**

DEEDI, on behalf of RTA and DSEWPaC, will advertise the release of the EIS for advisory agency and public review and comment. The document will be placed on display at nominated locations for a period to be specified by the Commonwealth Minister and Queensland Coordinator General, of at least 20 business days.

RTA will make CD ROM copies of the EIS available free to interested persons upon request. The EIS will be available in hard copy format for purchase from RTA. Persons with special needs (e.g. visually impaired, English as a second language) can contact RTA to make arrangement to access the information in the EIS.

The EIS will be available on the RTA web site for interested parties to view and download if required:

http://www.riotintoalcan.com/ENG/whatweproduce/1812_south_of_embley_project.asp

Information on the EIS and the assessment processes for the State and Commonwealth governments will also be available on the respective websites:

http://www.dlgp.qld.gov.au/projects/mining-and-mineral-processing/bauxite-and-aluminium/south-of-the-embley-project.html

http://www.environment.gov.au/cgi-bin/epbc/epbc_ap.pl?name=current_referral_detail&proposal_id=5642

Any person, group or organisation may make a written submission about the EIS to the DEEDI. Such submissions do not have to relate to the whole of the Project and may relate to any aspect or section of the document. EIS submissions must be made in writing and submitted to the DEEDI within the designated comment period.

All submissions, comments and enquiries for the purposes of the SDPWO Act or EPBC Act should be addressed to:

EIS Project Manager—South of Embley Project
Significant Projects Coordination
Department of Employment, Economic Development and Innovation
PO Box 15009, Brisbane City East Qld 4002

Telephone	+ 61 7 3224 8351
Facsimile	+ 61 7 3225 8282
Email	SOE@deedi.qld.gov.au

http://www.deedi.qld.gov.au (under the Coordinator-General tab)

Both the State and Commonwealth will have access to all submissions.

RTA will respond to each submission as an addendum to this EIS. The addendum will in effect represent a "Supplementary EIS" under the SDPWO Act and a "Final EIS" under the EPBC Act.

1.9 Legislative Framework and Project Approvals

In addition to the approval of the EIS under the SDPWO Act and approval of the "controlled action" under the EPBC Act (refer **Section 1.9.2**), the Project will require a number of other approvals, permits and licences for various components of the development (refer **Table 1-2**).

Table 1-2 Project Approvals, Permits and Licences

Permit/Approval/Licence	Legislation	Authority	Comments
Project Wide			
Environmental Impact Statement	*State Development and Public Works Act 1971* (Qld) (SDPWO Act)	Department of Employment, Economic Development and Innovation (DEEDI)	Coordinator-General declared "a significant project for which an EIS is required" 21 November 2008.
Controlled Action Approval	*Environment Protection and Biodiversity Conservation Act 1999* (Cwlth) (EPBC Act)	Department of Sustainability, Environment, Water, Population and Communities (DSEWPaC)	Project was declared a "controlled action" on 29 October 2010. Required if project has, will have or is likely to have a significant impact on matters of national environmental significance.
Environmental Authority	*Environmental Protection Act 1994* (Qld) (EP Act)	Department of Environment and Natural Resources (DERM)	Covers mining and associated activities as per operational and environmental requirements of an environmental authority (mining activities).
Humbug and Hornibrook Terminals, Tug Berths			
Barge and ferry terminals – development approval	*Sustainable Planning Act 2009* (Qld) (SP Act)	North Queensland Bulk Ports (NQBP) (assessment manager)	Required for operational works on land and operational works in the tidal areas of NQBP Strategic Port Land (DERM is a concurrence agency for operational works in tidal waters).
Commonwealth sea dumping permit (for dredged spoil)	*Environmental Protection (Sea Dumping) Act 1981* (Cwlth)	DSEWPaC	Required for dredging and disposal of spoil at existing Albatross Bay spoil ground in Commonwealth waters.
Removal of marine plants – development approval for operational works	SP Act and *Fisheries Act 1994* (Qld)	DEEDI	Required if marine plants found to be present and required to be removed. Part of combined development application to NQBP (above) although DEEDI would be concurrence agency for assessment.
Hey River Terminal			
Commonwealth sea dumping permit (for dredged spoil)	*Environmental Protection (Sea Dumping) Act 1981* (Cwlth)	DSEWPaC	Required for dredging and disposal of spoil at existing Albatross Bay spoil ground in Commonwealth waters.
Port			
Port	*Commonwealth Aluminium Corporation Limited Agreement Act 1957* (Qld) (Comalco Agreement Act)		Harbour works are authorised under the Comalco Agreement Act, which includes dredging in tidal waters for the port on ML7024. Development approval under SP Act is not required.
Approach channel dredging	*SP Act*	DERM	Required for operational works in tidal waters outside ML7024. DERM is lead agency for operational works in tidal waters.
Commonwealth sea dumping permit (for dredged spoil)	*Environmental Protection (Sea Dumping) Act 1981* (Cwlth)	DSEWPaC	Required for dredging and disposal of spoil at proposed new spoil ground in Commonwealth waters.
SoE Mine Facilities			
Licence to take water (surface water)	Comalco Agreement Act and *Water Act 2000*	DERM	Pre-existing rights to take water for the Project are held under the Comalco Agreement Act and preserved under section 1037A of the *Water Act*

Permit/Approval/Licence	Legislation	Authority	Comments
	(Qld)		*2000*.
Water storage dam – development approval	Comalco Agreement Act and *Water Act 2000*	DERM	Pre-existing rights to build dams for the Project are held under the Comalco Agreement Act and preserved under the *Water Act 2000*.
Waterway barrier (fish barrier) works approval – development approval for operational works	SP Act and *Fisheries Act 1994* (Qld)	DEEDI	Required for a dam or water crossing that inhibits fish movement.
Failure impact assessment (of dams)	*Water Supply (Safety and Reliability) Act 2008* (Qld)	DERM	Required for dams with a wall height >8m in height and storage capacity of >500ML. Dam C water storage dam shall require failure impact assessment.
Licence to take water (sub-artesian)	*Water Act 2000*	DERM	Required if taking sub-artesian water in declared sub-artesian area under section 1046 of the *Water Act 2000*. A declared sub-artesian area exists. Use of sub-artesian water is not currently planned.
Licence to take water (artesian)	*Water Act 2000*	DERM	The Comalco Agreement Act permits 12 artesian bores under section 32(b) (or more with Minister's consent). A licence to take artesian water is still required.
Development approvals for artesian bores	SP Act and *Water Act 2000*	DERM	Required for installation of artesian groundwater bores.

1.9.1 State Development and Public Works Organisation Act 1971 (Qld)

The Project has been declared a "significant project" for which an EIS was required pursuant to section 26(1)(a) of the SDPWO Act. The application of the SDPWO Act is described in **Section 1.7.3**.

1.9.2 Environment Protection and Biodiversity Conservation Act 1999 (Cwlth)

The EPBC Act prescribes the Commonwealth's role in environmental assessment, biodiversity conservation and the management of protected matters. The Act identifies eight MNES and makes it an offence to take any action that has, or is likely to have, a significant impact on any of those matters, unless it is approved by the Minister. Such an action is a "controlled action". It is an offence to undertake a controlled action without the approval of the Commonwealth Minister responsible for the EPBC Act.

The Project was declared a controlled action on 29 October 2010 and the controlling provisions were:

- sections 18 and 18A (listed threatened species and communities);
- sections 20 and 20A (listed migratory species); and
- sections 23 and 24 (Commonwealth marine areas).

As a consequence of this decision, the Project requires approval under the EPBC Act. The Commonwealth has determined an EIS under the EPBC Act is required. The Minister issued *Tailored Guidelines for the preparation of the Draft Environmental Impact Statement* (the 'Tailored Guidelines') on 21 December 2010. This EIS has been prepared to meet both the Commonwealth and State EIS requirements.

The Tailored Guidelines specifically requires a stand-alone report addressing potential impacts of the Project on MNES. An EPBC Act assessment report has been prepared to satisfy this requirement, and is presented in **Section 22**. This report describes the proposed action in relation to MNES, the affected environment relevant to the controlling provisions, an assessment of impacts on MNES, and mitigation measures and summarises conclusions.

In addition, section 160 of the EPBC Act requires that Commonwealth agencies seek advice from the Minister before granting certain authorisations under other Acts. A permit under the Commonwealth *Environment Protection (Sea Dumping) Act 1981* to dispose of dredged material at sea is such an authorisation (refer **Section 1.9.3**).

The EPBC Act has the effect of allowing the Minister to require assessment of the sea dumping application as though it was a controlled action under Part 8 of the Act. In order to avoid duplication of assessment processes and to ensure that all relevant information is considered at once, DSEWPaC has requested that sufficient information be provided in this EIS to support the application for a Sea Dumping Permit for dredging and disposal associated with Stage 1 capital dredging at the proposed Port and capital dredging for the barge and ferry terminals. This information can be predominantly found in Sections 6 and 22 of this EIS.

1.9.3 Environment Protection (Sea Dumping) Act 1981 (Cwlth)

The *Environment Protection (Sea Dumping) Act 1981* (Sea Dumping Act) regulates the loading and dumping of waste and other matter in the sea. The loading and dumping of spoil from dredging operations in Commonwealth waters is regulated by the Act and such disposal requires a permit.

A permit will be required for the loading and disposal of dredged spoil from the proposed port to a proposed new spoil ground west of Boyd Point. A permit will also be required for loading and disposal of dredged spoil from the Humbug barge terminal, Hornibrook ferry terminal and Hey River barge/ferry terminal at the existing Albatross Bay spoil ground.

The assessment to support the application for a Sea Dumping Permit for dredging and disposal associated with Stage 1 capital dredging at the Port and capital dredging associated with the ferry and barge terminals is predominantly included in this EIS. A sea dumping permit has been applied for and the framework for the Dredge Management Plan drafted (refer **Section 6.10**). Detailed sediment characterisation reports have been provided separately to DSEWPaC and the data is summarised in Section 6 of the EIS. The Tailored Guidelines required the following guidelines to be utilised in preparation of that

- *National Assessment Guidelines for Dredging* (Commonwealth of Australia 2009)
- Annex 2 1996 Protocol to the Convention on the prevention of marine pollution by dumping of wastes and other matter 1972 (the London Protocol); and
- Waste Specific Guidelines for Assessment of Dredged Material. International Maritime Organisation

A detailed description and characterization of the sediment proposed to be dredged, the proposed disposal site, and assessment of the potential effects of disposal of dredged material, in accordance with the above guidelines, are presented in **Section 6** and summarised in **Section 22** (EPBC Assessment Report) of this EIS. Alternative options for disposal of dredged material are presented in **Section 1.6.10**.

Future capital dredging and disposal for Stage 2 of the Port (which would occur subject to market demand) and maintenance dredging and disposal associated with both the Port and the ferry and barge terminals, would be subject to obtaining a subsequent sea dumping permits.

1.9.4 Agreement Acts

RTA is the holder of ML7024 granted on 1 January 1958 pursuant to the Comalco Agreement Act, a Queensland "Special Agreement Act". ML6024 (granted 25 July 1985 and affirmed 26 August 2002) was granted pursuant to the Comalco Agreement Act and the *Mineral Resources Act 1989* for the purposes of providing transport access to ML7024. The current term of ML7024 and ML6024 runs until 31 December 2041; however, there is a right of renewal until 31 December 2062.

The Comalco Agreement Act confers certain rights and obligations relating to the development of bauxite resources, including provisions relating to the taking of water and harbour works (refer **Table 1-2**).

Rio Tinto is also the holder of ML7031 pursuant to the *Alcan Queensland Pty Limited Act 1965* (Qld) (which is also a "Special Agreement Act"). While RTA mines ore from ML7031 (known as the Ely mining lease), activities on ML7031 are not the subject of the Project.

Although the Comalco Agreement Act and the *Alcan Queensland Pty Limited Act 1965* are similar in many ways, there is no relationship from a tenure perspective.

1.9.5 Mineral Resources Act 1989 (Qld)

RTA does not require any new mining leases in addition to ML7024 and ML6024 in order to develop the Project.

1.9.6 Environmental Protection Act 1994 (Qld)

Mining and mining-related activities on ML7024 at Weipa have transitional authorisation under section 616B of the EP Act relating to "Special Agreement Act" mines. RTA has commenced the process to transition to an environmental authority (mining activities) under the EP Act with respect to ML7024 and ML6024. An application will be made to amend the environmental authority (mining activities) in respect to any requirements particular to the Project. To the extent of those amendments, the amendment application is likely to trigger the requirement for an EIS for the Project. The EIS under the SDPWO Act will satisfy such a requirement for an EIS.

The environmental authority (mining activities) will authorise mining and mining-related activities throughout ML7024 and ML6024, not just in relation to the Project area. These activities shall include the following environmentally relevant activities under the *Environment Protection Regulation 2008* (Qld)*:*

- 8. Chemical storage (petroleum product storage);
- 14. Electricity generation;
- 15. Fuel burning (heavy mobile equipment);
- 16. Extractive and screening activities (includes dredging);
- 21. Motor vehicle workshop operation;
- 31. Mineral processing;
- 43. Concrete batching;
- 50. Bulk material handling;
- 56. Regulated waste storage;
- 60. Waste disposal;
- 63. Sewage treatment; and
- 64. Water treatment.

In determining the conditions of the environmental authority, DERM shall have given regard to the provisions of the:

- Existing environmental authority (mining activities) authorisations on ML7024 and ML6024;
- *Environmental Protection (Water) Policy 2009* (Qld)*;*
- *Environmental Protection (Air) Policy 2008* (Qld)*;*
- *Environmental Protection (Noise) Policy 2008* (Qld)*;* and
- *Environmental Protection (Waste Management) Policy 2000* (Qld).

1.9.7 Sustainable Planning Act 2009 (Qld)

The SP Act and the *Sustainable Planning Regulation 2009* (Qld) (SP Regulation) establish the framework for planning and development assessment in Queensland, including the Integrated Development Assessment System (IDAS). Under Schedule 4 of the SP Regulation, mining and mining-related development is exempt from assessment against a planning scheme. However, certain Project development activities regulated by the SP Act and other natural resource

management legislation will be assessable development against Schedule 3 of the SP Regulation. These include:

- Removing marine plants (*Fisheries Act 1994*);
- Constructing a waterway barrier (*Fisheries Act 1994*);
- Operational works in tidal waters (SP Act); and
- Operational works to take artesian water (*Water Act 2000*).

The clearing of native vegetation for mining and mining-related activities is not assessable development under Schedule 3.

1.9.8 Land Act 1994 (Qld)

The *Land Act 1994* regulates land dealings relating to non-freehold land leases and permits to occupy and to the opening and closing of road reserves. The Project may require leases or modification to leases in respect of land presently held by North Queensland Bulk Ports (NQBP) for those barge and ferry terminals not located on ML7024 or ML6024. There are no proposed openings or closings of road reserves.

1.9.9 Native Title Act 1993 (Cwlth)

RTA has valid mining leases (ML7024 granted 1 January 1958) and ML6024 (granted 25 July 1985 and affirmed 26 August 2002) under the *Native Title Act 1993.*

The Western Cape Communities Co-existence Agreement (WCCCA) is a registered Indigenous Land Use Agreement (ILUA) (QIA2001/002) under the *Native Title Act 1993* between RTA, the State of Queensland and relevant Aboriginal parties.

The WCCCA recognises and respects the rights of Traditional Owners and allows for consultation over future development of mining operations. The WCCCA recognises RTA's entitlement and powers to develop the mining leases (ML7024, ML6024), property rights and other rights or interests granted under the Comalco Agreement Act. RTA will continue to engage with the Traditional Owners under the provisions of the WCCCA.

Where any proposed activities are outside the ILUA area, to the extent that native title has not been extinguished in relation to those areas, RTA will comply with the applicable process under the *Native Title Act 1993*. RTA does not expect this to arise.

The Federal Court of Australia determined on 29 July 2009 (*Wik and Wik Way Native Title Claim Group v State of Queensland [2009]* FCA 789) that the Wik and Wik Way people have native title over the land covered by the Project area. The native title rights and interests are subject to RTA's rights under the Agreement Act, WCCCA and the terms of the mining leases.

1.9.10 Aboriginal Cultural Heritage Act 2003 (Qld)

The *Aboriginal Cultural Heritage Act 2003* protects Aboriginal and Torres Strait Islander cultural heritage through imposing a duty of care for all persons to take reasonable and practical measures to avoid harming aboriginal cultural heritage. The Act empowers Traditional Owners to be directly involved in the assessment and management of their own cultural heritage.

The WCCCA provides for a system of cultural heritage management over the area covered by the ILUA. This area includes all land and waters on ML7024 and ML6024. Due to the operation of s86 of the *Aboriginal Cultural Heritage Act 2003,* this agreed cultural heritage management system satisfies the requirement of the Act and the cultural heritage assessment for granting of any new permits or approvals pursuant to an EIS that are required for development works on land or waters within the ILUA area.

1.9.11 Queensland Heritage Act 1992 (Qld)

The *Queensland Heritage Act 1992* provides for the conservation and protection of places and items of historical and/or non-indigenous cultural heritage, i.e. all places that derive from the post-settlement history of Queensland. Under this Act, places and items must be entered into a Queensland Heritage Register in order to be protected.

Where any project impacts on an item entered on the register , all aspects of development

which affects the registered interest require a development approval under IDAS. There are no registered items within the Project area.

1.9.12 Cape York Peninsula Heritage Act 2007 (Qld)

The *Cape York Peninsula Heritage Act 2007* provides for the declaration of Areas of International Conservation Significance. There have been no declarations of Areas of International Conservation Significance within the Cape York Peninsula region.

1.9.13 Water Act 2000 (Qld)

The *Water Act 2000* regulates the use of surface waters and groundwater and the interference with watercourses lakes or springs. Pre-existing rights to build weirs or dams and take surface water for the Project are held under section 1037A of the *Water Act 2000* due to the Comalco Agreement Act.

It is proposed to take water from the Great Artesian Basin and a licence to take artesian water will be required. The *Comalco Agreement Act* permits 12 artesian bores under section 32(b) (or more with the Minister's consent). RTA has an existing artesian water licence for 9GL per annum which allows abstraction from bores located on ML7024. RTA proposes to apply to increase the artesian allocation to a five-year moving average of 12GL per annum, with a peak abstraction of 15GL in any one year. A declared sub-artesian area (section 1046) exists in the Project area, however, the taking of sub-artesian water is not proposed.

Certain watercourses would be crossed by roads, pipelines and conveyors. Riverine Protection Permits are required for any activities that destroy riparian vegetation, or excavate or place material in a watercourse to the extent that such activities are not authorised under an environmental authority (mining activities) or the *Water Regulation 2002* (Qld).

The Cape York Peninsula Moratorium Area has been declared under the *Water Act 2000*. It covers most of northern Cape York, including the Project area south of Boyd Point. The Moratorium restricts the type and volume of new water licences that can be issued under the *Water Act 2000* for the taking of surface and sub-artesian water. The Moratorium recognises and does not affect the existing rights under the Comalco Agreement Act.

1.9.14 Water Supply (Safety and Reliability) Act 2008 (Qld)

The *Water Supply (Safety & Reliability) Act 2008* provides a framework to regulate "referable" dams. In general terms, a dam that is more than 8m high and meets certain storage capacity criteria requires a failure impact assessment. If a dam has a category 1 or 2 failure impact rating and the assessment is accepted by the chief executive administering the Act, the dam is classified as "referable" and is an assessable development under Schedule 3 of the SP Regulation. Dam C shall require failure impact assessment.

1.9.15 Wild Rivers Act 2005 (Qld)

There are currently no rivers in the Project area that are nominated or declared under the *Wild Rivers Act 2005.* The State Government has previously announced an intention to nominate the Watson River as a wild river under the Act. The Watson River is located south of the southern boundary of ML7024 and while part of the river's catchment is within ML7024 (refer **Figure 1-1**), the proposed footprint of the Project is outside the physical catchment/basin boundary of the Watson River. Pursuant to section 17 of the Act, rights and entitlements that pre-date the introduction of the Act are not affected by a wild river nomination or declaration.

1.9.16 Fisheries Act 1994 (Qld)

Approval is required under the *Fisheries Act 1994* to remove or destroy marine plants (such as mangroves and seagrass). Such activity is assessable development under Schedule 3 of the SP Regulation. An approval is likely to be required to remove some mangroves at the proposed Hey River barge/ferry terminal.

Approval is required under the *Fisheries Act 1994* to construct a waterway barrier that obstructs fish movement. Such operational works are assessable development under Schedule 3 of the SP

Regulation. An approval shall be required to construct the water storage dam on a freshwater tributary of Norman Creek (Dam C).

The Department of Employment, Economic Development and Innovation (DEEDI) (formerly the Department of Primary Industries and Fisheries) is proposing to declare parts of Albatross Bay (i.e. Pine River Bay) a Fish Habitat Area (FHA) under the *Fisheries Act 1994* (Qld). DEEDI has nearly concluded its public consultation and expects that the FHA will be declared in mid 2011.

The proposed Pine River Bay Fish Habitat Area is to the north of Weipa and the Embley River and is not adjacent to the Project area.

1.9.17 Coastal Protection and Management Act 1995 (Qld)

The objective of the *Coastal Protection and Management Act 1995* includes providing for the protection, conservation, rehabilitation and management of the coastal areas including resources and biological diversity. The Act provides for the preparation of State and coastal management plans which describe how the coastal zones are to be managed. Certain works carried out in these zones can be assessable development under IDAS.

The Act also provides for coastal management districts to be declared. Coastal management districts are either:

- declared through a regional coastal management plan as being a coastal management district; or
- by virtue of transitional provisions within the Act, declared to be those coastal management control districts and erosion prone areas previously declared under the Beach Protection Act 1968 (Qld).

The Project area falls within the northernmost part of the Gulf of Carpentaria Coast district. A regional coastal management plan has yet to be prepared for this district.

The Aurukun Shire Erosion Prone Areas plan SC4077A includes all land within approximately 50km of the coast between the Embley and Holroyd Rivers. However, all land within ML7024 and ML6024 are excised from plan SC4077A.

1.9.18 Vegetation Management Act 1999 (Qld)

The *Vegetation Management Act 1999* regulates the clearing of remnant native vegetation. Clearing of native vegetation for mining and mining-related activities is not assessable development under Schedule 3 and 24 of the SP Regulation. It is not proposed to clear native vegetation outside of ML7024 and ML6024.

1.9.19 Nature Conservation Act 1992 (Qld)

The *Nature Conservation Act 1992* and the *Nature Conservation (Wildlife) Regulation 2006* (Qld) regulate the taking or destruction, without authorisation, of certain listed flora and fauna species. The taking or destruction of wildlife in the course of authorised works associated with mining and mine related development on mining leases is allowed.

1.9.20 Land Protection (Pest and Stock Route Management) Act 2002 (Qld)

The *Land Protection (Pest and Stock Route Management) Act 2002* provides a framework for the management of weeds, pest animals and the stock route network.

As the holder of ML6024 and ML7024, RTA is under an obligation to take reasonable steps to keep the land and watercourses on-lease free from certain classes of declared pests.

There are no stock routes in the Project area.

1.9.21 Transport Infrastructure Act 1994 (Qld)

The *Transport Infrastructure Act 1994* provides for the management of transport infrastructure systems, including the state road network, rail, air services and ports managed by designated port authorities. RTA's proposed Project would not require transport infrastructure that requires regulation under this Act.

1.9.22 Transport Operations (Marine Pollution) Act 1995 (Qld)

The purpose of the *Transport Operations (Marine Pollution) Act 1995* is to protect Queensland's marine and coastal environment by minimising deliberate and negligent discharges of ship-sourced pollutants into coastal waters. Vessels using the proposed port near Boyd Point, the barge, and the ferry would be subject to this Act.

1.9.23 Transport Operations (Marine Safety) Act 1994 (Qld)

The purpose of the *Transport Operations (Marine Safety) Act 1994* is to regulate the maritime industry to ensure maritime safety while ensuring that operational issues are efficiently managed. Vessels using the proposed port near Boyd Point, the barge, and the ferry would be subject to this Act.

1.9.24 Civil Aviation Regulations 1988 and Civil Aviation Safety Regulations 1988 (Qld)

The purpose of the Act, the *Civil Aviation Regulations 1988* and *Civil Aviation Safety Regulations 1988*, is to provide a regulatory framework for maintaining, enhancing and promoting the safety of civil aviation. The Weipa airport is a certified aerodrome for the purposes of the *Civil Aviation Safety Regulations 1988*. The Project does not include any change to the operation of the existing Weipa airport or require the construction of a new airport.

Environmental Impact Statement

for South of Embley Project

Section 2

Project Description

2 PROJECT DESCRIPTION

This section describes the location of the Project components and a description of each component from the construction phase through to operations and decommissioning.

2.1 Overview of the Project

The key components of the Project are shown on **Figure 1-3**. The Project involves a staged increase in production up to 50 million dry product tonnes per annum (Mdptpa). The initial production capacity is subject to ongoing feasibility studies but is likely to be either 15Mdptpa or 22.5Mdptpa. Actual production rates and the timing and size of capacity expansions would depend on market conditions (refer **Table 1-1** for an indicative schedule).

The initial construction phase is expected to take approximately three years. The estimated capital cost to establish 15Mdptpa capacity would be approximately $1,450 million (final cost is subject to feasibility studies). The peak construction workforce is expected to be approximately 630, with an average of 310 full-time equivalent jobs over the three years.

The anticipated mine life is approximately 40 years, depending on production rate. The SoE mine would directly employ a workforce of 500 at 15Mdptpa, 760 at 30Mdptpa and 1,020 at 50Mdptpa.

2.2 Location and Tenure

The Project is situated on the western side of Cape York on the Gulf of Carpentaria (refer **Figure 1-1**, and **Figure 14-1)**. The Project area is predominantly located on the portion of ML7024 that is south of the Embley River and on ML6024. In addition, a ferry terminal would be located at Hornibrook Point and a barge terminal at Humbug Point. Both locations are on Strategic Port Land administered by the North Queensland Bulk Ports Corporation Limited (NQBP) and both are within the Port of Weipa. The Port of Weipa limits are shown in **Figure 2-9**. Dredging for the proposed Port and the ferry and barge terminals would be undertaken in offshore areas and the material disposed of in offshore disposal grounds (refer **Figures 2-3 to 2-7** and **Figure 2-9**). The land parcels and tenure within the Project area and adjacent properties, including Strategic Port Land, are summarised in **Table 2-1** and shown in **Figure 2-1**.

The northern end of ML7024 is bounded by the Embley and Hey Rivers and the southern end lies north of the Watson River. The Gulf of Carpentaria abuts the western boundary of ML7024, which extends over submerged land between Thud and Boyd Points. The eastern side of ML7024 adjoins mineral development licence (MDL) 378 granted to Aluminium Corporation of China Limited (Chalco) in 2007. The gross extent of the portions of ML7024 and ML6024 south of the Embley River is approximately 106,000ha.

Mining activities would take place on ML7024. A barge/ferry terminal would be located on the Hey River on ML6024. A new port facility would be constructed on ML7024 south of Boyd Point for shipment of bauxite product. A portion of the port's dredged departure channel would extend westward beyond the boundary of ML7024. The proposed port is located outside the Port of Weipa port limits.

Two mine infrastructure areas would be established in stages. The Boyd infrastructure area would be located near Boyd Point, approximately 40km south-west of Weipa and 40km north of Aurukun. Later, the Norman Creek infrastructure area would be established approximately 15km south-east of the Boyd infrastructure area.

Current access to the Project is from the Peninsula Developmental Road (PDR) via the Aurukun Road, Beagle Camp Access Road, Pera Head Access Road, and the Amban Access Road, which traverse MDL378. Once the barge/ferry terminals are constructed, access would be via barge/ferry to the Hey River Terminal and an "on-lease" mine access road to the Boyd infrastructure area.

5 0 5km

Datum/Projection: GDA94/MGA Zone 54 Date: 09/06/2010

There are no reserves, stock routes, easements or public road reserves within the Project area.

No additional land tenures would be required for the Project.

ML7024 lies within the Cook Shire Local Government Area and ML6024 lies within the Napranum Aboriginal Shire.

The Federal Court of Australia determined on 29 July 2009 (FCA 789) that the Wik and Wik Way people have Native Title over the land covered by the SoE Project area. The Western Cape Communities Co-existence Agreement (WCCCA) is a registered Indigenous Land Use Agreement (ILUA) (QIA2001/002) under the *Native Title Act 1993* (Cwlth) between RTA, the State of Queensland and relevant Aboriginal parties. The area covered by the ILUA includes all of ML7024 and ML6024 and is shown in **Figure 2-2**. Where any proposed activities are outside the ILUA area, to the extent that Native Title has not been extinguished in relation to those areas, RTA would comply with the applicable process under the *Native Title Act 1993*. RTA does not expect this to arise.

The location of areas proposed to be mined in years 1–13 and in years 14–40 area shown on **Figure 1-3.** The infrastructure associated with mining has been located so as not to sterilise bauxite reserves.

2.3 Construction

Initial construction of the Project is anticipated to commence in 2012 following receipt of relevant environmental approvals and Rio Tinto's internal project approvals and take three years. There may be opportunities to shorten the construction phase, possibly by up to 12 months depending on availability of certain contractors, equipment and labour.

The EIS has been prepared to assess the impact of several different levels of production: a minimum rate of 15Mdptpa, a maximum rate of 50Mdptpa, and a nominal intermediate rate of 30Mdptpa. However, the actual rates and the timing of production increases would depend on market conditions. Similarly, the timing and extent of associated construction activities is subject to market conditions. For the purposes of the EIS, the construction activities have been described for (a) a minimum initial production rate 15Mdptpa, (b) an expansion to 30Mdptpa, and (c) a further expansion to 50Mdptpa. While there is flexibility to undertake smaller or larger production increments depending on circumstances, the EIS has assessed these construction scenarios for the Project:

1. Construction of mine, beneficiation plant, port and associated infrastructure with a production capacity of 15Mdptpa;
2. Construction of second beneficiation plant, expansion of associated infrastructure and increase in mine production to 30Mdptpa;
3. Expansion of beneficiation capacity, port and associated infrastructure and increase in mine production to 50Mdptpa.

Note that the initial production capacity is subject to ongoing feasibility studies and would be either 15Mdptpa or 22.5Mdptpa (see **Section 1.3**). Wherever practicable and required, construction activities would be undertaken 24-hours a day. The high rainfall experienced in the wet season may restrict vehicle movements and thus curtail some construction activities in wetter months. All structures would be designed and constructed to the relevant cyclone loading specified in Australian Standards *AS1170 Structural Design Actions Infrastructure*.

2.3.1 15Mdptpa Production Capacity

The design and construction of the 15Mdptpa mine is estimated to take approximately three years. The initial priority would be to provide site access, power, telecommunications, water supply and accommodation for the construction workforce. The following works would be undertaken in the first year:

- Humbug barge terminal – construction of roll-on roll-off (RORO) facility, including floating ramp, mooring dolphins, access lane and vehicle parking. Approximately 10,700m^3 of material would be dredged and disposed of at the existing Albatross Bay spoil ground (refer **Section 6.5.2** for further information on dredging). A small area (about 400m^2) would be reclaimed behind a sheet pile wall (refer **Section 3.9.1** for further information on fill material). The location of the terminal is shown on **Figure 1.3** and the terminal layout is shown in **Figure 2-3.**
- Hornibrook ferry terminal – construction of vehicle parking, covered waiting area and walkway, pontoon and floating ramp. Approximately 19,000m^3 of material would be dredged and disposed of at the existing Albatross Bay spoil ground (refer **Section 6.5.2** for further information on dredging). An area of about 1,900m^2 would be reclaimed and supported by rock revetment and/or sheet piles (refer **Section 3.9.2** for further information on fill material). The location of the terminal is shown on **Figure 1-3** and the terminal layout is shown in **Figure 2-4**.

- Hey River barge terminal – construction of Roll-On Roll-Off facility, vehicle parking, covered waiting area and walkway, pontoon and floating ramp for ferry terminal. Approximately 17,300m^3 of material would be dredged and disposed of at the existing Albatross Bay spoil ground (refer **Section 6.5.2** for further information on dredging). An area of about 4,400m^2 would be reclaimed and supported by rock revetment and/or sheet piles (refer **Section 3.9.3** for further information on fill material). A thin band of mangroves would need to be cleared. The location of the terminal is shown on **Figure 1-3** and the terminal layout is shown in **Figure 2-5.**
- Construction of all-weather sealed 38km Mine Access Road from the Hey River Terminal to Boyd infrastructure area (refer **Figure 1-3** and **Section 2.7.2**).
- A temporary camp (up to 630 beds) to accommodate construction workforce at the Boyd infrastructure area (refer **Figure 1-3**). The existing Evans Landing camp, which has been previously used for construction projects north of the Embley River, would also be utilised as required. A mobile construction camp may be used during construction of the Mine Access Road and an accommodation barge may be used during dredging for the Port.
- Temporary concrete batch plant and temporary construction fuel storage facility.
- Dredging for a new port located between Boyd Point and Pera Head (refer **Figure 1-3** for location and **Figure 2-6** for port layout). Approximately 6,500,000m^3 of material would be dredged and disposed of at a new offshore spoil ground located approximately 17km west of Boyd Point (refer **Section 6.5.1** for further information on spoil disposal).
- Commencement of construction of port and ship-loading facilities. The port would include an approach jetty and two berths totalling 900m in length and a fair-weather mooring point along the jetty for tugs. Tugs would return to Weipa in bad weather to protected moorings to be constructed alongside the existing Lorim Point east wharf. A 1.2km conveyor would transport bauxite from the product stockpile to the ship loader. The port would be built with an initial capacity of 30Mdptpa. The location of the proposed port is shown in **Figure 1-3** and the layout of the proposed port is shown in **Figure 2-6**.
- Commencement of construction of mine support infrastructure at the Boyd infrastructure area (refer **Figure 1-3** for location and **Figure 2-7** for the Boyd infrastructure area detail), including a 15.4MW diesel-fuelled power station, fuel storage, workshops, warehouse, administration facilities, and package sewage treatment plant.

The following works would be commenced in the second year and completed in the third year:

- Water storage dam (Dam C) on a freshwater tributary of Norman Creek (refer **Figure 1-3**) and associated pipeline. Under the 15Mdptpa scenario, Dam C would have an initial capacity of 10.9GL, a wall height (at spillway) of 8m and wall length of approximately 2,550m. The surface area at full supply level would be approximately 3.6km^2. Note that the dam would be constructed in a single stage (capacity of 29.0GL) should expansion of production above 15Mdptpa occur quickly, or should an initial production rate of 22.5Mdptpa be adopted (see **Section 1.6.8**). This is the subject of ongoing feasibility studies.
- Installation of four artesian bores.
- Beneficiation plant and stockpile facilities at the Boyd infrastructure area near the port (refer to **Figure 2-7**). Plant would include: a primary and secondary crushing station with the option of a tertiary crushing station if required, 4.7km of conveyors, stacker and reclaimer, and 680,000dpt stockpile.

- Mining of bauxite from within parts of the footprint of the proposed tailings storage facility located south of the Boyd beneficiation plant (refer **Figure 2-7**), and stockpiling of ore for later processing. Construction of the initial cells of the tailings storage facility.

Construction of the wharf and jetty would utilise pre-assembled modules for the deck structure to reduce the site labour component where practical. The construction plan allows for the yard machines (stacker, reclaimer and ship loader) arriving in large pre-assembled modules transported via heavy lift ships.

Construction of the port would start with dredging of the berth pocket followed by driving the piles supporting the wharf and jetty structures as well as the separate berthing and mooring structures. Piles may be driven by a piling rig mounted on a jack-up barge to improve access to inshore shallow areas. Prefabricated headstocks would be lifted and welded in position to the piles. Placement of the prefabricated wharf and jetty decks is anticipated to be by heavy lift cranes mounted on barges or by a heavy lift vessel delivering the deck units. The jetty and wharf deck structures would have conveyor galleries and services pre-assembled to the extent practical to minimise work over water. Small bore piping conveyor belting and electrical cabling would be site run.

The Boyd beneficiation plant and the administration and maintenance infrastructure would be erected on-site using conventional construction methods. Construction materials and equipment would be trucked to site initially via the PDR and existing Access Roads (refer **Figure 1-3**) until barge facilities have been constructed at the Hey River barge/ferry terminal (approximately six months into the construction period). During this initial phase, some equipment and materials required for the commencement of construction may be brought ashore by barge between Boyd Point and Pera Head, and at Hey Point. Transportation of materials to the Project site is discussed further in **Section 14**.

Approximately 35,800m^3 of aggregate, 15,000m^3 of concrete and 8,000t of steel would be required for construction. Approximately 4,900,000m^3 of cut and fill earthworks would be undertaken in order to level ground surfaces for facilities and to construct a water storage dam, tailings storage facility and truck dump station. Ground levelling would typically not require more than 0.5m excavation, but may reach 2m for the southern end of the product stockpile area. Construction areas are generally the higher elevations in the landscape dominated by deep reddish massive gradational soil with aluminous concretions. Excavation to a depth of several metres would be required for the water storage dam and tailings storage facility. Material excavated would comprise subsoil, low quality bauxite/clay mix, kaolin clay and ironstone. This excavated material is suitable for construction of infrastructure, including dams (refer **Section 5.2.3** for details of dam construction). Topsoil from construction areas would be stripped and stockpiled for later use in rehabilitation of infrastructure areas.

Water for construction purposes would be obtained from Norman Creek until such time as the permanent water supply facilities are built. The indicative number and type of construction equipment is shown in **Table 2-2**.

2.3.2 30Mdptpa Production Capacity

The expanded 30Mdptpa production capacity scenario would be attained once mining at Andoom ceases.

A second mine infrastructure area would be established at the Norman Creek mining area (refer **Figure 1-3**).

At a 30Mdptpa production capacity scenario, the following additional works would be required:

- 24km sealed Norman Creek Mine Access Road (constructed as a spur from the existing Mine Access Road) (refer **Figure 1-3**).
- Dam C (refer **Figure 1-3**) would have a capacity of 29.0GL, through a raise in height (at spillway) of the existing wall from 8m to 12m (if not initially built at this capacity). The wall length would be approximately 3,850m and the surface area at full supply would be approximately 6.5km^2.
- Water pumping station on the Ward River (refer **Figure 1-3**) and associated 16km pipeline and power line. The annual volume of water pumped from the Ward River would be capped at 1% of mean annual river flow at the pump station (2.67GL).
- Three artesian bores.
- Primary crusher and beneficiation plant with 15Mdptpa capacity at the Norman Creek infrastructure area (refer **Figure 2-8**).
- 15km overland conveyor to the port product stockpiles (refer **Figure 1-3**). The port stockpile capacity would be increased to 1.26Mdpt.
- High voltage power line extension from Dam C to the Norman Creek infrastructure area.
- Associated infrastructure at the Norman Creek infrastructure area including fuel storage, workshops, warehouse, administration facilities and package sewage treatment plant (refer **Figure 2-8**).
- Tailings storage facility located in the vicinity of the Norman Creek beneficiation plant (refer **Figure 2-8**). This would be preceded by mining of bauxite from within parts of the footprint of the proposed tailings storage facility and stockpiling of ore for later processing.
- Power station expansion at the Boyd infrastructure area to 29MW.

The port does not need to be expanded until production exceeds 30Mdptpa.

2.3.3 50Mdptpa Production Capacity

50Mdptpa production capacity would be attained when market conditions allow. At a 50Mdptpa capacity scenario, the following additional infrastructure would be required:

- Expansion of beneficiation plant capacity at Norman Creek and/or Boyd infrastructure areas to an aggregate of 50Mdptpa. The size of the increment in capacity at either plant would depend on feasibility studies at the time. For the purposes of the EIS, both plants are assumed to have 25Mdptpa capacity.
- Installation of five artesian bores.
- Expansion of the power station at the Boyd infrastructure area to 54MW.
- Expansion of the port product stockpile capacity to 2.55Mdpt.
- Extension of the wharf to accommodate two extra berths at the port. To accommodate the extra berths and departure areas, approximately 2,400,000m^3 of material would be dredged and disposed of at the offshore spoil ground located approximately 17km west of Boyd Point.

2.4 Bauxite Mining

2.4.1 Ore Reserves

Ore reserves are reported in accordance with the *Australasian Code for Reporting of Exploration Results, Mineral Resources and Ore Reserves* (known as the JORC Code) as required by the Australian Securities Exchange (ASX). As of 31 December 2010 a total of 1,602 million tonnes of bauxite reserves with a 53% grade have been reported within RTA's Weipa mining leases, with a considerable proportion of the reserve within the portion of ML7024 south of the Embley River.

Exploration activities are ongoing throughout the Project area and involve prospecting, the establishment of access tracks, drilling, test pits, use of instruments and equipment for mineral detection, sampling and digging to extract test material and ore samples to determine mineral content, land clearance, and trucking of ore and test samples extracted. Resource evaluation would be ongoing throughout the life of the mine to better define the bauxite reserves.

2.4.2 Mine Development and Schedule

The Project currently has bauxite reserves that could sustain a mine life of about 40 years, depending on annual production rate. Mine life also depends on the extent to which mineable reserves may change in the future subject to resource evaluation and economic factors.

The conceptual 40-year mine plan is shown in **Figure 1-3**. Mining would commence in the Boyd Point – Pera Head area, and would later be extended to the Norman Creek area. **Figure 1-3** shows the areas to be mined in years 1–13 (i.e. at a production rate of 15Mdptpa) and in years 14–40 (i.e. at a production rate of 30Mdptpa and above).

The areas to be mined comprise *Eucalyptus tetrodonta* woodlands on bauxite plateaus. Approximately 5,300ha of woodland would be cleared for mining over years 1–13 and 21,980ha over years 14–40. The areas and the conservation status of vegetation to be cleared during the construction and operation phases of the Project, as well as mitigation measures, are discussed in **Section 7.9**.

Vegetation would be cleared by bulldozers, following the wet season when the ground is sufficiently moist to allow tree roots to pull clear of the ground rather than breaking. Consideration would be given to the selective extraction of structural-grade timber in the Project area prior to mining, where practicable and where the timber can be beneficially used. The cleared vegetation would be pushed into windrows and burnt.

Approximately 60cm of soil would be salvaged and returned by scraper or haul truck directly to mined-out areas undergoing rehabilitation, where possible, or stockpiled for later respreading. The overburden above the bauxite would then be removed by front-end loader and returned to mined-out pits by trucks.

2.4.3 Mining Equipment and Methods

The top of the bauxite strata is generally less than 1m below the natural ground surface. The average ore thickness across the Project area is approximately 3.4m.

A shallow open pit would be developed whereby bauxite would be mined by front-end loader or excavator. Bauxite is relatively easy to dig and does not require blasting. The ore would be loaded into 180t dump trucks and transported via dedicated haul roads to a truck dump station adjacent to the beneficiation plant.

A list of the mining equipment used at 15, 30 and 50Mdptpa production rates is presented in **Table 9.3**.

2.4.4 Final Landform

After overburden and soil are returned to mined-out pits the final landform would be at a lower elevation than the original landform due to the removal of the bauxite, but the overall slope of the landform would be similar. Where mining leaves batters on the edges of the pit, these

would be recontoured to a maximum slope of 20% (1 in 5). The final landform would not have any out-of-pit dumps of excavated waste material or soil.

2.5 Bauxite Processing (Beneficiation)

Product-grade bauxite is processed by beneficiation, a process where oversized particles are removed by screening and fine particles are removed by washing. After beneficiation, product bauxite would be stockpiled prior to shipping from the proposed port.

The beneficiation process generates tailings, which are pumped to a tailings storage facility where water is decanted and recycled back to the plant. Each stage of the process is discussed below. The indicative layout of the Boyd and Norman Creek beneficiation plants is shown in **Figure 2-7** and **Figure 2-8** respectively.

2.5.1 Beneficiation Plant

Crude ore is transported to a truck dump station and dumped into a hopper. The ore is then sized to <300mm in a primary crusher and then <90mm in a secondary crusher. Ore is then conveyed to the beneficiation plant. The plant function is to disperse the crushed crude bauxite by using water and separate oversize tramp and high-silica fines fractions from the product bauxite fractions, and then to dewater the product bauxite. No chemicals are used in the beneficiation process. The oversize rejects would report to a tertiary crusher for blending with the product stream or be conveyed directly to a rejects stockpile for subsequent disposal. The high-silica fines fractions would report to a tailings storage facility via the tailings pumping system. The dewatered product bauxite would report to the product stockpiles.

In the plant, crushed ore and dispersion water is fed to single-deck scalping screens. Water sprays over the scalping screen decks complete the dispersion of the crude ore. The decks of the scalping screens classify and separate oversize rejects (+25mm) from the crude bauxite feed. The underflow slurry (–25mm) from each scalping screen flows by gravity onto a dedicated product screen for final classification and dewatering of the product (+0.6mm). The product from all screens collects on the product conveyor and the underflow from the product screens would flow by gravity to tailings sumps.

The oversize material from the scalping screens would be conveyed to a nominal 4,000t stockpile adjacent to the plant. A larger 100,000t oversize stockpile would be located between the plant and the tailings storage facility. This material would be reprocessed, used for construction (e.g. roads, tailings storage facility walls) or returned to mined-out pits.

The beneficiation plant building structure would support the scalping and product screens, and outgoing conveyors. Elevated concrete frames would support the scalping screens. Ground level steel beams located over the below-grade screen-underflow sumps would support the scalping screens. Steelwork supports would provide all other supports and access-ways in the building structure. Stair towers would provide access at each end of the beneficiation plant to allow two points of egress. A concrete apron slab would drain area sumps.

The initial Boyd and Norman Creek beneficiation plants would be similar "low dispersion energy" plants designed to process approximately 3,400 wet crude tonnes per hour and each plant would use approximately 1t of water to produce 1t of product bauxite. Each plant would be designed so it can be expanded in the future. Approximately 40% of the crude ore in the Norman Creek mining area has elevated fines content that may require "high dispersion energy" beneficiation. This ore would be processed through a "high dispersion energy" module that would be added to the existing plant. This module would use approximately 1.9t of water to produce 1t of product bauxite.

Approximately 35% of the water used in the beneficiation plants would be recycled from tailings storage facilities. Overall bauxite product recovery from crude ore would average approximately 70%.

2.5.2 Tailings

Beneficiation produces tailings consisting of water, fine bauxite pisolites, sands and clays. Approximately 0.4Mt of tailings is produced for every 1Mdpt of product bauxite. Depending on the source of crude ore, the geotechnical classification of tailings ranges from a sandy silt with clay to a clayey silt. Bauxite tailings are benign, contain no added chemicals and are not classed as hazardous under the DERM criteria for *Determining Dams Containing Hazardous Wastes* (refer **Section 13.3.4**).

The tailings would be pumped in slurry form (30% solids by weight) from a tailings sump at the beneficiation plant to a tailings storage facility. The tailings storage facilities are "turkey's nest" dams where tailings are discharged from the perimeter wall into cells within the dam. The tailings solids would beach and suspended solids would settle out and water would be decanted and pumped back to the beneficiation plant for reuse in processing. The tailings storage facilities are divided into cells to facilitate the cycling of tailings perimeter deposition within a cell, and between cells, to enhance formation of a broad tailings beach adjacent to the perimeter walls that dries quickly to a consistent density over its full depth. Tailings storage facility walls would be raised in lifts of approximately 3m using an upstream raising technique (refer **Section 13.3.4**).

The tailings storage facility for the Boyd and Norman Creek beneficiation plants would be located close to the plants and each would have four cells which would be constructed and commissioned over several years. Prior to construction of each cell, the bauxite from within each cell would be mined and fed into the plant if it is operating, or stockpiled for later processing if not. This approach would avoid sterilization of economic bauxite reserves and reduce the extent of clearing of vegetation. The Boyd tailings storage facility would have a capacity of approximately 182Mt, cover an area of approximately 580ha and be about 22m high upon completion. The Norman Creek tailings storage facility would have a capacity of approximately 204Mt, cover an area of approximately 580ha and be about 25m high upon completion. These tailings storage facilities would have sufficient capacity for the 40-year mine plan.

2.5.3 Product Stockpiles

Product bauxite from the beneficiation plants would be conveyed to a stacking feed conveyor which supplies a travelling luffing and slewing stacker which deposits bauxite onto a stockpile pad. The stacker would stack product into a range of discrete stockpiles varying in product quality. The stacker would operate at a nominal rate of 2,500dptph. A bucket wheel reclaimer would reclaim selected stockpile material at a nominal rate of 9,000dptph and feed this onto a reclaim conveyor, which in turn feeds a load-out conveyor to the wharf.

The stockpile area would be expanded in stages as production increases. Should ore from neighbouring mines operated by others be shipped through the proposed port, such ore would be conveyed by others across ML7024 to the stockpile area. Allowance has been made in the stockpile layout to enable additional stockpile capacity to be added adjacent to RTA's facilities to accommodate product from third parties following agreement on suitable commercial terms.

At a production rate of 15Mdptpa, the stockpile capacity would be 680,000dpt and it would occupy 17ha. At a production rate of 30Mdptpa, the stockpile capacity would be 1.36Mdpt and it would occupy 34ha. At an RTA production rate of 50Mdptpa, and assuming 13Mdptpa production from third parties as well, the stockpile capacity would be 2.55Mdpt and it would occupy 59ha.

The fully-developed product stockpile layout, including provision for third parties, is shown in **Figure 2-7.** The extension of the stockpiles to the north of the beneficiation plant would require an additional stacker and reclaimer.

2.6 Port Facility and Shipping

RTA proposes to construct and operate port facilities located between Boyd Point and Pera Head. Works would include an approach jetty, wharf, berths, ship-loader and dredging of berth pockets and departure areas. The proposed port is located outside the Port of Weipa port limits.

Initially, RTA proposes to construct and operate a port capable of shipping 30Mdptpa. The first stage of the Port would enable replacement of bauxite exports from the existing Port of Weipa Lorim Point wharf in the Embley River as bauxite reserves at East Weipa and, later, Andoom are depleted. The port would be designed to permit future expansion to ship up to 63Mdptpa. Capacity may be provided for third parties following agreement on suitable commercial terms.

2.6.1 Facility details

The port would include an approach jetty approximately 568m long and, initially, a 342m wharf with two berths. A further two berths would be added when production rises above 30Mdptpa. The four-berth wharf would be approximately 696m long. The berths consist of an "I" berth aligned perpendicular to the shoreline (at 300 degrees). The port would be capable of accepting bulk carrier vessels of up to 185,000 dead weight tonnage and 18.1m draft. Separate berths would be provided for tugs and line boats. Separate berthing and mooring dolphins are provided which isolate ship berthing loads from the main wharf structure. The port is also equipped with the appropriate navigational aids.

The approach jetty would support the product load-out conveyor and a vehicle access roadway from the Boyd infrastructure area. The wharf supports a rail-mounted travelling luffing and slewing ship loader capable of loading at a rate of 9,000t/hr. Ships would not be refuelled at the proposed port. The port layout is shown in **Figure 2-6.**

Initially, approximately 6,500,000m^3 of marine sediments would be dredged to establish the berth pockets and departure areas over a period of about 300 days. For the purposes of evaluation studies, it has conservatively been assumed that vessel departures are unrestricted by tides and hence the depth of dredging required has been matched to this assumption. The dredging would be carried out by a cutter suction dredger re-depositing material on the sea bottom and retrieved by a trailing suction hopper dredge (TSHD). Dredged spoil would be transported by the TSHD to a new offshore spoil disposal ground located approximately 17km west of Boyd Point (refer **Figure 2-9** for location). Initially, annual maintenance dredging of approximately 890,000m^3 is expected to be required to maintain under keel clearance for ships. Once the wharf is extended, an extra 280,000m^3 of maintenance dredging would be required annually equating to annual maintenance dredging of the port of approximately 1,170,000m^3.

When the wharf is extended in a second stage to expand its capacity to at least 50Mdptpa, a further 2,400,000m^3 of dredged spoil would be generated and disposed of at the same offshore spoil ground.

Dredging and spoil disposal would be conducted 24 hours a day, seven days a week. Further details of the proposed dredging and spoil disposal are presented in **Section 6.5.1**.

2.6.2 Shipping

When a ship arrives near the port and has to wait to berth, it would generally anchor in an offshore mooring area in water approximately 20m deep (refer **Figure 2-9**). However, some ships may be able to anchor in waters between 20 and 14m deep and therefore the specific location of the anchorage areas would be subject to the approval of the operator of the Port, who would direct ships according to conditions at the time through the shipping agent.

The Port would be designed for continuous hours of operation. When the port is ready to receive a ship, tug boats would assist to manoeuvre the ship safely and efficiently to the berth.

RioTintoAlcan

The estimated shipping frequencies at each production level are summarised below:

- 15Mdptpa – up to 215 ships/annum (4–5 ships/week)
- 30Mdptpa – up to 430 ships/annum (8–9 ships/week)
- 50Mdptpa – up to 700 ships/annum (14 ships/week).

The operation of the proposed port would require the services of three tugs at maximum production. When not in use, it is proposed to berth these tugs in unprotected moorings alongside the approach jetty or, if weather conditions require, at protected moorings alongside the existing Lorim Point east wharf. Modification to the existing east wharf at Lorim Point would be required with the installation of berthing frames and walkways on the landward side of the east wharf.

Once loaded, bulk carriers travelling to Gladstone would continue sailing the existing route through the Gulf of Carpentaria, the Torres Strait shipping route, and transit the inner route of the Great Barrier Reef under pilotage.

RTA operates the existing Lorim Point ship-loader at the Port of Weipa and has implemented the MarineSafe system developed by Rio Tinto Marine. This system implements the requirements of the Australian Maritime Safety Authority (AMSA), ISO14001 and other relevant international statutory authorities, relevant class rules, regulations and ship management contracts. The proposed port would operate under this system.

Further details regarding shipping are presented in **Section 14.4**.

2.7 Associated Infrastructure

This section describes infrastructure that would be constructed as part of the Project to support the mining, processing and shipping activities.

2.7.1 Workforce and Accommodation

The construction phase would take three years and workforce numbers would vary over that period, peaking at about 630 and averaging approximately 307 full-time equivalents over three years. There may be opportunities to shorten the construction phase, possibly by up to 12 months depending on availability of certain contractors, equipment and labour. Should this occur, the average and peak construction workforce would rise in approximate inverse proportion to the reduction in the length of the construction phase.

The Project construction workforce would be a "single status" workforce. When not on roster, the construction workers would return to their point of hire. The large majority of these would be from the east coast of Australia and they would fly-in and fly-out of Weipa airport and be transported back and forth to the construction site by RTA in buses. Local hire construction workers would return to their existing residences in Weipa, Napranum, Aurukun or Mapoon when off roster. No changes to the Weipa airport infrastructure would be required, although additional commercial flights would be required during the construction period.

A temporary construction camp would be established 2km north-east of the Boyd infrastructure area, away from any noise and dust arising from construction works. The camp design would enable expansion up to 630 beds for the peak construction workforce. The camp would consist of:

- sleeping quarters;
- canteen, kitchen and crib preparation;
- mess hall, recreational areas and sporting facilities;
- training room;
- ablution facilities; and
- laundry.

The camp layout is shown in **Figure 2-10**.

Date: 15/07/2010

There would be a licensed wet mess at the temporary camp near Boyd Bay for the responsible service of alcohol to camp occupants only. The consumption of alcohol would be well regulated and confined to the wet mess and immediate delineated area (refer **Section 16.3.8** for further information). The following additional alcohol controls would apply:

- secure storage;
- limits on daily consumption;
- restricted hours of operation/availability;
- close supervision of premises;
- RTA's standard drug and alcohol testing protocols, including random testing as a part of the Fitness for Work program;
- alcohol from the wet mess or elsewhere would not be permitted to be taken into the rest of the camp by occupants or visitors; and
- management approval would be required to drink alcohol outside the wet mess area.

The camp has been designed to meet the relevant requirements of the Building Act 1975 (Qld) and Building Fire and Safety Regulation 2008 (Qld). The camp does not require local government planning approval. Where necessary, control programs for vermin and mosquitoes would be undertaken on a regular basis by a licensed Pest Control Technician. Camp wastes would be disposed of in the existing Evans Landing landfill at Weipa.

During construction there would be an emergency services facility located at the Boyd infrastructure area staffed by qualified personnel. A site emergency response plan would be prepared which would document the methods and procedures to accommodate visiting police and emergency services to deal with any major incident (refer **Section 19.3** for further information). Safety management standards and procedures are discussed in detail in **Section 18**.

The on-site construction camp would be removed at the completion of construction.

The existing Evans Landing camp, which has been previously used for construction projects north of the Embley River, would also be utilised as required. A mobile construction camp may be used during construction of the Mine Access Road and an accommodation barge may be used during dredging for the Port. These camps would be utilised for a limited number of people over a shorter timeframe.

The SoE operational workforce would be based in Weipa. Details of operational workforce numbers at RTA's existing operations (including ML7024 and ML7031) and the estimated SoE operational workforce are shown in **Table 2-3.** While SoE and Andoom/Ely are both in production, the SoE employee component is estimated to be 500. The predicted generation of direct and indirect employment in the local economy is detailed in **Section 17.4.3**.

Table 2-3 Operations Workforce

Production Scenario	Average Operations Workforce		
	Employee	Contractor	Total
2006 – East Weipa, Andoom and Ely	777	107	884
2007 – East Weipa, Andoom and Ely	825	345	1170
2008 – East Weipa, Andoom and Ely	912	245	1157
2009 – East Weipa, Andoom and Ely	826	85	911
15Mdptpa – South of Embley, Andoom and Ely	800	200	1000
30Mdptpa – South of Embley	760	190	950
50Mdptpa – South of Embley	1020	255	1275

The effects of the Project on the size of the local population and demand for accommodation are discussed in **Section 16.2.1** and **Section 6.3.11** respectively.

The occupational groupings of the SoE workforce would be unchanged from the current workforce and would include engineers and other professionals, technicians, tradespeople, plant operators and semi-skilled and unskilled labour. RTA would continue to work with the local community to invest in employment and training to create a locally-based labour pool with the appropriate skill sets and knowledge to meet the particular employment needs of the Project. Information on employment opportunities, recruitment and training programs, including those conducive to the recruitment and retention of local Aboriginal employees, is included in **Section 16.3.4**.

In 2008, Rio Tinto Alcan, together with numerous other partners, signed the Regional Partnership Heads of Agreement (RPA). The RPA was a statement of intent by the parties to work together to improve opportunities for employment and training of Indigenous people in the Western Cape region. The Agreement established a job placement target of 50 additional local Indigenous people into mainstream jobs within the Western Cape region each year for five years (refer **Section 17.4.7**). RTA would identify and pursue Indigenous employment opportunities related to the Project in the following areas:

- youth development, education, vocational programs and bursaries;
- pre-work development, including school-to-work pathways and work readiness programs;
- local Aboriginal Traineeship and apprenticeship programs;
- leadership development; and
- employment opportunities with RTA contractors and other local businesses.

2.7.2 Transport

Prior to construction of the barge and ferry terminals, construction workers would travel by road to the SoE site via the PDR, Aurukun Road, Beagle Camp Access Road and Pera Head Access Road. Once the ferry terminals and new Mine Access Road have been constructed, they would be transported from the Hornibrook Terminal by ferry to the Hey River Terminal and then by bus to the construction camp at the beginning and end of each roster. Access to the barge, ferry and Mine Access Road would be subject to authorisation by RTA.

The maximum vehicle trip ends (vte) anticipated during the construction phase is 20 per day for the link between Weipa and site via the PDR and Aurukun Road. A full description of transportation requirements, infrastructure and potential impacts is provided in **Section 14**. The proposed transport infrastructure is shown in **Figure 1-3**.

During operations, the workforce would be housed in the existing Weipa community and commute to SoE on a daily basis via ferry and the Mine Access Road. The ferry would be sized according to the number of people on each shift and would be sufficiently seaworthy to sail in all but severe weather events. Ferries would operate as needed, however 3–4 ferry crossings per day is estimated for 15Mdptpa, increasing to 4–6 crossings per day at 50Mdptpa. The ferry crossing would take approximately 12 minutes each way.

Roads

RTA proposes to upgrade the intersections from the Humbug barge terminal and the Hornibrook ferry terminal with the PDR to improve traffic flow and safety. No other changes affecting State or local Government controlled roads are required to support the Project.

A new 38km "on-lease" Mine Access Road from the Hey River Terminal to the Boyd infrastructure area is proposed. It would have a sealed pavement with a design speed of 110km/hr. The number of vehicle movements along the Mine Access Road would be very low, with most employees and contractors travelling to and from the mine on buses. Signs would be posted to raise awareness of possible fauna movement across the Mine Access Road.

The road alignment and creek crossings are designed to provide all weather access up to a 1 in 10-year storm event. A section of the access road near the Boyd infrastructure area would be

widened to meet the Royal Flying Doctor Service standards to provide for emergency aircraft evacuation of sick or injured people.

A typical cross section of the Mine Access Road is shown in **Figure 2-11.** The maximum clearing width is 45m to account for the following in both directions:

- 1.5m shoulder;
- 3.5m traffic lane; and
- up to 17m for table drains and also setback area to provide roadside visibility.

The Mine Access Road alignment follows elevated portions of the landscape wherever possible to enable all weather access; however, box culvert causeways would be required at certain watercourses. The road would transverse nine separate watercourse crossing points and require up to eight adjacent box culverts (3.6m wide x 1.8m high) at each crossing.

When the Norman Creek infrastructure area is developed, a 24km spur road would be constructed from the main Mine Access Road. Four box culvert causeways would be required along the Norman Creek access road.

The locations of the proposed culvert causeways are shown on the vegetation maps presented in **Section 7** (refer **Figure 7-4a and Figure 7-4d**). Smaller culverts would also be used as necessary in lower parts of the landscape similar to those used in conventional roads of similar design standard. Sediment controls are described in **Section 3.6.2**.

Borrow pits would be utilised where necessary to provide material for the construction of the roads.

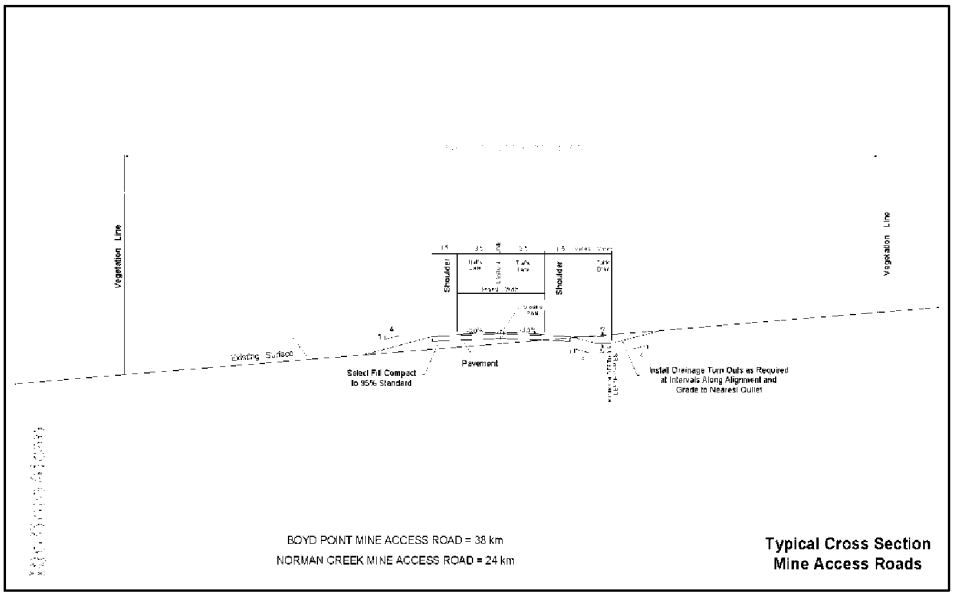

Figure 2-11 Mine Access Road Cross Section

Watercourse crossings may also be required for certain internal mine haul roads that link mining blocks to the beneficiation plants. Haul road alignments would be planned during the mine construction phase and are subject to change to meet mine development requirements. It is anticipated that haul roads would be approximately 45m wide. Watercourse crossings would use similar culvert designs to the Mine Access Roads.

Barge and Ferry Terminals

Plant, equipment and materials coming in by barge from Cairns would be offloaded at Humbug Wharf. The Humbug barge terminal would be located adjacent to Humbug Wharf to enable the efficient transfer of equipment and material bound for SoE without the need to use public roads. The proposed Humbug Terminal is shown in **Figure 2-3.**

The Hornibrook ferry terminal would be constructed at Hornibrook Point, south-east of the Lorim Point Ship Loading Wharf (refer **Figure 2-4**). The Hey River barge/ferry terminal would be located on the southern bank of the Hey River on ML6024. It would operate as a joint RORO barge and ferry terminal (refer **Figure 2-5**).

The RORO barge when loaded would have a displacement of approximately 300 tonnes and a draft of 1.6m. The ferry would have a displacement of less than 30 tonnes and a draft of 1.1m. The vessel movements and amount of materials moved through the terminals during construction and operations is detailed in **Section 14.4**.

2.7.3 Water Supply and Management

The Project's principal water requirements are for process water, haul road watering, vehicle wash-down, dust suppression and potable supplies. The Project's principal sources of supply are local surface waters (water storage dam and direct pumping from stream), deep artesian groundwater and recycled water from the tailings storage facilities. The overall water balance for the Project is summarised in **Table 2-4.**

Table 2-4 Average Annual Water Balance

Production Rate	Average Annual Demand (GL)	Average Annual Supply (GL)					
		Recycle from tailings	Artesian	Dam C	Slots*	River	Total Supply
15Mdptpa	16.4	4.7	3.1 (5.2 peak)	7.8 (Stage 1)	0.8	0	16.4
30Mdptpa	33.0	9.4	6.0 (10.6 peak)	13.8 (Stage 2)	1.6	2.2	33.1
50Mdptpa	63.7	22.1	11.9 (15 peak)	25.4 (Stage 2)	1.6	2.5	63.5

* Trenches dug adjacent to tailings storage facilities to recover water

Typically, water would be drawn in order of preference from tailings recycle, recovery slots, surface water dam (Dam C), and artesian bores. Some supplementary surface water would be drawn directly from the Ward River to minimise the risk of inadequate supply from Dam C. The artesian demand would therefore fluctuate depending on whether there is above or below average rainfall runoff into the dam. RTA has an existing artesian water licence for 9GL per annum which allows abstraction from bores located on ML7024. RTA proposes to apply to increase the artesian allocation to 12GL on a five-year moving average with a maximum of 15GL in any one year to cover peak artesian demand (refer **Section 5.4.3**).

A reverse osmosis potable water treatment plant would be used to treat raw water to a standard that meets the *Australian Drinking Water Guidelines* (NHMRC 2004). Approximately 200kL/day of potable water would be treated during the construction phase to service the construction camp and the plant construction sites. At the commencement of operations, potable water use would decline by about 90%. Potable water use would then increase pro-rata with future production increases. Treated water would be stored in two 160kL ground level storage tanks.

The water supply infrastructure for the Project would not be connected to the water supply infrastructure for the existing Weipa operations. However, water may be trucked or barged from Weipa operations in the early stages of construction if required, prior to water infrastructure for the Project being commissioned.

Dam C would be a conventional earth-fill dam constructed on a tributary of Norman Creek and would have a catchment area of 77.3km^2. The dam spillway would be designed to pass the peak flow from a 1:2,000 Annual Recurrence Interval (ARI) flood event. The spillway would also be designed to facilitate fish passage during flow events (refer **Section 8.16.2**). The cross-section of Dam C is shown in **Figure 5-10**.

To supplement the Dam C supply at production rates between 30Mdptpa and 50Mdptpa, some water would be pumped directly from the lower reaches of the Ward River. The proposed pump station layout is shown schematically in **Figure 5-19** and **Figure 5-20**. Further information on the water storage dam and the Ward River pump station is provided in **Section 5.2.3**.

Schematic diagrams of the proposed water management systems for the Boyd infrastructure area and Norman Creek infrastructure area are shown in **Figure 5-8** and **Figure 5-9** respectively. Sediment ponds are sized to capture runoff equivalent to a 1 in 10-year 24-hour event.

Stormwater runoff generated within mine areas would mostly be captured within the internally draining mine pits. The post-mining landscape effectively provides internally draining sumps that contain stormwater runoff which then infiltrates through the pit floor and walls. In the event that the post-mining topography is not an internally draining pit, stormwater runoff would be directed via a sediment pond. Sediment traps would also be included as part of the drainage designs at points where haul roads cross watercourses.

No watercourses would be diverted as part of the Project.

2.7.4 Sewage

During the initial construction phase, prior to a sewage treatment plant (STP) being commissioned, the construction areas would be serviced by portable ablution facilities. Sewage would be stored in holding tanks and regularly trucked by a licensed regulated waste transporter back to Weipa for treatment in an existing licensed STP. This method would also be utilised if temporary mobile construction camps were used for the Mine Access Road or an accommodation barge used during dredging of the Port.

The construction camp and Boyd infrastructure area would be serviced by separate package STP's. The effluent would be treated to Class A standard and would be recycled for use in dust suppression, process water, landscape watering or other appropriate uses on-site that are suitable for the quality of water.

An additional package STP would be installed in the Norman Creek infrastructure area when it is developed.

The construction camp STP would be designed to a capacity of 630 people, while the Boyd and Norman Creek STPs would be designed to a capacity of 150 people. Based on the predicted average workforce, the total treated effluent volume during construction and at various production rates would be:

- 90kL/day during construction;
- 8kL/day at 15Mdptpa;
- 15kL/day at 30Mdptpa; and
- 20kL/day at 50Mdptpa.

Further details about sewage treatment are presented in **Section 13.3.7**.

2.7.5 Power Generation and Supply

Electricity for the Project would be generated by a diesel-fuelled power station located at the Boyd infrastructure area. The power station would be expanded in stages using multiple generating units in the range of 1.4 to 6MW capacity to meet the following demands:

- 15.4MW at 15Mdptpa;
- 29MW at 30Mdptpa; and

- 54MW at 50Mdptpa.

Transmission lines would be installed as required to reticulate power to artesian bores, dam and river water supply pumps and the Norman Creek infrastructure area. Power transmission lines would comprise a single circuit with three active conductors and an overhead earth elevated on 20m poles, similar to conventional transmission lines used throughout Queensland. The power station would not be connected to the existing Weipa electricity grid north of the Embley River.

To minimise energy consumption to the extent practicable, the following actions would be undertaken for the Project:

- diesel and electrical efficiency considerations would be included in assessments of new fixed equipment, such as using high efficiency motors;
- equipment not in use would be switched-off where practical – e.g. conveyors, lighting, air conditioning;
- transmission line voltages would be selected to minimise electrical losses;
- a process to monitor use, efficiency, emissions and regularly review new opportunities to reduce emissions and use energy efficiently would be established;
- RTA would participate in the Australian Government's Energy Efficiency Opportunities program which is designed to encourage large energy-using businesses to improve their energy efficiency;
- equipment would be regularly maintained to retain high levels of diesel efficiency; and
- employee training on greenhouse gas awareness and energy efficiency would be implemented.

2.7.6 Mine Infrastructure Areas

The Boyd and Norman Creek mine infrastructure areas are shown on **Figure 2-7** and **Figure 2-8** respectively and comprise the following facilities:

- heavy equipment workshop and service bay;
- fixed plant workshop;
- warehouse;
- diesel and oil storage;
- light vehicle and heavy vehicle wash-down areas;
- tyre store and change bay;
- offices and crib room; and
- emergency service centre.

Two 250kL diesel storage tanks are proposed, providing a minimum of three days supply at a production rate of 15Mdptpa. As production increases, additional tank storage would be added to maintain the minimum three-day storage capacity. Hydrocarbons would be stored in accordance with Australian Standard *AS1940 The Storage and Handling of Flammable and Combustible Liquids*. Fuel would be trucked in via the Mine Access Road from existing storage facilities in Weipa. The storage of fuel and other dangerous goods is described in **Section 19.1**.

The Boyd and Norman Creek mine infrastructure areas would be linked by a 15km infrastructure corridor approximately 64m wide. The corridor would contain an overland conveyor, access road, transmission line and water supply pipeline. The corridor would traverse four watercourses (tributaries of Norman Creek), each requiring up to six adjacent box culverts (3.6m wide x 2.1m high). A second 16km long, 50m wide corridor would link the Norman Creek infrastructure area with the Ward River pumping station and provide space for an access road, transmission line and water supply pipeline.

2.7.7 Telecommunications

New telecommunications facilities would be developed for the Project and would be operated autonomously from the existing Weipa telecommunication system. The technology adopted would depend upon that which is most feasible and technically appropriate at the time of implementation. Facilities are likely to include a mobile phone tower and underground land lines connecting infrastructure areas.

2.8 Decommissioning and Rehabilitation

2.8.1 Decommissioning

On the completion of mining, buildings, structures and other infrastructure would be treated as follows:

- The barge/ferry terminals, port, water storage dams and certain roads may have some ongoing beneficial use. Subject to agreement with relevant regulators and Traditional Owners, some of these facilities may be left in place. Otherwise, RTA shall remove these facilities.
- Buildings, plant, equipment, tanks, conveyors, pipelines and transmission lines would be removed and the surface rehabilitated. Concrete pads would be broken up, buried, and then the area rehabilitated.

2.8.2 Mine Rehabilitation

Rehabilitation would be undertaken progressively during the life of the mine. RTA's objective for the rehabilitation of areas disturbed by SoE Project mining activities is to establish a self-sustaining vegetation community using appropriate local native tree, shrub and grass species. Under the WCCCA, and at the request of the relevant WCCCC sub-committee, RTA may establish post-mining land use options other than those required by regulation, subject to obtaining all necessary government approvals (refer **Section 3.10.1**). While it is not currently envisaged that land uses other than native vegetation be established, RTA would consult with Traditional Owners about rehabilitation objectives and rehabilitated land completion criteria and objectives. The overall objective would be to return the land to a post-mining land use that would be stable, self-sustaining, and requires minimal maintenance, and protects downstream water quality.

Rehabilitation success criteria suitable for the Project area would be developed and these would form criteria against which rehabilitation performance could be measured.

The approach to rehabilitation has been based on the *Technical Guidelines for the Environmental Management of Exploration and Mining in Queensland* (DME 1995a) and is described in more detail in **Section 3.10**.

Soil Management

The dominant soil type of the Project area is Red Kandosol, which is weathered and low in nutrients, and supports vegetation adapted to such conditions. The majority of seed readily able to germinate is present in the upper 5cm of soil.

Approximately 60cm of soil would be stripped and then placed directly back on previously mined areas or stockpiled for future use in rehabilitation once a suitable area becomes available. If soil is stockpiled, it would be managed so as to maintain optimum growth media properties by maximising the stockpile surface area and minimising compaction. Stockpiled soil would be typically used within one year to maximise the benefits of the natural seed bank and conserve symbiotic micro-organisms.

The rehabilitation strategy and topsoil management are described further in **Section 3.10.**3 and **Section 3.10.4** respectively.

Revegetation

Revegetation is likely to include ripping the mine floor and compacted areas, respreading of freshly stripped topsoil or stockpiled topsoil, soil surface scarifying prior to seeding, seeding and fertilising. Pit floor ripping and pre-seeding scarification assist in providing suitable growing media properties which optimise plant growth (e.g. porosity and water holding capacity). Revegetation techniques are described further in **Section 3.10.5.**

At current RTA operations north of the Embley River, direct seeding has been found to be the best method for establishing desired plant species. Seeding would occur in November and December of each year to help ensure the soil moisture and follow-up rainfall is favourable to seedling establishment.

Native species seed mixes would be tailored to the anticipated post-mining conditions of the area to be rehabilitated. Free draining areas would be seeded with a range of tree, shrub and groundcover species from *Eucalyptus* and *Corymbia* dominated woodlands. In areas that are likely to be less free draining and seasonally inundated, species from *Melaleuca* and *Lophostemon* dominated vegetation communities would be used.

This page has been left intentionally blank

Environmental Impact Statement

for South of Embley Project

Section 3
Land

3 LAND

3.1 Land Use

3.1.1 Existing Land Use

Current land uses within and adjacent to the Project area are shown on **Figure 3-1**. Lands within the Project area are not used for agriculture and are relatively undisturbed by development. There are no rural properties within the Project area. The nearest residential areas and rural properties to the Project area are shown on **Figure 3-1** and described in **Section 12.3**. Tracks to various parts of the Project area are used by recreational vehicle users, Traditional Owners and for access for exploration. Exploration activities, including drilling and associated road development, have taken place throughout the Project area; on-going activities such as drilling, ore sampling, creation of associated road access and other exploration activities are continuing. Some cattle grazing took place within the Project area in the early to mid 1900s but has been discontinued (refer **Section 11.2.2**). Some limited logging and sawmilling activity also took place during this period and has been discontinued (Venn 2004).

The use of the Project area by Traditional Owners and management of access to the Project area by Traditional Owners are discussed in **Section 16.3.2**. Areas of cultural and recreational importance to Traditional Owners include Hey Point, Boyd Bay, Pera Head, Norman Creek, Amban (False Pera Head), Waterfall (near Ina Creek) and Six Ti-Tree. Use of the Project area and surrounds by tourists and the general public is also discussed in **Section 16.3.2**.

While overall there has been very little direct disturbance and the terrestrial environment is generally in good condition, some areas have been affected by camping and rubbish dumping, and some areas have been significantly affected by the frequent fires and damage from feral pigs. The effect of the current fire regime on the *Eucalyptus tetrodonta* ecosystem has been the development of a homogeneous vegetation structure that varies little throughout the Project area.

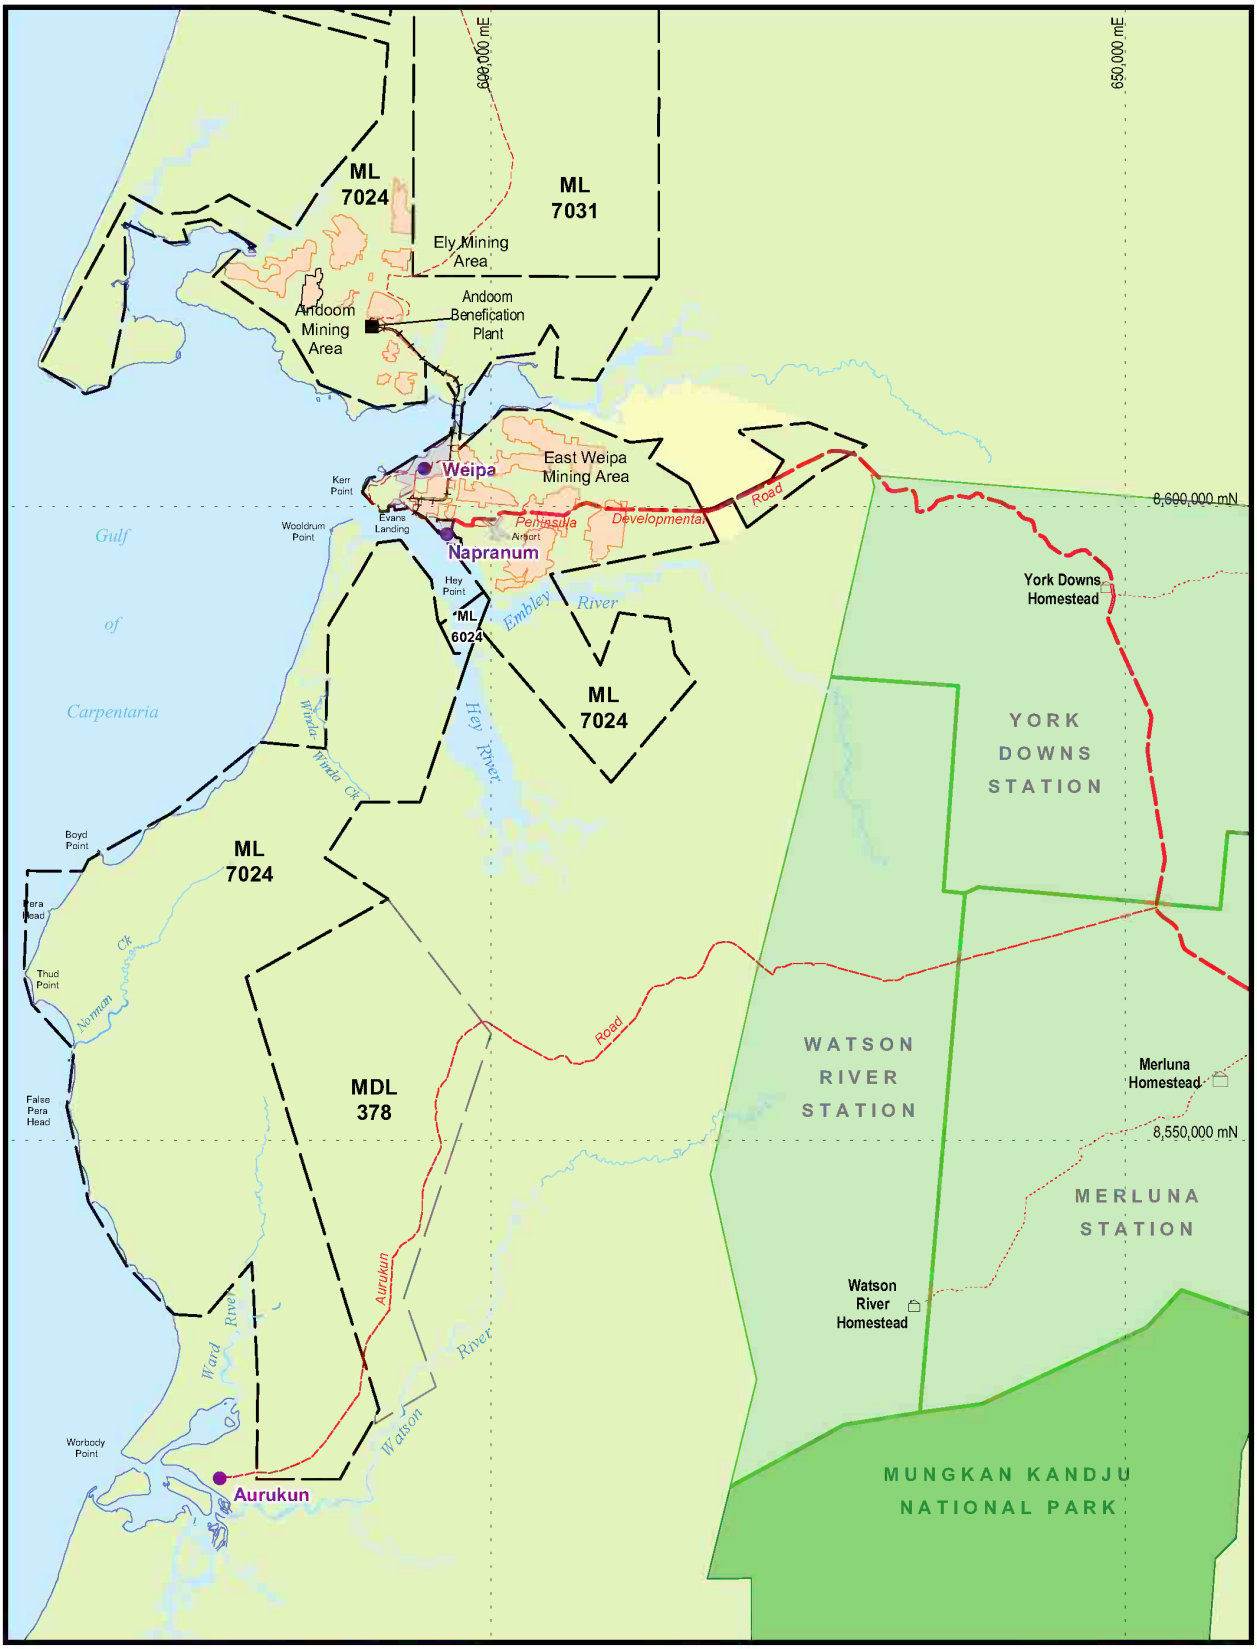
The proposed port site, Hey River barge/ferry terminal site and Hornibrook ferry terminal site have no existing infrastructure and no specific existing land use. The proposed Humbug barge terminal site is adjacent to the Humbug Wharf and to cattle yards. The existing wharf is used by incoming barges carrying general cargo and fuel for Weipa and RTA's existing operations. There are infrequent live cattle exports from this wharf.

The current land tenure of the Project area and adjacent areas are discussed in **Section 2.2** and shown on **Figure 2-1**.

3.1.2 Impact on Existing Land Use

There are no rural properties within the Project area and therefore no properties would be directly affected by the Project. There has been no cattle grazing in the SoE area for many years and there would be no direct impact on agricultural land uses or management practices of surrounding land. Further information on primary industries is presented in **Section 16.2.8**. The Humbug barge terminal would be designed to minimise interference with the adjacent live cattle export facility. Access is typically required to Humbug Wharf once or twice each year over a 3–4 day period. Direct impacts by the proposed Project on live cattle exports are anticipated to be minimal as long as appropriate forward planning is undertaken.

When evaluating the impact of the Project on current and potential future land uses of surrounding land, the local and regional planning provisions are relevant to consider. ML7024 lies within the Cook Shire Local Government Area, ML6024 lies within the Napranum Shire, and land adjacent to the Project area is within the Napranum and Aurukun Shires (refer to **Figure 2-1**). The Cook Shire has a Planning Scheme where all land to which the scheme applies is placed within a zone. The Cook Shire Planning Scheme does not apply to ML7024. The Napranum Aboriginal Shire and Aurukun Shire do not have a Planning Scheme. There are no regional plans that cover the Cook, Aurukun or Napranum shires. Therefore there are no local or regional planning provisions that apply to the Project area or surrounds.



P:\RTA\Plans\SoE\EIS Report Figures\Chapter3\Fig 3-1 Current Land Use.wor

RioTintoAlcan

South of Embley Project

Fig. 3-1: Current Land Use

Construction and operation of the Project would affect the ability of Traditional Owners and the general public to access certain parts of the Project area from time to time for cultural reasons, fishing, hunting and recreational purposes. The prime restriction on access relates to the need to separate the public from active mining and development areas to maintain safety. RTA would continue to manage access for Traditional Owners to specific areas, including the three outstations in the Project area at Amban (False Pera Head), Waterfall (near Ina Creek) and Six Ti-Tree (just south of Waterfall). Amban, Waterfall and Six Ti-Tree are generally utilised in the dry season for varying periods. Access would be managed in accordance with RTA's obligations outlined within the Western Cape Communities Co-existence Agreement (WCCCA). This would be monitored on a regular basis in line with the mine plan, safety requirements during construction and operational phases and the needs of Traditional Owners of the Project area. RTA would work collaboratively with Traditional Owners and the relevant WCCCA sub-committee to develop a land access strategy aimed at causing as little disturbance as possible to Traditional Owner access. The strategy would aim to provide access for Traditional Owners both during active and non-active mining periods for areas including Hey Point, Boyd Bay, Pera Head, Amban / Norman Creek and Waterfall / Six Ti-Tree / Ina Creek.

To mitigate the impacts of the Project on recreational use of the Project area, RTA would work with Traditional Owners and other relevant stakeholders to develop an effective permit system to protect significant cultural heritage sites and environmental values and allow controlled access for recreational purposes. The administration of such a system by Traditional Owners would be subject to discussions between Traditional Owners, RTA and other stakeholders. Existing uses of the Project area and surrounds, potential impacts on those uses and proposed mitigation strategies are discussed in detail in **Section 16.3.2**.

Stakeholder groups consider that improved access to the Project area, via the proposed Mine Access Road and barge/ferry terminals, may increase some recreational activities that are considered to have negative impacts on the Project area and adjacent coastal and beach areas. Potential impacts of the Project on these recreational uses of the Project area and adjacent beach and coastal areas, and proposed mitigation strategies, are discussed in **Section 16.3.1**.

RTA is committed to continuing support for the development of Indigenous businesses in the Western Cape, particularly as it relates to the Project. RTA supports the establishment of a timber harvest operation south of the Embley River that would harvest timber on areas of the mining lease proposed to be mined, or cleared for development of Project infrastructure, in a manner that does not impede development work. This may include joint venture arrangements that support the further creation of employment, training and business development opportunities for local Indigenous people, and in particular, for the Traditional Owners whose land is being proposed for development. Potential impacts on business development and mitigation strategies are discussed in further detail in **Section 16.3.7**.

3.2 Geology

The Project area is located in the Carpentaria Basin, which consists of marine and fluvial sediments. The geology units of the Project are shown in **Figure 3-2** and **Figure 3-3**. The geology of the Project area is represented by the following geological units which are listed in descending stratigraphic order:

- Coastal dunes
- Estuarine and delta deposits
- Ferruginous duricrust, including bauxite (the Aurukun Surface which is derived from laterised Bulimba Formation). This formation is part of the Wyaaba beds
- Bulimba Formation
- Rolling Downs Group
- Gilbert River Formation
- Garraway Beds
- Permian Basement Rock.

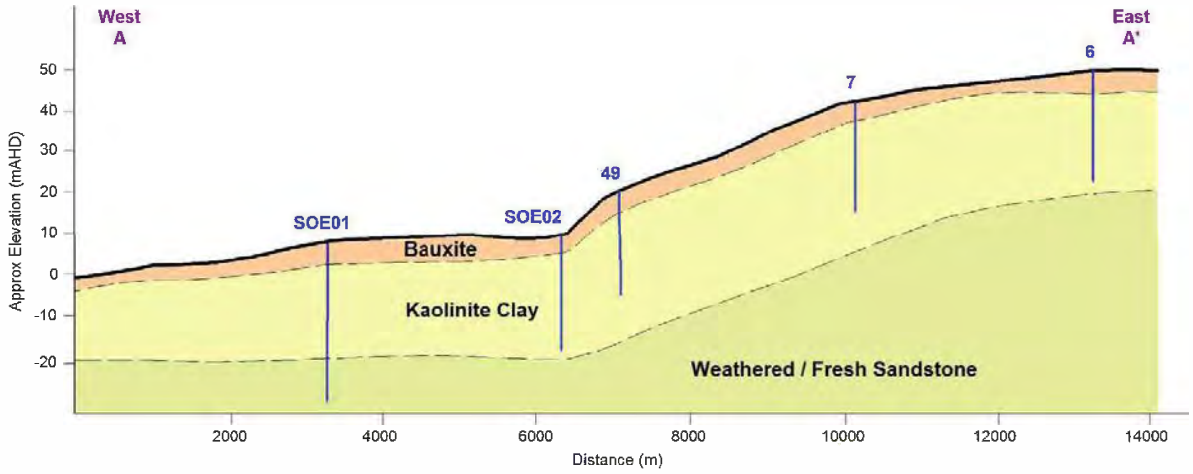
Figure 3-3 Geological Cross Section from East to West (Project Area)



The dominant geological unit of the Project area is the Ferruginous Duricrust, which is derived from heavily laterised sandstones of the Bulimba Formation. Ferruginous Duricrust is essentially the same as the Andoom land system as defined by Godwin (1985) and Gunness *et al.* (1987). The Bulimba Formation underlies the Ferruginous Duricrust. Between the bauxite and sandstone there is a transitional zone consisting of kaolinite clay, unlike the sharp ironstone-bauxite contact as in the East Weipa and Andoom mines. The depth of mining in the Project area would be determined by the grade of ore. The stratigraphy of the surface layers in the Project area is shown in **Figure 3-4**.

The Bulimba Formation is associated with channels cut into the underlying Rolling Downs Group and outcrops along drainage lines within the Project area. The Rolling Downs Group sediments have been exposed where the overlying Bulimba Formation has been eroded. Estuarine and delta deposits consisting of mainly silts and clays are associated with alluvial deposits along rivers. Coastal dunes are associated with coastal areas and consist of coquina, calcarenite and shelly quartzose sand.

Drilling and resource evaluation work has been undertaken in the Project area since the 1970s. In the 1970s much of the Project area was drilled at a spacing of 800m x 400m. In 2005 two of the Project area ore bodies, the Boyd Bay and Norman Creek ore bodies, were drilled on a 800m x 1200m grid to gain more bauxite quality information. Over 2006 and 2007 the Boyd Bay and Norman Creek ore bodies were drilled at a spacing of 400m x 200m to gain additional information for mine planning purposes. Further in-fill drilling was under taken in 2008 and 2009 at spacings of 200m x 100m and 100m x 100m.

The areas proposed to be mined in years 1–13 and in years 14–40 are shown in **Figure 3-5** along with other mineralised areas within the Project area. As of 31 December 2010, a total of 1,602 million tonnes of bauxite reserves with a 53% grade have been reported within RTA's Weipa mining leases, with a considerable proportion of the reserve within the SoE portion of ML7024. Ore reserves are reported in accordance with the *Australasian Code for Reporting of Exploration Results, Mineral Resources and Ore Reserves* (known as the JORC Code) as required by the Australian Securities Exchange (ASX). The bauxite overlies kaolinite but exploitation of the kaolinite is not economically viable. Bauxite mining would not prevent any future exploitation of kaolinite should it ever become viable.

The infrastructure associated with mining has been located as far as practicable so as not to sterilise bauxite reserves. The Boyd tailings storage facility and parts of the Norman Creek tailings storage facility are located on bauxite reserves. The economic bauxite reserves would be mined from each relevant area before tailings are deposited so as not to sterilise economic reserves (refer **Sections 2.2** and **2.5.2**).

The selected mining schedule and method, as well as the beneficiation method, have been designed to best utilise bauxite reserves and minimise resource wastage. The mining method is described in **Section 2.4.3** and the beneficiation method is described in **Section 2.5**.

Bauxite ore and tailings are geochemically benign. The geochemistry of ore and tailings and potential for land and water contamination are discussed in detail **Section 13.3.4**. The use of oversize material for road construction or other productive uses is described in **Section 13.3.5.**

3.3 Topography

The location of the Project in a regional context is shown on **Figure 1-1**, and the topography within the Project area is shown on **Figure 3-2**. The topography within the Project area comprises a gently undulating bauxite plateau landform cut by a network of rivers and smaller creeks. Landfall is from the east to the west toward the Gulf of Carpentaria. There are bauxite cliffs along the coastline, particularly between Boyd Point and Thud Point. The highest elevations (95m AHD) within the Project area are along the eastern boundary. A number of semi-perennial watercourses plus numerous smaller ephemeral creeks traverse the Project area and flow in a westerly direction eventually discharging into the Gulf of Carpentaria. Bauxite is not usually found in the main drainage lines. There are large estuaries associated with the Hey,

The landscape character and broad-scale topography and vegetation character of the Project area is discussed in **Section 12.2**.

The Indigenous and non-Indigenous cultural heritage values of the Project area are described in **Section 11.1** and **Section 11.2** respectively. Archaeological, anthropological and historic places are discussed, along with landscape features and aspects of the natural environment that have cultural significance.

3.4 Soils

3.4.1 Previous Studies

Broad scale soil mapping on Cape York Peninsula was first undertaken as a part of the compilation of the *Atlas of Australian Soils* (Isbell *et al.* 1968). The Queensland and Commonwealth Governments established the Cape York Peninsula Land Use Strategy (CYPLUS) in 1992 to assist government make sustainable land use and planning decisions regarding Cape York Peninsula. CYPLUS included a Natural Resource Analysis Program, which included a soil survey and agricultural land suitability assessment (Biggs and Philip 1995). This assessment used site and chemical analysis data from previous soil surveys as well as profile descriptions and chemical analyses from a new field survey to produce detailed soil descriptions and a soil map at a scale of 1:500,000.

Biggs and Philip (1995) also identified and described seven soil landscapes on the Cape York Peninsula based on distinctions in physiography and geology as well as elements of vegetation and current land use. These soil landscapes are useful for providing an overview of the soils and explaining their position in the landscape. The landscape for the Project area is located entirely within the Batavia Landscape.

3.4.2 Survey Methodology

A soil survey of the Project area was undertaken for the EIS by Landline Consulting for RTA in December 2007. The objective of the survey was to describe and map soil types, map current land use suitability and quantify topsoil volumes. A free survey method was adopted as described by Reid (1988). 174 soil profiles were described to a depth of 1.2m. The soil profile locations are shown on **Figure 3-6**. Soil profiles were augered by hand to a depth of 1.2m or until resistance was reached. Additional descriptions were made of relatively intact soil profiles exposed in track cuttings and road-side borrow pits. The survey was constrained to a degree by wet season conditions which restricted access to some areas, particularly the drainage lines. Profile descriptions were consistent with the *Australian Soil and Land Survey Field Handbook* (McDonald *et al.* 1990). The previous soils mapping undertaken at 1:500,000 scale indicated major uniformity across the Project area and relatively distinct drainage areas (Biggs and Philip 1995). The number of soil profiles described and the scale of soil mapping for this study is appropriate considering the uniformity of soil types.

Ten soil types were identified on the Project area. The characteristics of the soils, particularly in relation to landscape position, are discussed in **Section 3.4.3**. Locations of the soil types in the Project area are discussed in **Section 3.4.4**, and the soil types are described in **Section 3.4.5**. A profile and detailed description for each of the ten soils is presented in **Appendix 3A.** Australian Soil Classification nomenclature has been adopted; however, the soil nomenclature of Biggs and Philip (1995) is also provided. Soil types that were consistent with those of Biggs and Philip (1995) have been noted as having "affinities with" these soil types, but the descriptions reflect the 2007 survey. Certain soil units that were generally outside the footprint of disturbance were not described during the survey. In these cases, soil descriptions from Biggs and Philip (1995) were used.

Profiles at 14 representative sites were sampled and analysed for pH, electrical conductivity (EC), nitrate, chloride, extractable-phosphorus, extractable sulphate sulphur, organic carbon, total nitrogen, cation exchange capacity, exchangeable cations (calcium, magnesium, potassium and sodium) and total copper, zinc, iron and manganese, as well as particle size distribution. Analyses were undertaken at a NATA registered laboratory. Chemical and particle size analyses are presented in **Appendix 3B** and discussed in **Section 3.4.6**.

3.4.3 Soil Types

Biggs and Philip (1995) described seven soil landscapes on the Cape York Peninsula, which are based on distinctions in physiography and geology as well as elements of vegetation and current land use. These soil landscapes are useful for providing an overview of the soils and explaining their position in the landscape.

The landscape for the Project area (the Weipa plateau) is located entirely within the Batavia Landscape and is associated with the lateritised Bulimba Formation and Rolling Downs Group (siltstone, labile glauconitic sandstone, and mudstone). The soils are largely related to the overlying Aurukun Surface, which is derived from lateritised sandstones of the Bulimba Formation. Some soil elements of the Heathlands Landscape located north of Weipa are also represented within the Project area. The Heathlands Landscape consists principally of soils derived from sandstone that are vegetated with heaths and *Eucalyptus tetrodonta* woodlands.

On the Weipa plateau the lateritic horizons are aluminous (bauxitic) in nature. These soils are infertile, with their moisture holding capacity restricted by their lighter texture and the presence of bauxite or ironstone segregations within the profile.

Red Kandosols occur in upper to mid landscape positions with smaller areas of Yellow Kandosols occasionally found in lower slope positions. Red Kandosols have affinities with the Weipa soil type, and Yellow Kandosols have affinities with the Andoom soil type of Biggs and Philip (1995).

Weakly ferruginised Yellow Kandosol acid soils are associated with the footslopes of the lateritic remnants. They are derived from recent exposures of the underlying sediments of the Rolling Downs Group and are more acidic.

Redoxic Hydrosols (the Mapoon soil type of Biggs and Philip (1995)) occur in swamps common to the lower parts of this landscape. These soils have a clay subsoil texture in the swampy areas, but commonly have less developed gradational texture profiles (kandosolic) in the more common minor drainage lines. Redoxic Hydrosols are restricted to the Aurukun Surface. Biggs and Philip (1995) noted that the formation of these swamps is considered by some authors as a laterite-karst feature. Flooding and poor drainage are the over-riding restrictions on the use of these soils for agriculture.

Orthic Tenosols, Supratidal Hydrosols and Aquic or Grey Vertosols (the Caravan, Marina, George and Somerset soil types of Biggs and Philip (1995)) are associated with the Heathlands Landscape. Areas of beach ridge material and sand dunes (Orthic Tenosols) occur on the western coastal margin. In some areas, older beach ridge deposits may have a red colour which is a result of influence by the adjacent and underlying lateritic surface (Somerset soils). Minor occurrences of marine clays (Supratidal Hydrosols and Aquic or Grey Vertosols) occur on the coastal alluvial areas often associated with estuarine deposits (Intertidal Hydrosols) and mangroves.

A summary of the soil types identified within the Project area and their topographic position is provided in **Table 3-1**.

Table 3-1 Soil Types Identified in the Project Area

Australian Soil Classification [1]	Great Soil Group [2]	Biggs and Philip (1995) Name	Occurrence	Comment
Soils of the Rolling Downs Group and Lateritised Bulimba Formation				
Red Kandosol	Red earth	Affinities with Weipa (Wpa)	This is the most common soil on crests and slopes of gently undulating slightly elevated plains.	Surface and subsoil colour variations were recognised during the survey but were unable to be mapped at the scale of this survey.
Red Kandosol	Red earth	Affinities with Weipa – Deep red phase (WpDr)	Usually occurs on upper level crests and well drained areas.	The more significant variation of Wpa. This soil was described during this survey but is unable to be mapped at the scale of this survey.
Red Kandosol	Red earth	Affinities with Weipa – Ferric phase (WpFp)	Usually occurs in lower landscape positions and on change of slope.	This soil was described during this survey (as part of the Wpa soil type) but is unable to be mapped at the scale of this survey.
Yellow Kandosol	Yellow earth	Affinities with Andoom (Ada)	This soil or its equivalent occurs in association with Weipa soil type on the less well drained areas – lower slopes, and along drainage lines.	These soils are not extensive and only some minor occurrences could be mapped separately.
Yellow Kandosol	Yellow earth	Yellow Kandosol acid soil (YKa)	These deep, often acid soils occur on lower slopes and along drainage lines.	Commonly with many Fe/Mn nodules. Most occurrences of this soil are unable to be mapped at scale of this survey.
Soils of the Drainage lines and Swamps				
Redoxic Hydrosol	Humic gley	Affinities with Mapoon (Mpa)	A soil of low lying drainage depressions and lines on gently undulating plains and swamps.	Has affinities with Mapoon, but often lighter textured subsoil. Limited sampling during the survey.
Soils on the Coastal Margin – Beach ridge and dune deposits				
Orthic Tenosol	Siliceous sands	Caravan (Cv) [3]	A soil of the narrow coastal margin associated with younger sand dune deposits and beach ridges. Very minor distribution.	Not described during this survey.
Orthic Tenosol	Earthy sand/ Siliceous sands	Somerset (Ss) [3]	A soil of the coastal margin associated with beach ridges.	Not described during this survey.
Soils on the Coastal Margin – Estuarine and near coastal plains				
Supratidal Hydrosol	Solonchak	George (Go) [3]	A soil of minor distribution on estuarine deposits, usually as bare areas along tidal flats and estuaries. Associated with saltpans.	Not described during this survey.
Aquic or Grey Vertosol	Grey clay	Marina (Mn) [3]	A soil of the coastal margin which occurs along flooded plains and tidal flats. Minor distribution on coastal drainage areas.	Not described during this survey.
Intertidal Hydrosol	No suitable group	Skardon (Sd) [3]	A soil of minor distribution on estuarine deposits under mangroves along tidal flats and estuaries.	Not described during this survey.

1. Australian Soil Classification (Isbell 2002).
2. Great Soil Group (Stace *et al.* 1968).
3. Soils not described during survey, therefore soil type descriptions are directly from Biggs and Philip (1995).

3.4.4 Soil Mapping

The locations of soil types within the Project area are shown in **Figure 3-7**. Previous studies (refer **Section 3.4.1**) were used to assist in mapping.

South of Embley Project

Fig. 3-7: Soil Mapping Units

N

5 0 5km

Datum/Projection: GDA94/MGA Zone 54 Date: 01/04/2011

Most of the area to be disturbed contains Red Kandosol (Affinities with Weipa) soil type on slightly elevated plains with a level to gently undulating surface. For this soil type there is noticeable variation in soil surface colour from dark red to yellow-brown or grey. A deep red phase of the Red Kandosol was described and is the more significant variation, and a ferric phase of the Red Kandosol was also described. No significant morphological or chemical differences could be shown to be associated with these colour variations, and they are still consistent with the description for Red Kandosol. Although variations related to surface and subsoil colour were recognized within this soil type, these could not be mapped at the scale of this survey.

There are smaller areas of (Yellow Kandosols) (Affinities with Andoom) and Yellow Kandosol acid soils in areas of lesser drainage and on lower slopes fringing drainage lines. These soil types could not be mapped consistently but some areas have been tentatively mapped where they could be expected to occur. Areas of these soils are expected to also occur in association with Redoxic Hydrosols (Affinities with Mapoon), particularly in the narrow drainage lines and along their margins.

Orthic Tenosols (Caravan and Somerset soils) have been mapped on the very coastal margin. The distinction between Caravan and Somerset soil types was not always possible so in some areas they have been mapped as one unit.

There is a mixture of soil types associated with alluvial areas on estuarine and marine sediments. These are mapped as predominantly Aquic or Grey Vertosols (Marina), Supratidal Hydrosols (George) and Intertidal Hydrosols (Skardon) but most units include bare areas associated with areas of low groundcover and mangroves.

3.4.5 Soil Descriptions

Soils of the Rolling Downs Group and Lateritised Bulimba Formation

Red Kandosol (Affinities with Weipa (Wpa))

Red Kandosol is the most widespread soil type in the Project area and is the dominant bauxitic soil of the Aurukun surface, generally occurring on plains (**Plate 3-1**). The Red Kandosol contains aluminous concretions throughout the profile, but most commonly concentrated in a band below depths of 55 to 75cm. It may also contain some ferruginous concretions. Its surface colour is red-brown or red, but varies reflecting differing profile or landscape drainage conditions and the influence of differing levels of organic matter. Surface soils tend to be paler in lower sloping positions in the landscape due to restricted drainage. Soil colour grades to red or red brown, and occasionally yellowish-brown or brown, with depth. These variations in colour could not be mapped and they do not suggest major differences in physical or chemical soil features. There is little variation in profile texture, commonly grading from loamy surfaces (20 to 30cm) to clay loam subsoils. Uniform texture profiles may occur.

Mine infrastructure, mining areas and the Mine Access Road would be generally located on the higher elevations in the landscape, which are dominated by Red Kandosol soils. Cut and fill earthworks would be undertaken to level ground surfaces for facilities, and to construct a water storage dam, tailings storage facilities, a truck dump station and access roads. The suitability of excavated soil for construction is discussed in **Section 2.3**.

Red Kandosol (Affinities with Weipa – Deep red phase (WpDr))

A very deep phase of the Red Kandosol soil occurs on some upper slope and flat crest areas. These are commonly very red soil profiles to depth with the band of bauxitic concretions not encountered before 120 to 150cm. This soil variant is often more acidic than the Red Kandosol soil, however it is difficult to map consistently and has been mapped within the Red Kandosol soil unit. It is a fairly consistent observation that aluminous concretions do not occur in these acid to occasionally-strongly-acid profiles, but deeper drilling is required to confirm this relationship.

Plate 3-1 Red Kandosol soil

Red Kandosol (Affinities with Weipa – Ferric phase (WpFp))

A ferric phase of the Red Kandosol was identified on lower elevations or where there is a significant change of slope. This soil is characterised by iron–cemented bands or ferricrete layers within the bauxite layer, but was mainly detected by exposures or in areas of soil disturbance. Its extent was not able to be mapped. This soil phase is described as part of Red Kandosol with which it is otherwise consistent.

The Red Kandosols are consistently vegetated with Darwin Stringybark (*Eucalyptus tetrodonta)* and Grey Bloodwood (*Corymbia clarksoniana*) tall woodland, frequently with Cocky Apple (*Planchonia careya*) and Cooktown Ironwood (*Erythrophleum chlorostachys*) (**Plate 3-2**). Species less frequently associated include *Alphitonia excelsa* and minor patches of palms. *Acacia* spp., *Hakea* spp., Milky Pine (*Alstonia spp.*), Sandpaper Fig (*Ficus opposita*), *Brachychiton* spp. and *Grevillea glauca* may also occur with varying frequency.

Plate 3-2 Tall Darwin stringybark and bloodwood woodland on the Kandosol soils

Yellow Kandosol (Affinities with Andoom (Ada))

The Yellow Kandosol is a deep Bauxitic Yellow Kandosol occurring on the Weipa Plateau. It occurs in conjunction with Red Kandosols and Redoxic Hydrosols, and is sub-dominant to Red Kandosol. This soil type occurs in less well-drained areas – for example, the lower sloping positions and margins of drainage lines. The concentration of aluminous concretions is variable and lower in the surface than the yellow subsoil. These soils are not extensive and only some minor occurrences could be mapped separately.

Vegetation is similar to that for Red Kandosols, *Eucalyptus tetrodonta* and *Corymbia clarksoniana* tall woodland with a greater presence of the Bloodwood. *Planchonia careya* and *Erythrophleum chlorostachys* are frequently associated with *Alphitonia excelsa* and *Grevillea glauca* less commonly associated. *Eucalyptus leptophleba* was also recorded.

Yellow Kandosol (Yellow Kandosol acid soil (YKa))

The Yellow Kandosol acid soil is a deep yellow, often acidic soil occurring predominantly along low lying drainage lines and in areas with restricted drainage which temporarily pond shallow water. In lower slope positions it appears to be formed on less weathered underlying sediments with a paler A2 horizon and mottling in the yellow to yellow-brown B horizons. Ferruginous concretions often occur in the deeper B horizons. It occurs in conjunction with Red Kandosols and Yellow Kandosols.

Vegetation on Yellow Kandosol acid soils consists of *Eucalyptus tetrodonta* and *Corymbia clarksoniana* medium to tall woodland. In wetter areas this woodland is more open with *Corymbia clarksoniana* often more prominent than *Eucalyptus tetrodonta.* These areas are also associated with *Acacia* spp. and occasionally *Erythrophleum chlorostachys* and *Banksia* species.

Soils of the Drainage Lines and Swamps

Redoxic Hydrosol (Affinities with Mapoon (Mpa))

The Redoxic Hydrosols have been mapped to include the small swamps and defined drainage lines of the alluvial country associated with the Rolling Downs landscape. Clay soils of the Redoxic Hydrosol type soil predominantly occur in seasonal swamp areas with the more gradational profiles with clay loam subsoils predominant in the drainage lines. The morphology of Redoxic Hydrosols varies a great deal and it typically consists of an organic-influenced, medium-textured surface overlying an occasionally bleached, grey medium-textured horizon. Below this are mottled grey or pale clay B horizons that are usually structured. Redoxic Hydrosols shows evidence of organic matter accumulation and may be classified as a Humose Orthic Redoxic Hydrosol. The gradational lighter-textured profiles tend to be Humose or Dystrophic Kandosolic Redoxic Hydrosols. Field pH of the profile ranges from very strongly acid to slightly acid.

Melaleuca species dominate in the swamp areas with *Melaleuca leucadendron* dominant along watercourses. In the drainage lines open woodlands are more common on the margins with *Banksia* species and *Melaleuca viridiflora* commonly associated. Insectivorous plants are commonly present in the ground layer in more open areas.

Soils of the Coastal Margin

The descriptions of soils of the coastal margin are based on the descriptions of Biggs and Philip (1995) as they were not described as part of the 2007 survey.

The soils of the coastal areas are divided into two categories that are principally related to texture and mode of formation.

(a) Beach ridge and dune deposits

Soils within this category are all dominated by the sand fraction and have been deposited by wind and/or wave action. Windblown dune deposits are a minor feature of the site and are a small feature of the coastal margin in this area. The beach ridges have been reworked by coastal movement and only narrow strips remain.

Orthic Tenosol (Caravan (Cv))

Orthic Tenosols (Caravan soil type) occur in the narrow coastal strip. Colour within the profile varies considerably, with yellow-brown or grey common. It consists of an A1 horizon showing some evidence of organic matter accumulation, over a paler A2 horizon. Below the A2 are B2 horizons displaying distinct to prominent mottling. Following the B2, two scenarios are possible. Some of the remnant deposits of Orthic Tenosols lie directly on marine clays, and this is evident as a D horizon. It is likely that the B2 and 2B2 horizons reflect wet season and dry season water table fluctuations. Vegetation on Orthic Tenosols varies from open woodlands to heath or herblands.

Orthic Tenosol (Somerset (Ss))

A second type of Orthic Tenosol was identified by Biggs and Philip (1995) and they named this soil type Somerset. It is found in areas of sand that have been deposited on, or influenced by, another surface (usually lateritic in nature in this area). The profile consists of multiple A2, B1 and B2 horizons below a dark A1. Textures range from sand to loamy fine sand throughout. The profile is red or red-brown throughout except for the A1 and A21 horizons. Vegetation is often *Eucalyptus tetrodonta* woodlands, but in exposed areas it may be heath.

(b) Estuarine and near coastal plains

Extensive estuarine and near coastal plains are found in the Project area. These plains typically consist of large areas of Vertosols and saltpans. The plains are often incised by rivers and variable amounts of localised alluvial influence exist. The mapped units often comprise mixes of these soil types.

Supratidal Hydrosol (George (Go))

Supratidal Hydrosols are associated with saltpans. The observations of Biggs and Philip (1995) were limited but they noted that the soil varied according to degree of tidal influence. It was also found in some non-tidal areas where it appears to be more consolidated. The only site described was in a bare saltpan with mangroves found on the margins. The surface of the soil consisted of a very thin yellow-brown alkaline light clay below which occurred a grey light medium clay. The profile trends moderately acid in the brown heavier textured B2 horizons and then mottled yellow in the B3. Presence of a saline water table prevented extensive description of the neutral grey C horizon.

Aquic or Grey Vertosol (Marina (Mn))

Aquic or Grey Vertosols are an extensive soil type on the coastal plain on the Weipa peninsula. Close to the coast, or in low lying areas, Aquic Vertosol are usually found, but further inland the older deposits are generally Grey Vertosols. The plains are typically flat but in some areas may be gently undulating. Gilgai are commonly (but not always) found. The soil surface is a mottled dark or grey light clay to light medium clay that is usually pedal, but on occasion massive. It is followed by a B1 horizon with a similar range of characteristics. The extensive B2 horizons are mottled grey medium clay to heavy clay although texture may change to light clay below 1m, in which case it is usually interpreted as a B3 horizon. Field pH is variable but is typically extremely acid to moderately acid in the surface, remaining either very strongly acid to moderately acid throughout, or trending alkaline with depth. Tussock grasslands with occasional halophytes are the dominant vegetation on Marina.

Intertidal Hydrosol (Skardon (Sd))

Intertidal Hydrosols are found where mangroves occur along the estuarine coastline. The only site recorded by Biggs and Philip (1995) was difficult to excavate and describe due to a watertable just below the surface. The soil was described as arenaceous (sandy) in nature but it is likely that it varies considerably. Intertidal Hydrosols, and the associated mangroves, are often found in narrow strips intermittently along the coast.

3.4.6 Soil Chemical and Physical Properties

Laboratory analysis of soil chemical and physical parameters was undertaken on samples from 14 soil profile sites. The profiles were sampled at standard depths of 0–10cm, 20–30cm, 50–60cm, 80–90cm and 110–120cm below surface. The top of the bauxite layer was sampled where required. Thirteen sites representing Red Kandosols (including one site representing Red Kandosol – Deep red phase), and one site representing Yellow Kandosol acid soil were sampled. These soil types were selected for sampling and laboratory analysis because they are the dominant soil types in the area to be disturbed. The results of the laboratory chemical and physical analyses are presented in **Appendix 3B**. Field pH analyses were undertaken on all soil profiles and field pH data are presented with soil profile descriptions in **Appendix 3A**.

Results of laboratory analyses indicate Red Kandosols are slightly to moderately acid with a pH range generally of 5.7 to 6.5. Field pH assessments of Red Kandosol soil profiles ranged from slightly acidic in the A horizon (pH 6.0 to 7.0) becoming more neutral at depth (pH 6.5 to 7.0). Laboratory analysis of one sample representing Red Kandosol – Deep red phase was strongly acidic (pH 4.9 to 5.4). However, field pH assessments of soil profiles representing Red Kandosol – Deep red phase were less acidic and within expected ranges (pH 6.0 to 7.0). Yellow Kandosol acid soils and Redoxic Hydrosols are more acidic with pH range ranges of generally 5.0 to 6.5 and 4.5 to 6.5 respectively. Laboratory Electrical Conductivity (EC) analysis on Red Kandosols – Deep red phase and Yellow Kandosol acid soil types indicate these soil types have low salinity (EC < 0.5 deciSiemens (dS/m). Low chloride levels throughout the soil profiles for these soil types indicate good drainage.

All soil profiles sampled and analysed were non-sodic (exchangeable sodium percentage (ESP<6), with only two profiles becoming slightly sodic (ESP 6) below 50cm. However, both exchangeable sodium and cation exchange capacity (CEC) concentrations are very low, making ESP results less meaningful in these soils.

Observations and results for this study are consistent with those of Biggs and Philip (1995). Red Kandosols generally have low levels of calcium, magnesium and potassium, which limit their suitability for a range of crops and improved pasture plants. The low CECs are associated with low clay contents (<35%) and the predominance of kaolin (which has a low CEC), common in lateritic landscapes. There is a consistent trend of higher CEC values in the surface than in the rest of the profile, which is linked to higher organic carbon in the surface. Levels of all cations are higher in the surface and decline consistently with depth. Biggs and Philip (1995) found the CEC of Hydrosols increased with depth, reflecting increasing clay contents.

The Kandosol soils are extremely infertile with low levels of Colwell extractable phosphorus (<1mg/kg) and very low exchangeable potassium (<0.35mg/kg). The average calcium/ magnesium (Ca/Mg) ratio in the top 30cm is 1.6, and at 50-60cm depth the average Ca/Mg ratio is 0.95. These ratios are within the range considered desirable for good plant growth. At depths below 70cm the Ca/Mg ratio is on average 0.8, indicating an imbalance that could result in calcium deficiency and poor root growth if that layer was exposed at the surface during rehabilitation. Nutrients such as nitrogen, calcium and potassium are concentrated in the surface 10cm of soil, due to nutrient recycling in the litter layer. This layer represents the main nutrient storage capacity for tropical soils, and therefore would need to be preserved to facilitate rehabilitation following mining.

3.4.7 Particle Size Distribution

The Red Kandosols consistently have higher coarse and fine sand contents than clay reflecting the sandstone parent material. Red Kandosols with high fine sand contents appear to hardset when leaf litter is removed and the soil surface is exposed; however, these appear to be uncommon. The Yellow Kandosol acid soils have significantly higher clay content, reflecting the lower landscape position. They also have higher silt content in the surface, which is consistent with their hardsetting nature.

3.5 Salinity hazard

A report on land degradation in the Cape York Peninsula was prepared under the CYPLUS Land Use Program (AGSO *et al.* 1995). The report outlines a number of characteristics of saline soils in the region and stated that the Rolling Downs Landscapes has a localised salinity hazard. However, the 2007 survey revealed very low soil EC levels throughout the well-drained soil profiles, relatively low levels of sodium, and no evidence of a salinity hazard. Although the Weipa plateau is well vegetated, the high rainfall for the area and well drained nature of the bauxitic soil profiles suggest that any lower landscape salinity problems would already be evident. The low soil salinity indicates that the risks of salinity developing, associated with clearing and development for mining, would be low in the survey area.

The salinity rating for each soil type identified within the Project area is presented with the soil profile descriptions in **Appendix 3A.**

3.6 Erosion Potential and Control

3.6.1 Erosion Potential

The Kandosol soil types encountered in the survey area in mid to upper landscape positions have low potential to develop accelerated erosion when cleared of vegetation for mining or infrastructure development. The predominantly sandy surface soils together with the low slopes on the bauxite plateau facilitate infiltration and reduce the rate of runoff. Rainfall runoff modelling indicates surface runoff from rainfall is a very low proportion (about 1%) of total incident rainfall due to the very high infiltration rates of the bauxite plateau and the flat topography (refer **Section 5.1.1**). The results of erosion monitoring of rehabilitated mined areas at the existing Weipa operations indicate that once soil profiles have settled (usually five years after topsoil has been respread) little active erosion is observed.

The Hydrosol and Tenosol soil types in the drainage lines and coastal margins have a higher erosion potential. Any of these areas to be disturbed by the Project have a risk of erosion during the wet season.

The erodibility rating for each soil type identified within the Project area is included in the land use limitations in **Appendix 3A.**

3.6.2 Erosion and Sediment Control

The erosion potential and proposed erosion and sediment control measures to be employed for each area throughout the life of the Project are summarised in **Table 3-2**.

Table 3-2 Erosion Potential and Erosion and Sedimentation Control

Area	Erosion Potential	Control Measures
Land cleared of vegetation for mining	Bauxite does not occur in swamps and drainage lines where soils with higher erosion potential occur. Most of the area to be disturbed for mining is on Red Kandosol soil, which has low erosion potential.	- Clearing would be restricted to areas essential for mining to minimise length of time soil is exposed to wind and rain. - Vegetation clearing would occur following the wet season, to reduce risk of water erosion and downstream sedimentation. - Vegetation buffers would be established to provide "setback" distances of mining areas from riparian, wetland and estuarine vegetation to minimise sediment transport into streams and to protect sensitive vegetation types (refer **Section 7.9.2**).
Active mining pits and backfilled pits awaiting rehabilitation	Bauxite does not occur in swamps and drainage lines where soils with higher erosion potential occur. Most of the area to be disturbed for mining is on Red Kandosol soil which has low erosion potential.	- Active mining pits and backfilled pits awaiting rehabilitation would be lower than surrounding landform, which effectively provides internally draining sumps that contain stormwater runoff. Contained stormwater runoff then infiltrates through the pit floor and walls. - Backfilled pits would be revegetated as soon as is practicable to reduce the risk of wind and water erosion. - In the event that active or backfilled pits are not fully internally draining, stormwater runoff would be directed via a sediment pond. - Vegetation buffers would be established to provide "setback" distances of mining areas from riparian, wetland and estuarine vegetation to minimise sediment transport into streams and to protect sensitive vegetation types (refer **Section 7.9.2**). - Where mining leaves batters on the edges of the pit, these would be recontoured to a maximum slope of 20% (1 in 5 or 11 degrees).
Boyd and Norman Creek infrastructure areas (including proposed port infrastructure)	Infrastructure construction would involve ground levelling, which would typically not require more than 0.5m excavation but may reach 2m. Boyd and Norman Creek infrastructure areas and the proposed port infrastructure are located on Red Kandosol soils, which have low erosion potential. Infrastructure related ground levelling has low potential to cause erosion.	- Construction work would be completed during the dry season where possible to reduce the risk of water erosion. - Disturbed areas around construction sites would be rehabilitated promptly to reduce the risk of wind and water erosion.
Haul road crossings of drainage lines	The Hydrosol soil types in the drainage lines have a higher erosion potential. These areas where vegetation is removed have a risk of erosion during the wet season.	- Sediment traps would be included as part of the drainage designs at points where haul roads cross watercourses. - Construction of the haul roads, including construction of sediment traps, would be completed during the dry season where possible to reduce the risk of water erosion and downstream sedimentation.
Mine Access Road	The access roads to both the Boyd and Norman Creek infrastructure areas would be constructed using cut and fill techniques. There is potential for runoff from the road surface to cause erosion of cleared areas adjacent to the road. To enable all weather access, the road alignment follows elevated portions of the landscape. Elevated portions of the landscape are dominated by Red Kandosols, which have low erosion potential.	- Roads would generally be constructed on Red Kandosols, which have low water erosion potential. - The Mine Access Road would be sealed, which would reduce the risk of wind and water erosion. - Road construction work would be completed during the dry season where possible to reduce the risk of water erosion and downstream sedimentation. - Table drains and culverts would be installed along Mine Access Roads to reduce the risk of water erosion and

Area	Erosion Potential	Control Measures
		downstream sedimentation. Drainage turnouts would be installed as required at intervals along the alignment and would be graded to the nearest outlet (refer **Figure 2-11**).
Water storage and tailings storage facilities	The water storage dam would be constructed on a watercourse using conventional earth-fill construction techniques. Areas adjacent to the watercourse are Red Kandosol soils, which have low erosion potential; however, soils in areas along the water course are Hydrosols, which have a higher erosion potential. There is some potential for erosion of construction areas along the watercourse during dam construction. Impacts related to sediment runoff during dam construction are discussed in **Section 5.1.3.** The tailings storage facilities would each have four cells, which are constructed over several years. The tailings storage facilities are located on Red Kandosols, which have a low erosion potential. The downstream face of water storage and tailings storage facilities have the potential to erode.	- Dam construction work would be completed prior to the wet season where possible, to reduce the risk of water erosion and downstream sedimentation. - Impacts and mitigation of impacts related to sediment runoff during dam construction are discussed in **Section 5.1.3**. - Prior construction of each cell, the economic bauxite reserves from within each cell would be mined. The tailings storage facilities cells would be internally draining and contain stormwater runoff, to reduce the risk of water erosion and downstream sedimentation. - Grasses would be established on the downstream face of water storage and tailings storage facilities, to reduce the risk of water erosion and downstream sedimentation.
Stockpiles of topsoil and excavated waste	Approximately 60cm of soil is stripped and then placed directly back on previously-mined areas or stockpiled for future use in rehabilitation once a suitable area becomes available. Topsoil stockpiles have the potential to erode.	- Generally, soil and overburden would be placed directly back on previously mined areas wherever possible, rather than being placed in stockpiles which are at risk of water and wind erosion. - If soil is stockpiled it would be typically used within one year. - Topsoil stockpiles would be sown with a native local seed mix to control weeds and erosion. - The final landform would not have any out-of-pit dumps of excavated wastes or soil (refer **Section 3.10.2**).

3.6.3 Erosion Monitoring and Maintenance

An erosion monitoring procedure would be developed and implemented for the Project. Prior to, and after, the end of the wet season each year, mined areas and other potential erosion sites would be visually monitored to identify active erosion rills and gullies. Areas where erosion has been remediated previously would also be monitored. Active erosion would be stabilised by grassing and/or constructing engineered structures.

There are no State soil conservation plans over the Project area.

3.7 Land Use Suitability

3.7.1 Pre-mine Land Use Suitability

Biggs and Philip (1995) assessed the suitability of the soils of Cape York Peninsula for a number of land uses using the methods described by DPI (1990). Interpreting land suitability using these methods is a requirement in the *Planning Guidelines: The Identification of Good Quality Agricultural Land* (DPI & DHLGP 1993). The following five land uses were directly assessed by Biggs and Philip (1995):

- peanut cropping;
- sorghum and maize cropping;
- high input pastures;
- medium input pastures; and
- low input pastures.

These land uses were chosen because they are currently practiced at certain locations on Cape York Peninsula.

The suitability of each of the soil types present on the Peninsula was assessed for each of the above land uses. The land suitability assessment for the selected agricultural uses was based on an evaluation of 12 land use limitations.

The nomenclature used for each limitation by Biggs and Philip (1995) is shown in brackets:

- Climate (C)
- Moisture supply (M)
- Fertility (N)
- Wetness (W)
- Flooding (F)
- Rockiness (R)
- Topography (T)
- Physical condition (P)
- Vegetation (V)
- Water Erosion (E)
- Landscape complexity (X)
- Salinity (S).

The final suitability classes for a particular land use are defined as follows:

- Class 1 – Suitable land with negligible limitations
- Class 2 – Suitable land with minor limitations
- Class 3 – Suitable land with moderate limitations
- Class 4 – Marginal land which is presently considered unsuitable due to severe limitations
- Class 5 – Unsuitable land with extreme limitations.

Land allocated a final suitability class of 4 or 5 for a particular land use was assessed as unsuitable for any of the five selected land uses. Class 5 land includes mangroves and is designated as "land not suitable for the nominated uses". Class 4 land is land with a very low fertility status. Land assessed as Class 4 for low input pastures is designated as "land suitable for low intensity grazing of native pastures".

The land suitability assessment for this EIS was undertaken using similar methodology to Biggs and Philip (1995). However, the suitability assessment by Biggs and Philip (1995) for cropping uses assumes there are no infrastructural restrictions in relation to product handling and marketing. That assumption was not considered appropriate for the land suitability assessment of the Project area, therefore cropping land uses were not considered.

The suitability of each soil type within the Project area for the non-cropping land uses (low and medium input pasture and high input pasture) was assessed based on the land use limitations (refer **Table 3-3**). The full land use limitations of each soil type are presented with the profile descriptions in **Appendix 3A** and a summary of land use limitations for each soil type is presented in **Table 3-3**. Biggs and Philip (1995) provide an explanation of each limitation used in their study, how each limitation was assessed and the relationship between limitation level and limitation class. The nomenclature, codes and relationship between limitation and limitation class developed by Biggs and Philip (1995) have been adopted for this land suitability assessment.

Each soil type was given an Agricultural Land Classification based on the agricultural land class definitions in the guidelines for the identification of good quality agricultural land (DPI / DHLGP 1993), and these are also presented in **Table 3-3**. According to these definitions, crop land (Class A), marginal crop land (Class B) and land suitable for improved pastures (Class C1) are good-quality agricultural land (GQAL). Pasture land not suitable for improved pastures (Class C2) and land not suitable for agricultural uses (Class D) are not GQAL. The soils suitable for low intensity grazing were assessed as Class C2 and soils not suitable for pasture or grazing were assessed as Class D.

Table 3-3 Land Suitability Classes

Soil Type	Low-medium input pasture	High input pasture	Suitability for low intensity grazing of native pastures	Land use Limitations[1]	Agricultural Land Classification
Red Kandosol	Class 4	Class 5	Suitable	C2, M4, N8, W2m, F0, Rf4, T0, P1, Vc2e2, E2s, X0, Si1	C2
Red Kandosol - Deep Red phase	Class 4	Class 5	Suitable	C2, M4, N8, W2m, F0, Rf4, T0, P1, Vc2e2, E2s, X0, Si1	C2
Yellow Kandosol	Class 4	Class 5	Suitable	C2, M4, N8, W4m, F0, Rf4, T0, P1, Vc2e2, E2s, X0, St2	C2
Yellow Kandosol acid	Class 4	Class 5	Suitable	C2, M4, N8, W4s, F0, R0, T0, P1, Vc2e2, E2s, Xi, So2	C2
Redoxic Hydrosol	Class 4	Class 5	Suitable	C2, M4, N8, W5s, F3, R0, T0, P0, Vc2e2, E1s, X1, X0, Sn	C2
Orthic Tenosol (Caravan)	Class 4	Class 5	Suitable	C1, M6, N8, W4h, F0, Ro, T0, Po, Vc2e2, E2u, Xi, Sn	C2
Orthic Tenosol (Somerset)	Class 4	Class 5	Suitable	C2, M6, N8, W1h, F0, R0, T0, Po, Vc1e2, E2u, Xi, Sn	C2
Supratidal Hydrosol	Class 5	Class 5	Not suitable	C1, M6, N8, W6v, F3, R0, T0, P7, Vc1e1, E1v, Xi, Ss	D
Aquic or Grey Vertosol	Class 5	Class 5	Not suitable	C1, M5, N7, W6v, F3, R0, T2, P8, Vc1e1, E2u, X0, Ss	D
Intertidal Hydrosol	Class 5	Class 5	Not suitable	C1, M6, N8, W6m, F3, R0, T0, Po, Vc1e1, E1u, Xi, Ss	D

1 – Land use limitation codes are from Biggs and Philip (1995)

The outcome of the land suitability assessment shows that none of the soil types within the Project area are suitable for improved pasture land uses. Most of the soils are suitable for low intensity grazing of native pastures. Land suitable for low intensity grazing of native pastures represents native pasture grazing land with a very low fertility status. However, it is often associated with areas suitable for pastoral development and is a useful component of the total grazing system. Soils associated with estuarine areas and near coastal plains within the Project area are not suitable for any improved pasture or native pasture grazing land uses. There is no GQAL within the Project area.

The areas of each land suitability class within the Project area are presented in **Table 3-4**. A map of pre-mine suitability for low intensity grazing is shown in **Figure 3-8**. The land suitability areas shown in **Figure 3-8** are based on the distribution of soil types (refer to **Figure 3-7**) and the suitability of each soil type for low intensity grazing, as presented in **Table 3-3**.

Biggs and Philip (1995) mapped land suitability of the Cape York Peninsula at a scale of 1:700,000. The land suitability mapping was based on the suitability of the dominant soil type of each map unit, and the dominant soil types were based on soil survey data from air photo interpretation and ground observations. Biggs and Philip (1995) mapped most of the Cape York Peninsula north of Aurukun as "land suitable for low intensity grazing of native pastures".

Table 3-4 Land Suitability of the Project Area

Land suitability – Pre mine	Area within Project Area (ha)	Area within Project Area (%)
Low intensity grazing of native pastures	95,500	95
Not suitable for nominated land uses	4,750	5
Medium and low input improved pastures	0	0
High, medium and low input pastures	0	0
Total	100,250	100

3.7.2 Post-mine Land Use Suitability

Mining involves removing around 1m of soil and overburden above the bauxite and then excavating the bauxite (which has an average thickness of approximately 3.4m). The overburden would be returned to mined-out pits and then soil would be respread during rehabilitation. The final landform would be at a lower elevation than the original landform due to the removal of the bauxite, but the overall slope of the landform would be similar. Where mining leaves batters on the edges of the pit, these would be recontoured to a maximum slope of 20% (1 in 5, or 11 degrees). The rehabilitated mined landform would be predominantly internally draining. During the wet season there are likely to be some areas at the lowest topographical locations of previously mined areas that would receive increased inundation and have elevated soil moisture. Rehabilitated infrastructure areas would not exhibit this changed drainage effect. During the dry season there is unlikely to be any change in the capacity of native grasses to exploit soil moisture. Overall, the post-mining land suitability for low intensity grazing is likely to be the same as the pre-mining suitability. The rehabilitated tailings storage facilities would be an exception due to slopes, and would not be suitable for low intensity grazing.

RTA's objective for the rehabilitation of areas disturbed by SoE Project mining activities is to establish a self-sustaining vegetation community using appropriate local native tree, shrub and grass species (refer **Section 3.10.1**). In the past in its operations north of the Embley River, RTA has, with the encouragement and support of Queensland Government agencies, experimented with the establishment of improved pasture, forest plantation species and horticulture on mined land. Based on this experience, it has been concluded that post-mining land is most suited to the establishment of native vegetation communities.

Under the WCCCA and at the request of the Western Cape Communities Coordinating Committee (WCCCC), RTA may establish post-mining land use options other than those required by regulation subject to obtaining all necessary government approvals (refer to **Section 3.10.1**). While it is not currently envisaged that land uses other than native vegetation be established, RTA would consult with Traditional Owners about rehabilitation objectives and rehabilitated land completion criteria and objectives.

3.8 Contaminated Land

3.8.1 Potential for Contamination from Existing and Past Uses

Contaminated land refers to land contaminated by hazardous substances that may pose a risk to human health and/or the environment. Lands south of the Embley River are relatively undisturbed by development. Some cattle grazing took place within the Project area in the early to mid 1900s. Exploration activities have taken place throughout the Project area. While there has been domestic rubbish dumping at some camping locations, there is no known historic land contamination south of the Embley River.

Activities identified as being likely to cause land contamination are listed as Notifiable Activities in Schedule 3 of the *Environmental Protection Act 1994* (Qld). Landowners and local government must inform the Department of Environment and Resource Management (DERM) that land has been or is being used for a Notifiable Activity. Land that has been or is being used for a Notifiable Activity, and about which DERM is notified, is recorded on the Environmental Management Register (EMR). Sites recorded on the EMR pose a low risk to human health and the environment under the current land use. Entry on the EMR does not mean the land must be remediated or that the current land use must stop. The Contaminated Land Register (CLR) is a register of known contaminated land that is causing, or may cause, serious environmental harm. Land is recorded on the CLR when scientific investigation shows it is contaminated and action needs to be taken to remediate or manage the land.

The land parcels and tenure within the Project area are summarised in **Table 2-1** and shown in **Figure 2-1**. Not all land parcels within the Project area would be disturbed by Project activities. Searches of the EMR and CLR were undertaken to identify land that may be contaminated from past and current Notifiable Activities and/or land that is known to be contaminated, only for land parcels that would be disturbed by the Project.

Land to be disturbed by the Project that is on the EMR or CLR is detailed in **Table 3-5**. Most of the Project area is covered by Lot 7024 MP41159, which also covers existing RTA mining operations north of the Embley River. Where the EMR and CLR search identified Notifiable Activities that were known to occur within existing RTA mining operations north of the Embley River, and not within the Project area, those activities were excluded from the results presented in **Table 3-5**.

Table 3-5 Environmental Management Register and Contaminated Land Register Status

Aspect	Mining Tenement	Land Parcel	Environmental Management Register	Contaminated Land Register
Mine, port, infrastructure	ML7024 (RTA)	Lot 7024 MP41159 Note: This land parcel covers the area of existing RTA mining operations north of the Embley River as well as the Project area.	No notifiable activities occur within the Project area portion of this land parcel	No
Hey River barge/ferry terminal	ML6024 (RTA)	Lot 121 SP 135863	No	No
Humbug barge terminal	Not applicable. Located within Strategic Port Land	Lot 29 SP116854	No	No
		Lot 14 SP120446	Yes – used for petroleum product storage A site within this land parcel has been subject to a hazardous contaminant. Possible contamination with heavy metals due to accidental burning of batteries. The barge terminal is not at the location of the above sites.	No
Hornibrook Ferry Terminal	Not applicable. Located within Strategic Port Land	Lot17 SP116853	No	No
		Lot 14 SP120446	Yes – used for petroleum product storage A site within this land parcel has been subject to a hazardous contaminant. Possible contamination with heavy metals due to accidental burning of batteries. The ferry terminal is not at the location of the above sites.	No

3.8.2 Contamination Prevention and Control

A number of Notifiable Activities are proposed to be undertaken within the Project area (refer **Table 3-6**). These activities have the potential to cause land contamination through spills, leaks or uncontrolled runoff from contaminated areas.

Table 3-6 Project Notifiable Activities

Notifiable Activity	Description	Location
14	Engine reconditioning works	Boyd and Norman Creek infrastructure areas
25	Mineral processing	Beneficiation plants
29	Petroleum product or oil storage: b)(iii) petroleum products that are combustible liquids in class C1 or C2 in AS1940 – more than 25,000L capacity	Boyd and Norman Creek infrastructure areas
37	Waste storage, treatment or disposal	Temporary storage of regulated waste in mining infrastructure areas (e.g. batteries, tyres and waste oil)

Potentially contaminated runoff from the heavy equipment workshops and service bays, fixed plant workshops, and light vehicle and heavy vehicle wash-down areas would be directed to the mine industrial area drainage slot from where it would be recycled to the Process Water Pond for reuse (refer **Figure 5-8** and **Figure 5-9**). Runoff from infrastructure areas is unlikely to cause land contamination.

Water for dust suppression and bauxite washing would be drawn from tailings recycle and recovery slots (via the Process Water Pond), water supply dam (Dam C), surface water stream (Ward River) and artesian bores. Water from the heavy and light vehicle wash bays would be treated in oil water separators and drain to the Mine Industrial Area Drainage Slot prior to being pumped to the tailings storage facility. The Process Water Pond would not contain contaminants in concentrations that are hazardous. The water used for bauxite washing and dust suppression is not considered a potential source of land contamination. The site water management system is discussed further in **Section 5.2.2,** and tailings characteristics are discussed in **Section 13.3.4**.

Fuel storage areas have the potential to cause land contamination through leaks, spills and rupture of tanks. Contamination would be prevented by bunding fuel storage areas. Hydrocarbons would be stored in accordance with Australian Standard *AS1940 The Storage and Handling of Flammable and Combustible Liquids.*

Hydrocarbons would be handled in the heavy equipment workshop and service bays, fixed plant workshops, and diesel and oil storage areas within the Boyd and Norman Creek infrastructure areas. There is the potential for land contamination to arise from hydrocarbons spills in these areas during operations. This potential would be minimised through the development and implementation of standard operating procedures for transport, handling and storage of hydrocarbons. Employees would be trained in hydrocarbon handling and emergency spill response. Prevention and management of spills is discussed in **Section 19.1** and **Section 19.3.1.**

Management of regulated wastes (including temporary storage of regulated wastes in mining and infrastructure areas) to minimise risk of land contamination is discussed in **Section 13.3.6** and **Section 13.3.7**. Regulated wastes include batteries, heavy vehicle tyres, waste grease and oil, waste oil filters and oily rags, clinical waste and small amounts of waste chemicals. Standard procedures for the storage, handling, disposal and spill response for potentially hazardous waste materials would be adopted to minimise potential for generation of contaminated soil. These procedures are described in **Section 19.** Procedures for remediating soil that does become contaminated are discussed **in Section 13.3.3**.

Bauxite ore and tailings are benign. The chemical characteristics of bauxite and tailings are discussed in **Section 13.3.4.**

The disturbance of Acid Sulphate Soils (ASS) and placement of ASS sediments on land has the potential to cause contamination. The potential impacts and management of onshore ASS are discussed in **Section 3.9** and the acid sulphate soil potential of sediments excavated by dredging activities is discussed in **Section 6.5.**

3.9 Acid Sulphate Soils

Potential Acid Sulphate Soils (PASS) are soils that contain iron sulphides, commonly in the form of pyrite. When these soils are disturbed and exposed to air, they may oxidise to produce sulphuric acid, which may be released to waters. The release of acid reduces the pH and has the potential to mobilise toxic concentrations of iron, aluminium and heavy metals.

Dredging of sediments is required at the proposed port site between Pera Head and Boyd Point, and at the barge/ferry terminals at Hornibrook Point, Humbug Point and Hey River. Dredged sediments are proposed to be barged to spoil grounds at sea. However, in the event that dredged sediments are required to be placed on land they have potential to generate acid and cause land contamination through oxidation of sulphidic material in the sediments. The acid

sulphate soil potential of sediments from dredging activities was assessed and is discussed in **Section 6.5.** The acid sulphate soil potential of soils is discussed in this section.

Acid sulphate soil mapping in Queensland is undertaken by the DERM. No mapping is currently available for the Project area. In the absence of mapping, elevation is used as an indicator for mapping the distribution of PASS, as they are typically encountered at elevations below 5m AHD. Mangroves, salt marshes, floodplains, swamps, wetlands and estuaries are typical environments conducive to PASS formation.

Three locations within the footprint of disturbance have been identified as potentially containing PASS, based on elevation and soil type: the Humbug barge terminal, the Hornibrook ferry terminal and the Hey River barge/ferry terminal.

3.9.1 Humbug Barge Terminal

Construction activities at the Humbug barge terminal would include reclaiming a small area (about 400m^2) behind a sheet pile wall and constructing a road and parking area. The road and parking area construction would involve cut and fill to allow creation of a road base and possibly installation of shallow buried services. These proposed activities trigger the criterion listed in Section 2.3 of *State Planning Policy 2/02: Planning and Managing Development involving Acid Sulfate Soils*. To meet the requirements of this policy, ASS investigations were undertaken of soil at the proposed Humbug barge terminal.

The north bank of the Embley River at Humbug Wharf is known to have been reshaped and levelled. A superficial cover of fill was expected and the fill was known to potentially be derived from dredged alluvium as well as locally derived Ironstone and Weipa Bauxite. Soil sampling at the Humbug barge terminal was undertaken by Coffey Geotechnics on 12 May 2009. Six test pits were constructed using a backhoe and were located within the alignment of the proposed access road and parking area (refer **Figure 3-9**). The test pits were constructed to depths where they became unstable due to rapid water inflow (2.3 to 3.5m). Each test pit recorded a similar soil profile. A cover of fill was recorded at each point, ranging in thickness from 0.5m to in excess of the full depth of excavation of 3.5m closest to the riverbank. The fill was described as sandy (fine grained) rounded gravel of bauxite locally intermixed with subangular cobbles of low strength ironstone and moderately strongly cemented (medium strength) bauxite. In five of the six test pits (TP511 to TP515) the fill overlay possibly undisturbed medium to coarse grained loose sand with many shell fragments, identified as Marine (Estuarine) Alluvium. Firm sandy clay was identified at depth in test pits TP512 and TP511. Instability due to groundwater inflows prevented excavation progressing to the intended full depth of these test pits. The soil types at each depth are summarised in **Table 3-7**.

Soil samples were collected at 25cm depth intervals through the soil profile from three of the test pits. All soil samples collected underwent field ASS analysis (pH_F and pH_{FOX}). One sample from each of two pits and two samples from one pit were selected for laboratory ASS analysis. Reference was made to the *Guidelines for Sampling and Analysis of Lowland Acid Sulfate Soils (ASS) in Queensland 1998* (Ahern *et al.* 1998) for the specification of sampling and subsequent testing. Action criteria in the guidelines were used to interpret the results. The results of the field and laboratory ASS analyses are presented in **Table 3-7**, and a summary of the results is presented below.

The field pH (pH_F) of the soils tested ranged from 6.0 to 8.3, indicating the sulphide oxidation has probably not occurred in the past and that there are no actual ASS soils present. The field pH after oxidation with peroxide (pH_{FOX}) ranged from 5.7 to 8.9. All samples had a high pH_{FOX} (greater than 5) and there was little or no drop in pH between pH_F and pH_{FOX} (pH change less than 1 pH unit). This indicates the samples had little or no net acidifying ability.

The Titratable Actual Acidity (TAA), which measures the soil's actual acidity prior to any oxidation taking place, was low or below the detection level for all samples. This indicates no acid generation has yet taken place in the soil.

ND: No Data

The chromium reducible sulphur (S_{CR}) is a measure of potential sulphidic acidity. The S_{CR} results for three of the four samples that underwent laboratory analysis were below detection indicating they had no potential to generate sulphidic acidity.

One sample (TP 511 depth 2.0m) had a S_{CR} concentration of 0.21%, which is higher than the corresponding action criteria. The sample included a significant content of shells and the laboratory analyses indicated a high calcium and also magnesium content that is associated with shells. The shell content contributed to the relatively high acid neutralising capacity (ANC) of sample. The ANC was 0.15% S, indicating there was sufficient ANC in the sample to neutralise most of the potential sulphidic acidity. However, the net acidity of the sample was 37 moles H+/tonne, which was higher than the corresponding action criteria, indicating the material represented by this sample has the potential to generate sulphidic acidity.

Overall, given the depth of fill, the underlying marine alluvium is unlikely to be disturbed by land-based development for access roads and car parking. Where development creates disturbance to soils limited to superficial sand or gravelly sand/sandy gravel (fill) the potential to disturb soils susceptible to sulphide acidification is assessed to be low. In such a case no "acid sulphate soil management plan" would be needed. Where deeper excavation is proposed, whereby cohesive marine alluvium soil is to be exposed to air, there is a potential acidification hazard. The hazard would be (at least) partly ameliorated by the shell content enabling calcium and magnesium buffering.

Material represented by samples from sites TP510 and TP515 would require no management if placed on land. However, material represented by sample TP511 depth 2.0m would require the addition of lime to manage acid generation if the material was to be placed on land.

3.9.2 Hornibrook Ferry Terminal

Construction at the Hornibrook ferry terminal would involve an area of about 1,900m^2 being reclaimed and supported by rock revetment and/or sheet piles and the construction of road pavement. Any earthworks would be shallow cut and fill only, to allow creation of a road base and possibly installation of shallow buried services.

In October 2008 four test pits were excavated by Coffey Geotechnics using an excavator. Each pit progressed through fill extending to between 2.6m and in excess of the total depth of excavation of 3.3m.

Profile descriptions were completed on all four test pits. Hornibrook Point is known to be a reclaimed peninsula into the Embley River that was built up using locally-derived fill. The observations of the test pits confirm the peninsula comprises reclaimed (filled) ground. In each pit the initial cover of fill comprised kaolinite clay with some gravel of ironstone (ferricrete) and in some places pisoliths of bauxite, all derived from the laterite profile that prevails across the Weipa area. In one test pit fill below 1.1m was described as reworked alluvium (sand with some gravel and shells). A layer of alluvium-derived fill was also identified in another test pit below 1.4m depth, and a darker-coloured alluvial clay below 1.7m depth in a third test pit. Undisturbed alluvium might be present at about 2.6 to 2.9m depth in two of the test pits.

The superficial fill is not alluvial in provenance and would not be acid sulphate susceptible. There is the potential for alluvial-derived fill recorded at depth to be acid sulphate soil. However, the proposed construction works at the Hornibrook ferry terminal would be shallow cut and fill only and these potentially acid sulphate soils would not be disturbed.

Since there is no proposed disturbance of potential ASS or actual ASS at Hornibrook ferry terminal, ASS sampling and analysis were not undertaken at this site.

3.9.3 Hey River Barge/Ferry Terminal

Construction at the Hey River barge/ferry terminal would involve an area of about 4,400m^2 being reclaimed and supported by rock revetment and/or sheet piles. This activity triggers the criterion listed in Section 2.3 of *State Planning Policy 2/02: Planning and Managing Development involving Acid Sulfate Soils*. To meet the requirements of this policy, ASS investigations were undertaken of soil at the Hey River barge/ferry terminal.

An onshore drilling investigation was undertaken between 21 and 28 July 2008. Five drill holes (DH511to DH515) were bored using a track-mounted Hydrapower Scout rig equipped for continuous flight auger and wash boring techniques. A test pit (TP220) was excavated by backhoe on 9 July 2008.

The onshore boreholes (DH511 to DH515) typically encountered red soil topsoil, 0.2 to 0.4m thick, overlying Ironstone, 1.1 to 2.0m thick, overlying kaolinite rich clay, extending for the remaining depth of investigation (maximum 10m depth).

Samples from three of the drill holes and one test pit were collected by Coffey Geotechnics for laboratory analysis. Samples were collected at 0.5m depth intervals to a depth of 3m from the drill holes, and one sample was collected at a depth of 0.5m from the test pit. Locations of the drill holes and test pit are shown in **Figure 3-10**. PASS were tested using the Suspension Peroxide Oxidation Combined Acidity and Sulphate (SPOCAS) suite of analyses. Action criteria in the *Guidelines for Sampling and Analysis of Lowland Acid Sulfate Soils (ASS) in Queensland, 1998* (Ahern *et al.* 1998) were used to interpret the results. The results of the laboratory ASS analyses are presented in **Table 3-8**, and a summary of the results is presented below.

- The pH (pH_{KCl}) of the soils tested ranged from 5.0 to 8.9, indicating the sulphide oxidation has probably not occurred in the past and that there are no actual ASS soils present.
- The pH after oxidation with peroxide (pH_{OX}) ranges from 4.6 to 9.2. The pH_{OX} of all but three samples was greater than 5, indicating most samples had little net acidifying ability.
- Only three samples (DH513 0–0.5m, DH514 0–0.5m and DH514 2.5–3.0m) had a pH_{OX} between 4 and 5, indicating sulphides may be present either in small quantities and be poorly reactive or the sample may contain shell/carbonate, which neutralises some or all acid produced by oxidation. Equally, the pH_{OX} value may be due to the production of organic acids and there may be no sulphides. The potential sulphidic acidity (S_{POS}) for these three samples indicated the oxidisable sulphur content was lower than the corresponding action criteria. This indicates the material at these sites has little potential to generate sulphidic acidity.
- The Titratable Peroxide Acidity (TPA), which measures the soil's potential acidity, marginally exceeded the action criteria in only two samples (DH512 0.5–1.0m and DH514 2.5–3.0m). However, the potential sulphidic acidity (S_{POS}) for these samples was below detection. This indicates the material at these sites has no potential to generate sulphidic acidity.
- The potential sulphidic acidity (S_{POS}) results indicated the oxidisable sulphur content was below detection in most samples and was lower than the corresponding action criteria in all samples, except sample DH515 0–0.5m. This indicates the material at all sites, except DH515, has little or no potential to generate sulphidic acidity.
- The sample from site DH515 had a high S_{POS} result, however this sample has a significant neutralising capacity (ANCE 5.3%$CaCO_3$). The net acidity of this sample, which is used to predict the acid risk of a soil, was lower than the detection limit.
- If material represented by the samples tested was to be placed on land, the addition of lime to manage acid generation would not be required.

3.10 Rehabilitation

3.10.1 Post-Mining Land Use

The overall objective of the rehabilitation program would be to return the land to a post-mining land use that will be stable, self-sustaining, requires minimal maintenance, and protects downstream water quality. Specifically, the objectives for the rehabilitation of areas disturbed by mining activities would be:

- to establish a self-sustaining vegetation community using appropriate local native tree, shrub and grass species; and
- to ensure land is made stable – in both geotechnical and erosion terms – to ensure post-mine land use is not compromised by site instability.

Under the WCCCA, RTA has commitments to consult Traditional Owner groups about rehabilitated land completion criteria. RTA would jointly develop a rehabilitation process with the Traditional Owners and relevant WCCCC sub-committee prior to the commencement of mining. RTA would also consult with the Traditional Owners and WCCCC sub-committee regarding timelines for development of rehabilitated land completion criteria, aiming to have these developed within three years of commencement of mining. RTA would continue to report annually to the relevant WCCCC sub-committee on rehabilitation programs, including an inventory of areas disturbed by mining, timeframes for rehabilitation, and supporting reports pertaining to the monitoring of rehabilitated areas. Ongoing community consultation during the EIS process is described in **Section 15.4** and ongoing community engagement thereafter, including engagement with Traditional Owners, is discussed in **Section 16.3.3**.

At the request of the WCCCC, RTA may establish post-mining land use options other than those required by regulation, subject to obtaining all necessary government approvals. RTA also has commitments under the WCCCA to surrender parts of the mining lease after their rehabilitation. Such surrendering of parts of the mining lease would be undertaken where it is practical to do so, and would be subject to government approvals.

Traditional Owners have indicated during consultation that seed collection and rehabilitation are two potential business opportunities arising from the Project. RTA would continue to involve Traditional Owners in rehabilitation programs where practicable. The steps RTA would take to support the development of Indigenous businesses in the Western Cape region are detailed in **Section 16.3.7**.

3.10.2 Post-Mining Landform

Areas disturbed by mining activities and infrastructure would be rehabilitated to a stable landform with a self-sustaining vegetation cover. After overburden and soil are returned to mined-out pits, the final rehabilitated landform would be at a lower elevation than the original landform due to the removal of the bauxite, but the overall slope of the landform would be similar. Where mining leaves batters on the edges of the pit, these would be recontoured to a maximum slope of 20% (1 in 5, or 11 degrees). The final landform would not have any out-of-pit dumps of excavated overburden or soil.

Given the changes to topography due to mining and infrastructure at a local scale would be minor, and there would be no final out-of-pit dumps of overburden, there would be no significant changes to the broad scale topography of the Project area. Mining would involve clearing vegetation (refer **Section 7.9**); however, vegetation would be retained within environmental buffers along the coastline and beside waterways, with mining excluded within buffer areas (refer **Section 7.9.2**). Through the retention of vegetation buffers and proposed progressive rehabilitation with native species, no significant changes to broad scale vegetation character of the Project area at the landscape scale are expected.

The tailings storage facility embankments and surface would be revegetated after decommissioning and minor earthworks undertaken to install suitable water management features.

Topographical information is currently being prepared which would assist with preparation of a conceptual mine closure landform model for the mined areas.

3.10.3 Rehabilitation Strategy

The rehabilitation strategy for the Project has been based on the Technical Guidelines for the Environmental Management of Exploration and Mining in Queensland – Determination of Post-Mine Land Use (DME/DEH 1995). The strategy consists of the following integrated measures:

- implementation of practical landform designs, to prevent erosion and establish final landform stability;
- revegetation trials, for selection of appropriate revegetation species and methodologies;
- progressive rehabilitation of disturbed areas, using rehabilitation procedures appropriate to the type of disturbance;
- appropriate management of the final bauxite processing waste, including construction of an earth cover; and
- implementation of erosion control measures, consistent with the practices described in the *Technical Guidelines for Environmental Management for Exploration and Mining in Queensland – Erosion Control* (DME/DEH 1995).

Rehabilitation would commence progressively as areas become available and in accordance with the Plan of Operations. The Plan of Operations would be provided to the relevant WCCCC sub-committee in accordance with the requirements of the WCCCA.

A detailed operational rehabilitation procedure, including a quality assurance process, would be developed and implemented.

3.10.4 Topsoil Management

The dominant soil type of the Project area is Red Kandosol, which has a topsoil depth of 10 to 20cm. These soils are weathered and low in nutrients, and support vegetation adapted to such conditions. The majority of seed readily able to germinate is present in the upper 5cm of soil.

Prior to mining, all topsoil, subsoil and waste bauxite overlying the surface of the bauxite is stripped. Soil moisture levels would be assessed before soil stripping commences to ensure the soil is not so wet it would lose its structure when handled. Approximately 60cm of soil would be stripped and directly placed on mined-out areas in readiness for revegetation. This technique would help minimise the area of mined land exposed at any one time. If direct placement is not possible, soil would be stockpiled. If soil is stockpiled, it would be managed so as to maintain optimum growth media properties by maximising the stockpile surface area and minimising compaction. Stockpiled soil would be typically used within one year to maximise the benefits of the natural seed bank and conserve symbiotic micro-organisms. Any soil stockpiled for more than one year would be sown with a native local seed mix to control weeds and erosion. Areas receiving stockpiled material are sown with a special seed mix containing additional species to the standard seed mix, including seed of species that usually "volunteer" from natural seed store in freshly returned topsoil, such as grasses and Acacias.

Procedures for topsoil stripping, stockpiling and placement activities, including a quality assurance process, would be developed, implemented and included in the site rehabilitation procedure.

3.10.5 Revegetation

Revegetation is the component of the rehabilitation process that involves rebuilding the soil of disturbed land, seeding and/or planting plants. At RTA's current operations north of the Embley River the following approach is taken to revegetation:

- respreading freshly stripped topsoil or stockpiled topsoil;
- ripping the mine floor to 50cm at 3.4m centres to break up the compacted floor and increase water infiltration (note, sometimes the mine floor is ripped before topsoil is

replaced). Other compacted surfaces to be rehabilitated (such as haul roads) are repeatedly cross-ripped to ensure water infiltration and root penetration is achieved;

- scarifying along the contour prior to seeding;
- seeding with a seed mix of locally occurring native species at a density and richness to facilitate a self-sustaining local native ecosystem; and
- applying fertiliser at an appropriate rate, if required.

A similar revegetation methodology would be adopted and refined for the Project area.

The soil surface would be scarified prior to seeding, except where the topsoil has been ripped immediately prior to seeding and the soil surface forms an appropriate seedbed. Pre-seeding scarification assists in providing suitable growing media properties to optimise plant growth (e.g. porosity and water holding capacity). Scarifying also breaks up soil surface crusting and produces a soft soil bed for seeds, which maximises the chances of the seeded species germinating and establishing by increasing soil–seed surface contact. Scarification may be carried out using various means, such as a tractor-towed disc plough, a tractor-towed multi-tyne scarifier, a grader with a scarifier or a grader with a ripper beam attachment.

At current RTA operations north of the Embley River, direct seeding has been found to be the best method for establishing desired plant species. Direct seeding is generally undertaken using a belt spreader towed behind a tractor. The relatively small volumes of seed are bulked with a medium such as sand or sawdust to ensure a steady and adjustable delivery rate. Aerial seeding techniques are also currently being trialled. Seed is applied as close as practicable to the onset of the tropical monsoon rains (approximately December each year) to ensure the soil moisture and follow-up rainfall are favourable to seedling establishment.

Native species seed mixes would be tailored to the anticipated post-mining conditions of the area to be rehabilitated. The proximity of the post-mined landscape to the wet season water table is the key factor determining which native plant community is most appropriate for the post-mining landscape.

Free-draining areas are most suited to "Tall Darwin Stringybark woodland on lateritic red earths" and "Tall Darwin Stringybark woodland on yellow earths". Free-draining post-mining landscapes would be seeded with a range of tree, shrub and groundcover species from these communities. Suitable tree species are likely to include *Eucalyptus tetrodonta*, *Corymbia nesophila*, *Erythrophleum chlorostachys*, *Corymbia stockerii* and *Eucalyptus polycarpa*. Suitable mid-storey species may include *Acacia rothii*, *Alphitonia obtusifolia*, *Antidesma ghaesembilla*, *Breynia cernua*, *Exocarpus latifolius*, *Grevillea glauca*, *Grevillea parellala*, *Livistona muellerii*, *Parinari nonda*, *Petalostigma pubsecens*, *Planchonia careya* and *Xylomelum scottianum*. Suitable groundcover species may include *Heteropogon triticeus*, *Sorghum plumosum*, *Heteropogon contortus*, *Aristida macrantha*, *Eriachne triseta*, *Eriachne pallescens* and *Ectrosia leporina*.

Post-mining landscapes likely to be less free draining and seasonally inundated are most suited to Melaleuca swamp and Melaleuca/Swamp mahogany vegetation communities. Suitable species are likely to include *Lophostemon suaveolens, Melaleuca stenostachya, Melaleuca viridiflora, Melaleuca leucadendra, Banksia dentata, Asteryomyrtus symphyocarpa, Calycopeplus casuarinoides, Corymbia polycarpa, Eucalyptus brassiana, Syzygium suborbiculare, Livistona meulleri* and *Pandanus spiralis.*

At current RTA operations north of the Embley River, fertiliser is applied at the time of seeding, with an aim to provide the best possible nutrition to maximise initial establishment and plant growth during the first wet season. The type and rate of fertiliser application is determined by the nature of the rehabilitated soils and plant species being re-established. Generally, superphosphate is applied at a rate of 200kg/ha using a tractor-towed belt spreader.

3.10.6 Success Criteria

Preliminary rehabilitation success criteria for the Project area would be developed within three years of commencement of bauxite mining. On-site revegetation trials would be undertaken to test selected species, seeding rates and establishment methodologies. Success criteria would be

based on the outcomes of the rehabilitation trials and on-going monitoring. Rehabilitation performance would be measured against the adopted criteria. Different success criteria may be developed for different developmental stages of each relevant vegetation community. The criteria may change over time as more rehabilitation knowledge relevant to the Project area is gained.

Soil indicators such as bulk density, surface cover and soil invertebrates are potentially suitable for the Project area. Appropriate indicators of ecological function may include framework species presence, species richness and density, structural composition, native species recruitment, presence of weed species and fauna.

3.10.7 Maintenance

Rehabilitated areas would be regularly monitored to identify any areas in need of maintenance at an early stage. Rehabilitation maintenance activities are likely to include:

- re-seeding of areas that have not reached a sufficient growth density of vegetation or have not achieved the desired species diversity;
- a fire management program aimed at excluding wildfires from rehabilitated land through construction and maintenance of fire access tracks and a prescribed burning program. The burning program would include areas adjacent to new rehabilitation. Prescribed burning is conducted early in the burning season, when fuel flammability is sufficient to carry a fire but low enough to maintain a relatively cool, low intensity burn (refer **Section 7.10.2**);
- weed monitoring and management; and
- erosion monitoring and control.

The early establishment monitoring of rehabilitation areas would be undertaken annually around August and September to provide an indication of the success of earthworks and seeding undertaken in the previous year. Re-seeding in the first or second year following establishment offers the most effective rehabilitation remedial response if remediation is required.

Where supported by knowledge of rehabilitation ecology and fire impacts, controlled burning of rehabilitation may be conducted to influence rehabilitation vegetation composition, structure and function. Controlled introduction of fire to developing sites can ensure fire-sensitive species do not dominate, and that desirable fire-resilient species and characteristics are encouraged.

Any controlled burning of rehabilitation would be accompanied by a monitoring program including a pre- and post-burn vegetation survey, fuel load estimations and fire intensity calculations, and spatial data of burnt areas and degree of vegetation removal, including canopy scorch.

3.10.8 Monitoring

A monitoring program would be developed to regularly assess the success of rehabilitation against preliminary success criteria.

The monitoring would focus on a range of indicators that reflect vegetation composition and structure and may include species richness and density, structural composition, native species recruitment and presence of weed species. The monitoring methodology would be likely to be similar to that currently used for operations north of the Embley River and include:

- monitoring in the first year after establishment at a scale of one 500m^2 transect plot per 10ha of rehabilitation; and
- follow-up monitoring 4, 8 and 12 years after establishment.

Soil indicators such as bulk density, surface cover and soil invertebrates may be useful indicators in some situations and may also be monitored. Fauna indicators such as representative species of soil mites, ants, birds, mammals and reptiles may be useful indicators in some situations and may also be monitored.

The outcomes of the monitoring program would be used to refine rehabilitation success criteria, identify areas that may need remedial measures, plan progressive certification of the acceptability of rehabilitation areas and, in the longer term, relinquishment.

The impacts of both controlled burning and wildfire on rehabilitation areas would also be monitored.

Erosion monitoring and maintenance of rehabilitation areas is discussed in **Section 3.6.3**.

3.10.9 Decommissioning and Closure

The decommissioning and final rehabilitation of the Project would occur on a staged basis over several years. A Final Rehabilitation Report, which includes a contaminated site assessment, would be prepared prior to surrender of the mining lease. A contaminated site register would be maintained for the operation. Areas of soil contamination would be investigated prior to rehabilitation. Contaminated sites would be managed using methods developed on a case-by-case basis in accordance with DERM guidelines.

RTA would jointly develop an initial mine closure plan with the Traditional Owners and relevant WCCCC sub-committee prior to the commencement of mining and update this plan every five years.

On the completion of mining, buildings, structures and other infrastructure would be treated as follows:

- The barge/ferry terminals, port, water storage dam and certain roads may have some ongoing beneficial use. Subject to agreement with relevant regulators and Traditional Owners, some of these facilities may be left in place. Otherwise, RTA would remove these facilities.
- Buildings, plant, equipment, tanks, conveyors, pipelines and transmission lines would be removed and the surface rehabilitated. Concrete pads would be broken up, buried, and then the area rehabilitated.
- RTA would provide Traditional Owners with the opportunity to purchase decommissioned construction camp accommodation on fair, agreed commercial terms, once the construction phase is complete.

Environmental Impact Statement

for South of Embley Project

Section 4
Climate

4 CLIMATE

4.1 Meteorology

The Project area lies within the Australian Monsoon Zone which has a tropical climate with distinctive wet and dry seasons. The area typically experiences warm summers with high maximum temperatures and warm winters.

The summer wet season is relatively short, lasting from approximately December to March, and occurs with the change in the prevailing south-east trades to the north-west monsoons. Approximately 95% of the region's rainfall occurs between November and April.

A significant influence on the year-to-year weather variability is exerted by the El Niño Southern Oscillation (ENSO) phenomenon, an eastern Pacific system of atmospheric and oceanic interactions which affects the weather worldwide and can result in large variations in the timing and amount of wet season rainfall on Cape York.

The closest weather stations to the Project area are maintained by the Bureau of Meteorology (BoM). The stations are:

- Weipa Aerodrome (Station No. 027045) – records from 1972 to present;
- Eastern Avenue, Weipa (Station No. 027042) – rainfall records from 1914 to present and temperature, evaporation and wind records from 1959 to 1994; and
- Aurukun (Station No. 27000) – rainfall records only from 1914 to present.

The Weipa Aerodrome station is 7km south of the Eastern Avenue station, and presents similar average climatic data, with the exception of higher rainfall averages (1,967mm vs 1,769mm). A summary of records from the Eastern Avenue station is presented in **Table 4-1**. Daily rainfall is also recorded at Aurukun station, which has a mean annual rainfall of 1,647mm (refer summary in **Table 4-2**).

Source: BoM (2009b)

4.1.1 Temperature

Average daily maximum temperatures range from 30.4°C in July to 34.8°C in October, before the commencement of the wet season (BoM 2009a). Average minimum temperatures range from 18.8°C in August to 24.0°C in January and February. A highest temperature of 39.1°C was recorded in October 1980. A lowest temperature of 9.6°C was recorded in August 1990.

4.1.2 Humidity

Relative humidity is fairly consistent throughout the year with highest averages recorded in the morning (9am) ranging from an average of 66% in October to an average of 87% in February. Afternoon averages (3pm) are more variable between the dry and wet seasons, with an average of 44% in September and 78% in February.

4.1.3 Rainfall

The mean annual rainfall at Weipa is 1,769mm, falling on an average of 109 days per year, with the majority of rainfall occurring from December through to March. The mean monthly rainfall varies from 1.7mm in July to 448.8mm in January. January has also recorded the highest number of rain days with an average of 21.9 days.

The variability index of mean annual rainfall is classified by the BoM as low to moderate. Surface water storage is required to provide sufficient water for operations for the extent of the dry season. Water supply is discussed further in **Section 5.2.1** and water storage is discussed in **Section 5.2.3**. The high rainfall experienced in the wet season can restrict vehicle movements and is likely to curtail some construction activities in wetter months.

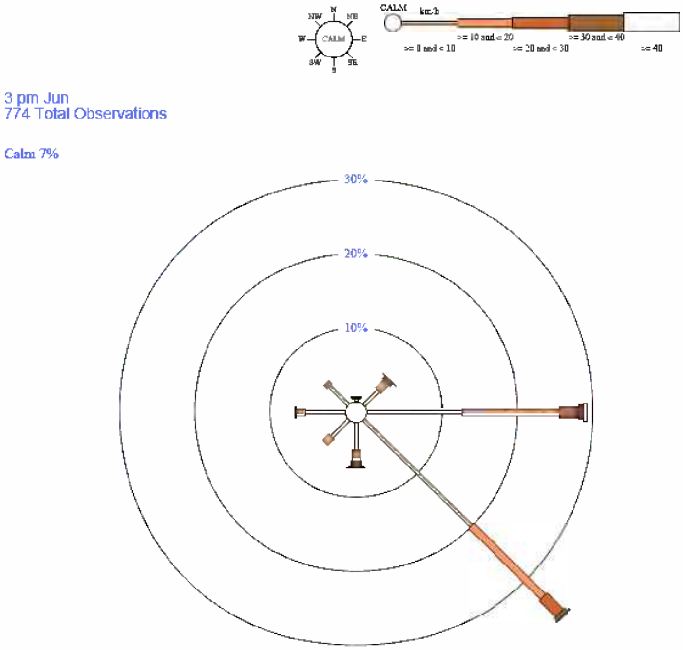
The mean annual evaporation rate is 1,825mm. Mean daily evaporation ranges from 4.0mm/day in February to 6.6mm/day in October.

The highest daily rainfall was 279.2mm, recorded on 31 January 1982. The mean number of days of rain over 25mm is at its highest in summer with 5.8 days recorded in the months of January and February.

4.1.4 Wind

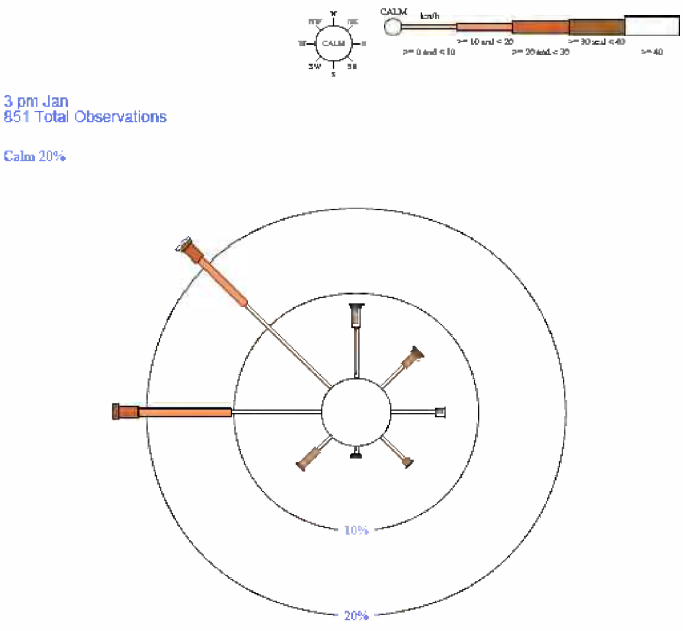
The region tends to have light to moderate south-east to easterly winds during the dry season (refer **Figure 4-1**). Over the wet season, winds are mostly light tending moderate westerly to north-westerly when the monsoon trough dips south of the area (refer **Figure 4-2**). Fresh winds (30–39km/h) occur occasionally but strong or gale force winds normally only occur with a tropical cyclone.

Figure 4-1 Wind Rose for Typical Dry Season (June), Weipa



(BOM 2009a)

Figure 4-2 Wind Rose for Typical Wet Season (January), Weipa



(BOM 2009a)

4.2 Extreme Events

4.2.1 Cyclones

Cyclones regularly affect the Project area between December and April and have a strong relationship with the ENSO phenomenon, with almost twice as many impacts during La Niña than during El Niño (BoM 2009c).

The severity of a tropical cyclone is described in terms of categories ranging from one (1) to five (5) related to the zone of maximum winds. The categories are described in **Table 4-3**, along with the typical impacts of each category.

Table 4-3 Tropical Cyclone Category Descriptions

Category	Strongest gust (km/h)	Typical impacts
1 Tropical Cyclone	Less than 125km/h Gales	Minimal house damage. Damage to some crops, trees and caravans. Boats may drag moorings.
2 Tropical Cyclone	125–164km/hr Destructive winds	Minor house damage. Significant damage to some crops. Risk of power failure. Small boats may break moorings.
3 Severe Tropical Cyclone	165–224km/hr Very destructive winds	Some roof and structural damage. Some caravans destroyed. Power failure likely.
4 Severe Tropical Cyclone	225–279km/hr Very destructive winds	Significant roof and structural damage. Many caravans destroyed and blown away. Dangerous airborne debris. Widespread power failures.
5 Severe Tropical Cyclone	More than 280km/hr Extremely destructive winds	Extremely dangerous with widespread destruction.

Source: BoM (no date)

From the available records, there are 1 to 1.5 tropical cyclones in the Gulf of Carpentaria per year on average; however the numbers range from 0 to 5 in any one year. There has been a total of 24 Category 3 and above tropical cyclones in the recorded history of the Gulf region, an average of one severe coastal crossing every six years. Only three of these cyclones have reached Category 4.

The landlocked nature of the Gulf means that, when a tropical cyclone develops, it is very likely to strike the coast and is also likely to do so within only a day or two of the commencement of its development, unless it has originated outside the Gulf. This very short life cycle means a relatively small proportion of the total number of tropical cyclones attain severe Category 3 status or higher. Many of the longer-lived and more intense tropical cyclones that have impacted the Gulf are cyclones that originally developed over the Coral Sea and crossed over Cape York Peninsula, weakening rapidly as they strike the Great Dividing Range then redeveloping again very rapidly once back over the waters of the Gulf.

Table 4-4 provides information on the impact of cyclones in the Weipa area.

Cyclones present a number of risks to the Project including:

- health and safety of employees and the community from storm surge, flooding and wind-blown debris;
- damage to port, ferry and barge infrastructure from storm surge and waves, and damage to other infrastructure from wind and flooding; and
- damage to revegetation from wind and heavy rain.

Table 4-4 Tropical Cyclones on the Eastern Coast of the Gulf of Carpentaria

Cyclone	Origin	Impact
Dawn 11 Feb 1970	South-west of the Gulf of Carpentaria	*Dawn* crossed the coast near Weipa as a Category 1 cyclone. Thursday Island reported a gust of 52 knots (96km/hr). There was minor vegetation damage and telephone lines were down. Weipa recorded 443mm of rain over six days.
Faith 13 Apr 1972	North of the Gulf of Carpentaria	*Faith* crossed the coast just south of Weipa as a Category 1 cyclone. Wind gusts up to 84km/hr were reported at Aurukun and these caused some tree damage. Aurukun registered 256mm of rain in 24hrs.
Otto 7 Mar 1977	Gulf of Carpentaria	*Otto* crossed the coast between Aurukun and Weipa as a Category 2 cyclone. Wind gusts to 94km/h were reported at Weipa, with rough seas, however no storm surge was reported. Tree damage was reported at Weipa.
Greta 10 Jan 1979	Gulf of Carpentaria	*Greta* crossed the coast 20km south of Weipa as a Category 2 cyclone. Weipa recorded a maximum wind gust of 42 knots (78km/hr). Little damage was experienced.
Stan 14 Apr 1979	Originally developed in the Coral Sea moving north to the Arafura sea then changed direction to track east across the Gulf of Carpentaria	*Stan* crossed the coast 40km north of Weipa as a Category 1 cyclone causing no damage. A 0.5m storm surge was reported at Weipa. The 24hr rainfall total was 84mm at Weipa.
Dominic 7 Apr 1982	North Gulf of Carpentaria	*Dominic* crossed the coast near Cape Keerweer, approximately 100km south of the Project area, strengthening to a Category 4. Storm damage occurred at Aurukun. A storm surge of 1m was recorded at Weipa.
Rebecca 22 Feb 1985	North of the Northern Territory coast in the Arafura Sea	*Rebecca* crossed the coast just to the north of Weipa as a Category 1 cyclone. Tree damage at Weipa.
Mark 10 Jan 1992	West Arafura Sea	*Mark* travelled east across the Gulf of Carpentaria and crossed the coast near Weipa as a Category 2 cyclone. Weipa suffered widespread minor damage with falling trees largely responsible for house and power line damage. Weipa recorded 167mm rainfall in 24hrs and a 1.2m storm surge.
Ethel 9 Mar 1996	Gulf of Carpentaria	*Ethel* made landfall 33km west northwest of Weipa as a Category 2 cyclone. Trees up to 1m in diameter were uprooted. Strips of up to 2km wide were completely defoliated. The beach area about the point of landfall was affected by large waves and storm surge. Wind gusts of up to 100km/hr and a 72hr rainfall of 320mm were recorded at Weipa. A peak storm surge of 1.18m was recorded at Weipa.
Bernie Jan 2002	North-west Gulf of Carpentaria	*Bernie* intensified to a Category 2 cyclone as it tracked southward through the Gulf of Carpentaria and crossed the coast near the Northern Territory border. A maximum storm surge height of 0.4m was recorded at Weipa.
Craig 7-12 Mar 2003	North Gulf of Carpentaria	*Craig* was a tropical cyclone that tracked east along the north coast of the Northern Territory until it moved south across the Gulf of Carpentaria, intensifying to Category 2 level. Weipa recorded a storm surge of 1.1m, significant wave heights of 3m, and peak wave heights of 5m.
Ingrid Mar 2005	North Gulf of Carpentaria	*Ingrid* originally developed north of the Gulf of Carpentaria in March 2005 and tracked east to the Coral Sea where it intensified into a Category 5 cyclone as it moved west towards the east coast of Queensland. Ingrid had weakened to a Category 1 cyclone as it tracked directly over the Project area before intensifying again to a Category 5 cyclone near the northeast corner of the Northern Territory.
Monica Apr 2006	Coral Sea	*Monica* tracked west across Cape York, weakening from a Category 3 to a Category 1 cyclone as it crossed the coast south of the Project area. It intensified again to a Category 5 cyclone as it moved west across the Gulf of Carpentaria. During the week of 23 April 2006, the Project area received between 200mm and 300mm of rain.
Nelson Feb 2007	Originally developed south Gulf of Carpentaria and tracked east to Queensland where it intensified into a Category 2 cyclone	*Nelson*, a Category 2 cyclone, caused storm surge up to 1.1m in height at Weipa.

Source: BoM (2009c)

The risk to the health and safety of employees and the community from potential cyclone impact is managed by a detailed Disaster Management and Recovery Plan and specific Cyclone Emergency Procedures. These are described further in **Section 19.3.4**.

Storm Surge and Wave Height

Storm surge, a dome of water pushed ahead of a cyclone by strong winds, can cause flooding, particularly when combined with high tides. Wave heights also increase as a result of cyclone activity and can cause coastal erosion and damage to infrastructure.

An Acoustic Doppler Current Profiler (ADCP) was deployed off Boyd Point between July 2006 and May 2008 (GHD 2008). The highest recorded level in this dataset was 3.55m above Lowest Astronomical Tide (LAT), which occurred during a low pressure system in the Gulf of Carpentaria (ex Tropical Cyclone *Helen*).

Modelling of storm surge at the proposed port has subsequently been undertaken using the Delft3D modelling system. The model uses a joint probability approach for tide level and cyclone-induced storm surge to identify design water level criteria for specified Annual Recurrence Intervals (ARIs). The ARI is the average value of the periods between exceedances of a given event, for example one in every 100 years.

The Queensland Department of Environment and Resource Management (DERM) operates a Waverider buoy system within Albatross Bay which measures wave height based on Mean Sea Level (MSL). The highest maximum wave height recorded was 6.96m on 9 March 1996 during the passage of Tropical Cyclone *Ethel*.

Waves at the proposed port site between Boyd Point and Pera Head have been modelled by Cardno Lawson Treloar (2009) using the SWAN wave model system and verified against measured data from the Waverider buoy. Based on a 1:100 year ARI high water level of 4.36mabove LAT, which reflects typical storm surge plus high tide conditions, the model predicted a maximum significant wave height (the average of the highest one-third of waves) of 7.1mabove LAT at the wharf end. The model also predicted a maximum breaking wave height of 11.9m at 1:100 year ARI.

The proposed port has been designed at a nominal level of 16.8m above LAT, which is 5m above the predicted 1:100 year ARI maximum breaking wave height. On-shore product stockpile pad levels would also be well above this level from 17.9 to 23.4m Australian Height Datum (AHD) (19.41 to 24.91m above LAT).

Modelling of storm surge in the Embley and Hey River systems was carried out in 1979 using the SURGE hydrodynamic model. From this model, the 1:100 ARI design level was determined to be approximately 3.6m above LAT.

A tidal station, operated by the BoM, is located at Weipa Port (near Humbug Point) in the Embley River. The highest recorded water level at the Weipa Port tidal station is 3.6m above LAT during Tropical Cyclone *Ethel* in 1996 (Harper 1998). This included a storm surge of 1.2m.

The proposed Humbug terminal, Hornibrook ferry terminal, and Hey River barge/ferry terminal would have fixed facilities designed to at least the Highest Astronomical Tide (HAT) level. Floating pontoons and ramps have been designed to move down to LAT level and up to a level higher than the 1:100 year ARI level. It is very unlikely the barge and ferry facilities would be used during levels higher than HAT, as operations would be limited during storm conditions. The facilities would incorporate foreshore protection designed to withstand water levels in excess of the 1:200 year ARI level.

Car parking areas for the ferry terminals would be above the 1:100 year ARI level. As previously stated, it is unlikely employees and contractors would utilise the ferry during storm or flood conditions.

Water level and design data are summarised in **Table 4-5**.

Table 4-5 Measured and Modelled Water Levels above Lowest Astronomical Tide

	Port	Humbug Barge Terminal	Hornibrook Ferry Terminal	Hey River Barge/Ferry Terminal
Lowest Astronomical Tide (LAT)	0	0	0	0
Australian Height Datum (AHD)	1.51m LAT [1]	1.75m LAT [2]	1.75m LAT [2]	1.75m LAT [2]
Mean Sea Level	1.76m LAT [1]	1.85m LAT [2]	1.85m LAT [2]	1.85m LAT [2]
Highest Astronomical Tide	3.09m LAT [1]	3.38m LAT [2]	3.38m LAT [2]	3.38m LAT [2]
Highest recorded level	3.55m LAT [1] (6 January 2008)	3.6m LAT [3] (including 1.2m surge from TC *Ethel* 1996)		
Design criteria	1:500yr ARI	1:100yr ARI	1:100yr ARI	1:100yr ARI
Modelled design water level*	5.14m LAT (3.63m AHD)	3.6m LAT	3.6m LAT	3.6m LAT
Approximate Relative Level (RL) of wharf facilities*	16.8m LAT	Sheet pile structure from 3.4 to 4.9m LAT. Floating ramp to move with water level	Covered walkway from 3.7m LAT to floating pontoon	Sheet pile structure from 4.9 to 3.4m LAT. Floating ramp to move with water level
Approximate RL of shore facilities*	19.4–24.9m LAT (17.9–23.4m AHD)		Car park 4.9m LAT (3.15m AHD)	Car park 9.7m LAT (8.0m AHD)

* The modelled design water level and relative levels of built infrastructure are approximate as the final heights are to be confirmed. The design criteria remains the same.

3. Harper (1998)

Wind

High winds occurring as a result of cyclones can cause structural damage and present a safety risk from flying debris.

Rehabilitation is at risk of damage from high winds, including defoliation and windthrow of trees. Species adapted to the local climate would be utilised in rehabilitation to maximise the ability of revegetated areas to withstand these types of storms and regenerate quickly.

All plant and infrastructure facilities would be designed and constructed to the relevant Australian Standards to reduce the risk of structural damage caused by high wind speeds. These include key design codes such as Australian Standard *1170 Structural Design Actions Infrastructure*.

This Standard specifies the design criteria appropriate for various structures, depending on their use and the annual probability of exceedance for wind. Most of the proposed buildings in the Project area, including the beneficiation plant and workshops, are defined by the Standard as "Normal" structures with a design working life of 25 years. These buildings would be designed to withstand wind gusts with an ARI of 1:200 years in accordance with the Standard. In the Project area which, according to the Standard, lies within Region C, Terrain Category 2, this is equivalent to wind gusts of up to 64m/sec (230km/hr).

The proposed administration building is rated at a higher importance level under the Standard, given its capacity to contain many people. The administration building would therefore be designed to withstand wind gusts with an ARI of 1:500 year, which is equivalent to wind gusts of 69m/s (248km/hr).

Structural damage to buildings could occur if a Category 4 or Category 5 severe tropical cyclone was to directly impact the Project facilities. Only three such cyclones have been recorded in the Gulf of Carpentaria area over more than 100 years. It should be noted that not all of these directly impacted the Project area. The likelihood of a direct hit of a Category 4 or Category 5 cyclone on the Project facilities is estimated to be 1:200 years.

The existing RTA Cyclone Emergency Procedure includes detailed instructions for the requirements in each area in relation to evacuation of personnel, securing loose items, taping windows, and tying down conveyor belts and stackers. This procedure would be updated as required for the Project area.

RTA's existing Disaster Management Plan also addresses the maintenance of essential services (electricity, telecommunications, water and sewage), should these be affected as a result of a cyclone.

Rain

High intensity rainfall can occur as a result of cyclone events and can cause localised flooding. The highest daily rainfall recorded at Weipa was 223mm, recorded on 6 March 1996, in association with Tropical Cyclone *Ethel*. Potential erosion impacts are assessed in **Section 3.6.1**.

4.2.2 Flooding

Wet season inundation of flood plains resulting from overtopping of the main channel banks is a seasonal characteristic of the area. The main impact is restricted access for vehicles rather than flood damage.

The risk of flood damage to people, property and the environment would be mitigated by:

- maintaining safety of people in accordance with RTA Weipa's Disaster Management and Recovery Plan;
- minimising the potential for damage to land-based infrastructure by designing to appropriate ARIs for storms (refer **Table 4-6**). The flooding criteria are based on guidelines by Pilgrim (1998). The design of dams is based upon guidelines by the Australian National Committee on Large Dams (ANCOLD);
- ensuring hazardous materials storage areas are designed and constructed in accordance with Australian Standard *AS1940 The Storage and Handling of Flammable and Combustible Liquids*; and
- ensuring essential services (electricity, telecommunications, water and sewerage) maintain function during a flood event (refer **Section 19.3.2**).

These measures are consistent with *State Planning Policy 1/03 Mitigating the Adverse Impacts of Flood, Bushfire and Landslide*.

Table 4-6 Flood Design Criteria for Land-based Infrastructure

Relevant Infrastructure	Flood Design Criteria (ARI)
Mine Infrastructure Areas	1:100yr
Mine Access Road	>300mm over top once in 10yr
Creek crossings for conveyor and for water pipelines	1:100yr
Tailings storage facilities spillways	1:1,000yr
Water supply dam spillway	1:2,000yr
Sediment pond spillways	1:100yr

4.3 Climate Change Adaptation

The Queensland Office of Climate Change has published projections with regard to climate change in Queensland (EPA 2008a). This report is based on the Intergovernmental Panel on Climate Change Fourth Assessment Report (IPCC 2007) and a technical report prepared by the CSIRO and the BoM (CSIRO 2007).

RTA has conducted internal modelling to assess the potential for changed weather patterns of the Weipa area as a consequence of climate change up to 2049. These results are summarised in the following sections.

4.3.1 Temperature

The Queensland Department of Environment and Resource Management estimates that, by 2030, annual average temperatures in the Weipa area, relative to the climate of recent decades, will increase between 0.6 ºC and 1ºC (EPA 2008a). By 2050, the annual average temperatures are projected to increase between 1 ºC and 1.5ºC.

RTA's modelling of the Weipa area predicts a mean annual temperature rise in the order of 2.0ºC by 2049. The model also indicates the extreme maximum of 39ºC is likely to rise to the vicinity of 42ºC by 2049.

Increases in extreme temperatures have the potential to adversely affect germination and seedling performance in rehabilitated areas. There is potential that such extremes could require certain areas of rehabilitation to be re-sown if plant establishment is poor.

Any change in evaporation due to increased temperatures is unlikely to have an appreciable influence on water supply as the volume storage in the system has been sized to accommodate a wide range of climatic variability.

4.3.2 Rainfall, Water Supply and Flooding

There is greater uncertainty with rainfall projections than with temperature projections (EPA 2008a). The CSIRO modelling indicates Weipa's annual rainfall will vary only slightly (-2% to 2%) due to climate change over the life of the Project.

RTA's modelling of the Weipa area indicates a slight seasonal shift in rainfall with a slight increase during the summer months, lasting further into autumn, little change in winter rainfall and a tendency towards slightly higher extreme rainfalls in spring. Annual rainfall is expected to change only slightly, with a slight increase the most likely outcome and an increasing trend towards higher rainfall totals for the wettest seasons.

The Project would rely on surface water and artesian groundwater sources for its water supply (refer **Section 5.2.1**). The volume of rainfall runoff into the surface water storage or the Ward River is not expected to change significantly as a result of climate change.

Similarly, there is unlikely to be any significant change in flooding regimes in the Project area as a result of climate change.

4.3.3 Sea Level

The Fourth IPCC assessment report on climate change predicts a sea level rise of 0.18 to 0.59m by 2100, with a possible additional contribution from melting ice sheets of approximately 0.1 to 0.2m (IPCC 2007). RTA's modelling of the Weipa area indicates that sea levels could rise between 0.08m and 0.12m by 2049. Based on these predictions, sea level rise would not impact the Project.

4.3.4 Bushfires

Bushfires and grassfires are an intrinsic part of the Cape York environment. Natural ecosystems have evolved with fire, and the landscape, along with its biological diversity, has been shaped by both historic and recent fires. The extent to which the current fire regime of annual burning is human or naturally induced is difficult to determine. Indigenous Australians have long used fire as a land management tool, however fire can also be initiated by tourists, hunters, hazard reduction burning and lightning.

In areas where climate change causes higher temperatures combined with lower rainfall to produce a drier landscape, bushfires would be expected to increase in intensity. However, in the Project area predictions indicate overall rainfall will increase slightly, generally in the wet season, with little change in dry season rainfall. Therefore it is expected that the risk of bushfires will remain unchanged.

4.3.5 Tropical Cyclones

RTA's modelling of climate change indicated the following in relation to tropical cyclone events:

- there is a likelihood of no change in the overall frequency of tropical cyclones, with a reduction, possibly by up to 20%, of the risk of a Category 3 or higher tropical cyclone; and
- although Category 5 cyclones remain a low probability event, the severity of the most intense cyclones may increase, due to a possible 10% increase in maximum wind speed, compared to the current climate regime.

In a climate affected by global warming, two factors may act to increase the impact of storm surges:

- sea-level rise caused mainly by thermal expansion of the oceans; and
- possible changes in cyclone characteristics, such as intensities and frequencies (McInnes *et al.* 2000).

Similarly to cyclones, modelling of the Weipa area indicated that the overall likelihood of storm surge (as a result of Category 3 cyclones or higher) would reduce by as much as 20%. However if a Category 5 cyclone does occur, storm surge and maximum wave height could be more severe, arising from an expected sustained 0.08m to 0.12m sea level rise and 10% increase in wind speed.

The potential increase in severity of impact from a severe cyclone is offset by decreased likelihood, resulting in a similar level of overall risk compared to the current climate regime.

4.3.6 Mitigation Measures

During the life of the Project (i.e. approximately 40 years) the risk that climate change impacts would affect the commercial feasibility of the Project is considered to be low.

RTA would adopt best practice safety design for major infrastructure to minimise impact caused by extreme events and would continue to implement emergency procedures to protect the safety of personnel and the community.

RTA has considered the impact of climate change in the initial design of the Project and would also use adaptive management where required to mitigate any impact arising from climate change.

Environmental Impact Statement

for South of Embley Project

Section 5

Water Resources

5 WATER RESOURCES

5.1 Surface Water

The Project is located on a gently undulating bauxite plateau landform cut by a network of rivers and smaller creeks. The elevated bauxite plateau is fringed for most of the coastal margin by low cliffs and lateritic outcrop. A number of semi-perennial watercourses plus numerous smaller ephemeral creeks traverse the Project area and flow in a westerly direction eventually discharging into the Gulf of Carpentaria. In terms of primary surface water bodies, the Project area is bound by the Hey and Embley Rivers to the north, the Ward River to the south, and the Gulf of Carpentaria to the west. There are large estuaries associated with the Hey, Embley and Ward Rivers.

The Watson River is located south of the southern boundary of ML7024 and, while part of the river's catchment is within ML7024, the proposed footprint of the Project is outside the catchment boundary of the Watson River. The Archer River, a declared Wild River, is located south of the Watson River catchment and is not affected by the Project. The Wenlock River is a declared Wild River with a catchment north of the Project area. That catchment extends west–north-west across the Cape and the river discharges into the Gulf of Carpentaria north of Mapoon. The catchment boundaries of the main rivers surrounding the Project area are shown on **Figure 5-1**.

5.1.1 Surface Water Hydrology

Numerous catchments are located within the Project area. The northern part of the Project area contains Triluck Creek, Winda Winda Creek and a small part of the Hey River catchment. The Norman Creek catchment and the Ina Creek catchment are within the western central portion of the Project area. The Ward River catchment encompasses the eastern and southern project area and includes the following sub-catchments: Coconut Creek, Tappelbang Creek, Sandy Creek and Possum Creek.

The principal catchment boundaries in the Project area are shown in **Figure 5-2** and the associated catchment areas are presented in **Table 5-1**.

Table 5-1 Catchment Areas

Project Area Catchments	Area (km^2)
Embley River	1,000
Hey River	756
Triluck Creek	108
Winda Winda Creek	94
Norman Creek (all tributaries)	259
Ina Creek	65
Ward River (all tributaries)	666

South of Embley Project

Fig. 5-2: Project Area Catchment Boundaries

The Watson River drains a relatively small area in the southern extremity of ML7024. The Embley River catchment is located north of the Project area and is partially within ML7024 (refer **Figure 5-1**).

The drainage patterns of the catchments in the Project area are dendritic (tree-like). These catchments are typified by confluences with one or more tributaries that join larger reaches at acute angles, which give way to broader flood plains downstream.

The characteristics of the creeks (including length, source and habitat) with catchments predominantly within the Project area are summarised in **Table 5-2**. Riparian vegetation associated with groundwater fed reaches of creeks is shown in **Figure 7-8**. Groundwater dependent ecosystems are discussed in more detail in **Section 7.5.1**, and **Table 7-4** and **Table 7-9**.

Table 5-2 Project Area Creek Characteristics

Creek	Approx. length (km)	Sampling Locations	Source	Habitat	Part of larger system?
Winda Winda Creek	13.8	9, 9A	Seasonal groundwater fed reaches with some isolated perennial pools (9)	Supports perennial pools /lagoons	Winda Winda Creek flows into Triluck Creek which discharges into the mouth of the Embley River estuary.
Triluck Creek	14.0	19, 21	Seasonal groundwater fed reaches with some isolated perennial pools (19)	Supports perennial pools /lagoons lower reaches (21) are tidal	Winda Winda Creek joins two branches of Triluck Creek which discharges into the mouth of the Embley River estuary.
Norman Creek	27.1	1A, 2A, 4, 5A, 7A, 10A, 10B, 11	Perennial stream with some seasonal/semi-perennial stream channels (4, 2A) and perennial groundwater fed reaches (7A)	Supports pools, lagoons and tree swamps (11) and lower reaches (10A and 10B) are tidal	Norman Creek has three main branches which join and discharge into the Gulf of Carpentaria.
Ina Creek	12.9	26, 31	Seasonal stream channel with isolated perennial pools	Supports perennial pools (26) and is tidally influenced at lower reaches (31)	Isolated. Discharges into the Gulf of Carpentaria.
Ward River	42.1	25A, WP8, WP16	Combination of seasonal surface flow and perennial groundwater fed reaches	Supports pools and tree swamp (WP16) and is tidally influenced at lower reaches (WP8, WP14)	Coconut Creek joins with Tappelbang Creek and becomes Ward River. Sandy Creek and Possum Creek enter downstream. Ward River estuary links to larger Watson and Archer estuary system.
Coconut Creek	21.2	14A, 22A	Seasonal stream channel	Supports tree swamp (22A), not tidally influenced	Coconut Creek is a tributary of Ward River which discharges into the Gulf of Carpentaria.

A network of stream gauging stations and rain gauges were installed in the Project area (refer **Figure 5-3**). The stream gauging stations were installed in October 2007 and were operational for various periods until the data was last downloaded in August 2009. Stations SW02 and SW03 use Level Troll 500 pressure transducer sensors and Stations SW01 and SW03 use Argonaut SW Acoustic Doppler sensors. The five rain gauges were installed for various periods throughout the Project area, starting in 2006.

The response of streamflow to rainfall at four various gauging stations (SW01, SW02, SW03, and SW04) is shown in **Figure 5-4.**

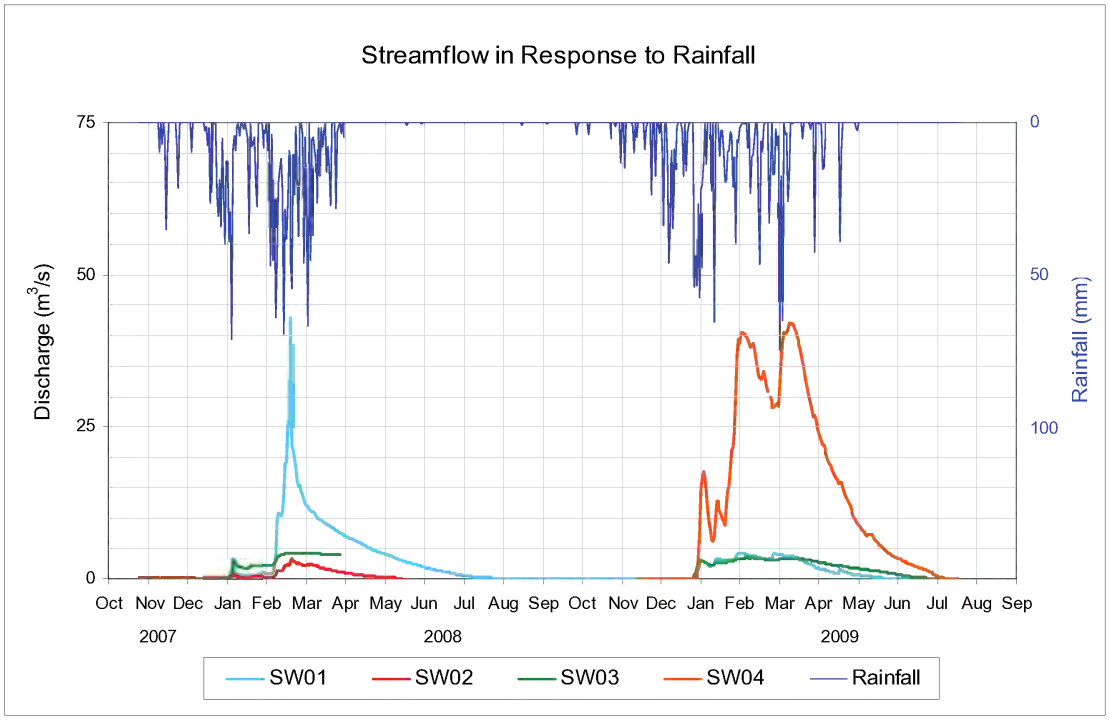
Figure 5-4 Streamflow in Response to Rainfall



Rainfall–runoff relationships were derived using Boughton's Australian Water Balance Model (AWBM) (CRC for Catchment Hydrology, undated). AWBM is a catchment water balance model that relates runoff to rainfall, based on a conceptualised representation of a catchment's temporary surface and baseflow stores, rainfall loss to evaporation and gradual release of water from both stores to streamflow at the catchment outlet. The sum of water released from surface and baseflow stores provides an estimate of daily runoff (Boughton 1993).

The model was calibrated to establish representative model parameters to use for predictive model simulations of streamflow. The model parameters are catchment specific and it is therefore necessary to calibrate to gauged streams in close proximity to the Project area where possible.

The AWBM has been calibrated at two streamflow gauging stations:

- SW01 (upstream of proposed Dam C on a Norman Creek tributary); and
- SW04 (on the Ward River).

The input data for calibration included:

- catchment area;
- rainfall;
- runoff (streamflow); and
- evapotranspiration.

The catchment area reporting to SW01 is 33.02km^2 and to SW04 is 281.73km^2. Local rainfall data recorded at RG04 was used for the calibration of AWBM at SW01 and at RG06 for the calibration at SW04. Data gaps in rain gauge records were filled at RG04 with data from RG06 and at RG06 from RG05.

Streamflow data was recorded by Argonaut SW Acoustic Dopplers (Dopplers) located at SW01 and SW04. Evapotranspiration data was obtained from SILO data drill (BoM 2009d). Data drill is gridded interpolated data from point observations provided by the Bureau of Meteorology (BoM).

The calibration procedure is undertaken to determine the model parameters that provide the best fit of "modelled" to "measured" streamflow in terms of runoff from the surface and recession curve (baseflow) components, and the overall total flow volume.

The following calibration parameters are identified by the model:

- C1, C2 and C3 (surface storage capacities);
- A1, A2 and A3 (partial areas of surface stores);
- Ks (surface recession constant) – the rate of discharge of water from the surface store;
- BFI (baseflow index) – the amount of runoff that becomes baseflow; and
- Kb (baseflow recession constant) – the rate of discharge of water from the baseflow store.

An initial visual assessment of the runoff hydrograph showed the falling limb (representative of baseflow) meets the zero flow axis at a greater angle than is typically the case. The falling limb typically asymptotes to a point of lowest flow (or zero flow). It was concluded that a proportion of baseflow continues below the invert of the stream channel and the actual asymptote of the falling limb occurs at a point approximately 0.5mm/day (d) below the axis of the hydrograph. This value of up to 0.5mm/d has been concluded to be representative of "deep baseflow" (baseflow that does not enter the stream at the flow measurement point) and is included as part of the calibration. The AWBM calibration parameters are shown in **Table 5-3.**

Table 5-3 AWBM Calibration Parameters

Calibration Parameter	Value
A1	0.134
A2	0.433
C1	0
C2	0
C3	260
Ks	0.1
BFI	0.99
Kb	0.979

The AWBM was used to estimate the annual partitioning of incident rainfall into the following components:

- evapotranspiration (evaporation and water vapour from vegetation);
- surface runoff (water that does not infiltrate);
- baseflow (water that infiltrates and moves as saturated flow to the stream); and
- deep baseflow (water that infiltrates and moves as saturated flow below the stream bed).

Deep baseflow may emerge as streamflow at a lower point in the catchment, or may emerge as a freshwater upwelling in estuaries or off the coast in the Gulf of Carpentaria. A small proportion may become recharge to a deeper aquifer.

The partitioning of the annual incident rainfall (1,741mm) is shown in **Table 5-4.** The annual average evaporation rate for the Project area is 2,289mm.

Table 5-4 Partitioning of Annual Rainfall

Component	Annual Incident Rainfall	
	mm	%
Evapotranspiration	735	42.6
Surface runoff	10	0.6
Baseflow	843	48.0
Deep baseflow/recharge	153	8.8
Total	1741	100.0

The annual evapotranspiration rate is 32.1% of annual evaporation, which is comparable to the rate found by Hutley *et al* (2000) and Vardavas (1988) for other tropical savannah woodlands in northern Australia.

The proportion of surface runoff (<1%) is unusually small and reflects the flat topography and the very high infiltration rates of the soils and lateritic strata. The consequence of this is that streamflow does not respond quickly to incident runoff until after the catchment is "wetted up" and there is no "first flush" response to rainfall at the start of the wet season. Wet season rainfall typically commences in November but it is usually not until January, after soil moisture stores are filled, that streams show appreciable flow. Thereafter, flows rise until March or April in response to wet season rainfall and then decline once rainfall ceases (refer **Figure 5-4**). In lower catchment locations within the Project area, flow may persist until late in the dry season.

In typical "hard" ephemeral catchments there are short-term spikes in stream-flow volume following rainfall events. The response of streams on the bauxite plateau to rainfall is much more modulated given that the baseflow component is so dominant and direct surface runoff component is usually very small. The low surface runoff component also means streams carry a low concentration of suspended solids, even during high flows (refer **Section 5.1.4** for further discussion on turbidity).

The stream gauge data from Norman Creek (SW01) and Ward River (SW04) was analysed to determine the ARI of "bank full" flow. Once bank full flow is exceeded, over bank flow occurs and any adjacent floodplains and wetlands are inundated. The timing and frequency of bank full flows may have significant ecological implications. The AWBM was used to generate synthetic streamflow records from SILO rainfall records. The bank full flow at the Norman Creek site ($4.5m^3/s$) was found to have an ARI of 1:2.5 and the bank full flow at the Ward River site ($30.5m^3/s$) had an ARI of 1:1.5. The 1:100 ARI flood event flows for these respective sites are $7.4m^3/s$ and $65m^3/s$. The relatively small increment in flow rate between bank full flow and a 1:100 year flood reflects the relatively minor contribution of direct surface to flow. The streamflow data indicates that adjacent floodplains and wetlands are inundated almost every year and the ecology of these areas is not dependent on extreme flood events. The streamflow information has been used to evaluate the potential impact of a water storage dam on the hydrological regime (refer **Section 5.2.3**). The potential impacts of the Project on aquatic ecology are discussed in **Section 8.13** through to **Section 8.17**.

5.1.2 Existing Surface Water Users

There are no existing surface water dams or weirs in the Project area. The surface waters of the Project area are used by Traditional Owners and visitors for fishing, camping and recreation. RTA uses very small amounts of surface water during mineral exploration activities. There are no cattle in the Project area.

5.1.3 Stream Geomorphology

This section describes the Project area geomorphology in terms of methodology and survey results from two field events: the first within the northern region of the Project area (Norman Creek, Triluck, Winda Winda, Coconut and Ina Catchments) during May 2008 and the second within the Ward River catchment during May 2009. Representative sites were inspected to record the baseline geomorphic conditions of the Project area and assess any potential impacts from mining activities, particularly in relation to construction of Dam C.

Northern Region

A total of twelve locations located up stream, down stream and within northern mining areas were inspected during May 2008 to provide a representative sample of stream types and hydrological regimes. The locations of the study sites are shown in **Figure 5-5**. The northern region includes the area for proposed Dam C.

An in situ, site based assessment of channel stability was undertaken using methodology based on Pfankuch (1975), Rosgen (2001), and the Australian Index of Stream Condition. Descriptive data (e.g. channel size, stream type, bed and bank material, active hydrology) was recorded and assessments of characteristics to determine bank, bed and overall channel stability, the potential for adjacent mass failure and the erodibility of bed and bank materials. Sites were categorised according to their stability score and stream type (Rosgen 1996). Field data and site photos are provided in **Appendix 5A**.

Stream types were classified according to Rosgen (1994, 1996, 2001; **Appendix 5A**). While streams generally fitted into the hierarchy of streams developed by Rosgen, there were some outliers (e.g. unique streams within wetlands). As such, they were grouped in the Rosgen Stream Type that most resembled what was observed. A classification scheme specific to the Project area was established to ensure correct stream groupings.

General Geomorphic Description and Assessment

The stream types observed within the northern region of the Project area are listed in **Table 5-5**.

Table 5-5 Northern region Project area stream types

Stream Type	Valley Description	Stream Description
1	Broad, flat wetland / swamp	Small, incised stream within a swamp, with low width:depth ratio
2		Large incised meandering stream within swampy surrounds, with low width:depth ratio
3	Broad, flat wetland / swamp	Very wide, shallow depression within a swamp
4	Broad, flat floodplain	Generally slightly incised channel with varying degrees of sinuosity
5	Moderately confined valley	Incised channel with varying sinuosity
6	Moderately confined valley	Chain of ponds

General observations regarding the geomorphic nature of the streams within the northern region of the SoE Project area include:

- Streams are classified into six broad categories, however diversity of stream form within these categories was great. Similarly, diversity within catchments, streams and reaches was also considerable.
- Regardless of stream type, boundary material was variable. All sites consisted of bed material finer than gravel, with gravel-like clay conglomerates prevalent at many sites. Bank material was generally composed of sandy loams, silty clays and clayey silts, although rock outcropping was observed at three sites (Sites 2A – lateritic facies; 25A and 9A – weathered rock; refer **Plate 5-1**).
- Riparian vegetation was generally composed of largely "undisturbed" moderately dense trees with variable ground cover providing additional stability. Swamp-like stream types generally had sparser trees with denser ground cover (refer **Plate 5-2**). Vegetation density generally decreased markedly with distance from the bank.
- Most streams within the study area had high sediment transport potential – incised channels, with high velocities allow for great sediment transport, irrespective of slope.
- Climate was wet dry tropical, yet many of these streams were perennial, with flows of up to 2m/s observed during May 2008 in the larger, more incised streams (e.g. Site 25a). All study sites were flowing at the time of inspection.
- The point at which aquifer discharge occurred within the catchment (refer **Plate 5-3**) varies in time throughout the dry season, moving downstream as the water table drops. The different streams have adapted to these variable hydrological conditions within the constraints of the underlying topography and geology.
- Most sites were stable, with very little active bed incision / deposition or major bank scour / failure occurring. Site 4a was an exception – at the point of observation major head cutting was occurring due to the particularly erodible material at that point below the surface layer. However, upstream (Site 4) and downstream of this point the stream was stable (refer **Plate 5-4**). It is likely that stability is a consequence of a very old, inherently stable landscape with both lateral and vertical stability controlled to a large degree by the lateritic facies within which most of the stream channels sit.

(a)

(b)

Plate 5-4 Site 4a (a) headcutting stream and upstream stability; (b) downstream stability

Detailed stability ratings for the study sites within Dam C are listed in **Appendix 5A** to provide the baseline required for future monitoring assessment. All sites were either moderately stable or stable. Vegetation protection was generally rated as moderate (due to the naturally moderately dense riparian vegetation communities), but still offered adequate additional stability. The channel types downstream of the proposed locations of the dam walls were both meandering incised systems. Both were, however, stable due to outcropping of the lateritic facies within the bank and bed and the stabilising effect of bank vegetation.

Ward River Catchment

The Ward River catchment was assessed in May 2009. The Ward River catchment was previously considered as a location for a water storage dam but this option has not been pursued. Some direct pumping of water from the lower Ward River is proposed (refer **Section 5.2.3**).

Aerial photographs were reviewed to understand the regional geomorphic setting and the long-term processes that have led to the current estuary and coastal form. Following the desktop assessment, the lower Ward River was navigated between WR1 and WR05 (refer **Figure 5-5**) to record field observations and provide an estuary-wide understanding of the general geomorphic condition, active low-flow (and tidal) processes and to understand high-flow condition and processes. At easily accessible points along the channel the adjacent floodplain was traversed to record floodplain characteristics and processes and to provide an in situ description of the valley sides bordering the floodplain. A total of 10 sites located upstream and downstream of the proposed Ward River pump location were inspected during May 2009. The locations of the study sites are shown in **Figure 5-5**.

General Geomorphic Description and Assessment

The Ward River flows into Archer Bay prior to entering the Gulf of Carpentaria. Archer Bay is an unrestricted, tide-dominated estuary. It is a branched bay with off-channel embayments. Freshwater input is dominated by that from the Archer River, although the Ward River is also a major tributary (OzCoasts 2008). The greater Archer–Ward estuary was observed to be dominated by several major features (refer **Figure 5-6**), including:

- beach ridges along the current coastline dissected by the Ward and Archer rivers. Historically these extended between about one and six kilometres inland and were a continuation of the Holocene beach ridges common to the eastern and southern

sections of the Gulf of Carpentaria (Eisma 1998, Smart 1976). These ridges have been shown to rise up to six metres above mean sea level. This elevation, along with the presence of shell layers within the ridges and the low variation in Holocene sea levels, suggests they were formed by storm surge and waves (Nott 2006). The deposition of these beach deposits appears to have redirected flow of the Ward River into Archer Bay from its previous mouth to the north;

- an infilling 'lake' at the most downstream point of the Ward River estuary (Ward River Lake) (refer **Plate 5-5a**), the condition and form of which appeared to be dictated by the "choke" point at its most downstream point created by the higher land adjacent to Aurukun on the east and the formed beach ridges to the west;
- an irregularly meandering river (Ward River) (**Plate 5-5b**) with a narrow floodplain comprised of marine-sourced sediments (**Plate 5-6**) set within the gradually sloping sides of the bauxite plateau (**Plate 5-7**). The meandering nature of the channel indicated homogeneous bank sediments (**Plate 5-8a**). Field observations supported this and active erosion was observed (**Plate 5-8b**), suggesting similarly homogeneous marine-sourced sediments within the greater floodplain (**Plate 5-6**). Windblown deposits of sands from coastal and terrigenous sources are expected to be mixed with the silts and clays, but these were not evident on the surface. The floodplain deposits that appeared to be recent have occurred as a result of more recent higher mean sea levels, backup of the Ward River flow by the Archer River, or a combination of the two. The deposits were assumed to be set within an old valley incised into the bauxite plateau. An extensive coring plan would be required for further understanding of the stratigraphy;
- small, irregularly meandering streams draining east to west that have cut into the bauxite plateau. The more downstream points of these consisted of similar (but smaller) floodplain features such as the Ward River;
- depressions along the western floodplain–plateau margins with small catchments draining the plateau, forming a combination of intermittent and perennial wetlands (**Plate 5-9**); and
- small, irregularly meandering streams draining from the depressions across the floodplain into Ward River.

The Ward River section of the Archer–Ward estuary consists of two main sections: the Ward River Lake and the narrower meandering section within the floodplain. Within these systems there are two main active processes dictating the form and condition of the Ward River estuary:

- a wet season backup of the Ward River by the larger discharge of the Archer River, resulting in a poor flushing capability of the Ward River and a largely depositional environment within Ward River Lake. This explains the apparent general infilling of the Ward River Lake and in conjunction with the more recent higher mean sea levels has probably contributed to past deposition further upstream on what is now the Ward River floodplain. The choke point located at the most downstream point of the Ward River Lake has probably contributed to these processes; and
- dry season channel maintenance flows within the meandering section of the Ward River estuary, where freshwater input dominated over the tidal influence, resulting in high enough stream velocities to cause bed and bank erosion, particularly considering the non-cohesive nature of the bank sediments. These flows would also maintain the thalweg within the Ward River Lake.

Geomorphic Potential Impacts and Mitigation

Geomorphic attributes may be affected by dam construction and operation and the mining process, as discussed below.

Dam-Related Impacts and Mitigation

Sediment-related geomorphological impacts may occur during dam construction although they are expected to be generally of a local and short-term nature. Unplanned sediment runoff may occur without adequate controls. This runoff would be of a temporary nature and composed predominantly of fine (clays, silts) material, although some coarser material may also be released. Finer material would run off in plumes following heavy rain events. Coarser material would likely be transported downstream as slower-moving pulses, depositing temporarily on bars and in pools. Due to its temporary nature and the existing high sediment transport capacity of the two streams in question, sediment input from construction activities would not produce long-lasting impacts on sediment load.

Erosion and sediment control procedures would be prepared prior to construction to mitigate potential impacts during dam construction.

Potential impacts associated with a typical dam may include:

- siltation of bed and banks within the upstream sections of the proposed inundation area;
- formation of deposition zones (and macrophyte colonisation of these);
- contraction of channel and reduction of flow conveyance within the upstream reaches of the proposed inundation area;
- major reductions in fine and coarse sediment load immediately downstream of the proposed dam resulting from trapping of sediment within the dam;
- release of "clear" water during dry season environmental flow releases from the dam, due to the trapping effect of the dam. This issue should be minimal considering the existing low suspended sediment concentrations within dry season flows discussed above;
- alterations to bank and bed erosion processes immediately downstream of the dam resulting from changes to flow characteristics; and
- a gradual reduction in the magnitude of hydrological and sediment transport impacts with distance downstream, including concurrent impacts on erosional, depositional or habitat maintenance processes.

However, water flow within the streams of the Project area are naturally "clear" and channels have adapted to these conditions. As such, many of the geomorphic impacts expected to occur following dam construction either would not apply in this case or the impacts would be negligible.

The primary impact associated with dam operation is change to downstream hydrological and sediment transport regimes and concurrent impacts to in-stream geomorphic integrity and hydraulic habitat. Reducing these flows within the meandering section (where freshwater flows were prominent during the middle of the dry season) may move the saltwater–freshwater interface further upstream and bring its upstream movement earlier in the seasonal cycle and, as such, may shift this section of the estuary towards tide dominance compared with the current dominance of fluvial processes.

The degree of potential impacts would be largely dependent on dam size, environmental flow releases and trapping efficiency. The mean natural flow at the proposed Dam C location is summarised in **Table 5-6**. The dam would be fitted with a low level outlet pipe which would permit the controlled release of environmental flows when required (refer to **Section 5.2.3**). Sufficient water would be reserved for environmental flows to enable continued release in the driest months (August to October) of a volume equivalent to 25% of dam inflows. When natural dam inflows cease, environmental flow releases would cease. Once the dam is full following the onset of the wet season, the spillway would typically overflow on a regular basis. Given the comparable volumes, environmental releases are anticipated to mitigate the effects of altered surface water flow on the upper estuary during the dry season.

Ongoing monitoring of geomorphic assessment sites in Norman Creek downstream of Dam C would be conducted. The results of the monitoring would provide a baseline between pre- and post- construction. If water quality sampling results (refer **Section 5.5.1**) indicate sedimentation is an issue the sites would be further investigated to evaluate erosion. In addition, the following mitigation measures and monitoring would be implemented:

- an Erosion and Sediment Control Management Plan would be prepared prior to construction;
- streamflow gauging stations would be used to monitor streamflows upstream and downstream of Dam C, as well as two Norman Creek sub-catchments (one to be mined and one non-mined); and
- saltwater–freshwater interface mapping: mapping of representative vegetation ecotonal boundaries (e.g. sclerophyll, riparian/wetland/estuarine) from aerial photography to detect any long-term (decadal) shift; monitoring of surface water for salinity at monitoring points located in each of the major estuaries.

Mine-Related Impacts and Mitigation

With implementation of the riparian vegetation buffer system, as described in **Section 7.9.2,** most mine-related geomorphic impacts would be negligible, in terms of impacts on stream geomorphic integrity. Minor impacts to sedimentation within channels would be expected to some degree in the most heavily mined catchments as a by-product of reduced velocities, mine runoff, changed hydrological regime (perennial to intermittent / intermittent to ephemeral) and resulting alterations to the sediment transport regime.

5.1.4 Surface Water Quality

This section describes existing surface water quality conditions both upstream, downstream and within the Project area. Where applicable, results are compared with the *Australian and New Zealand Guidelines for Fresh and Marine Water Quality* (ANZECC/ARMCANZ, 2000).

A total of 25 locations within different catchments and habitat types were sampled over multiple seasons. The spatial and seasonal variation in sampling was designed to account for the variation in wet and dry season climatic conditions that influence surface water in the Project area. The locations of the sampling sites are shown in **Figure 5-3.**

Four rounds of sampling were initially undertaken for the EIS:

- mid dry season between 30 August and 1 September 2007 (10 locations);
- late dry season between 26 and 30 November 2007 (12 locations);
- wet season between 26 February and 3 March 2008 (19 locations); and
- early dry season between 22 and 25 May 2008 (19 locations).

After this sampling, an additional water supply dam in the Ward River catchment was proposed for the Project, and additional sampling was completed in this river system (along with some repeat sampling elsewhere). Three additional rounds of sampling were undertaken:

- late dry season between 4 and 11 December 2008 (12 locations);

- wet season between 24 February and 3 March 2009 including the additional Ward catchment sites (22 locations); and
- early dry season on 18 and 19 May 2009 (5 locations; Ward only).

The category and catchment of each sampling location are summarised in **Table 5-7**.

Table 5-7 Sampling Location by Category and Catchment

Category	Catchment	Locations
Freshwater	Norman Creek	1A, 2A, 4, 5A, 7A
	Triluck Creek	9, 9A, 19
	Ward River	14A, 25A
	Ina Creek	26, 31
	Norman Creek	11, 24
Tree swamps	Ward River	WP16, WP18, 22
	Hey River	27
	Norman Creek	23
Estuarine	Ward River	WP8
	Norman Creek	10A, 10B, 21
Lagoon (back dune)	Norman Creek	16A
Marine	Ward River	WP05

Representative habitat types were sampled at multiple locations in the main catchments. The characteristics of sampling locations are summarised in **Table 5-8**.

At each site, physicochemical conditions were measured using a multi-parameter water quality meter and water samples were collected for laboratory analysis. Sampling was conducted in accordance with the Queensland EPA *Water Quality Sampling Manual* (EPA 1999), except where noted below. Samples were analysed for physiochemical parameters, cations, anions, nutrients and a suite of total and dissolved metals. Select samples were also analysed for hydrocarbons.

For the analysis of metals, other than calcium, magnesium, potassium and sodium, field and laboratory procedures were modified to achieve ultra trace levels (below 1µg/L). Ultra trace levels were sought because the default low reliability trigger value of ANZECC/ARMCANZ (2000) for aluminium in freshwaters with pH below 6.5 (as are the waters in this area) of 0.8µg/L is less than commercial laboratory detection limits. The only laboratory in Australia that is able to achieve levels of resolution for aluminium at or below this level on a commercial basis is the CSIRO Centre for Environmental Contaminants Research (CECR) laboratory at Lucas Heights, NSW. This laboratory was contracted to undertake the trace metals analyses, with other parameters subcontracted to the National Measurement Institute (NMI) in Sydney. CECR prepared all sampling and sample filtration equipment for the Project, and shipped them to Weipa.

Field sample collection required two persons, using a "clean hands"–"dirty hands" procedure. The person taking the sample wore two pairs of unpowdered nitrile gloves, and only handled the trace metals sample bottles after the seal on the two zip-lock plastic bags that contained the bottle had been opened by the other person, who also wore unpowdered nitrile gloves. The samples were collected below the water surface, by placing the opened bottle into the water, initially with the opening facing downstream, and then rotating the bottle underwater to face upstream. The bottle was rinsed three times in site water, then filled and capped underwater before removal from the water and placement back into the two zip-lock plastic bags and resealing of the bags. A paper label was placed inside the outer plastic bag. Field filtration for filtered metal samples was conducted either in an air-conditioned room, or in a dedicated tent

Table 5-8 Sampling Location, Habitat and Catchment

Sampling Location	Habitat type	Catchment

with dust-proof door seals, using acid washed and rinsed syringes and 0.45µm filters. All trace metal bottles and filtration equipment were acid washed, rinsed and sealed by CECR before shipment to Weipa. Bottles for other parameters were provided by NMI and were stored in eskies before and after sampling. Samples were kept cold in the field on ice bricks in an esky or a portable fridge/freezer, and kept in a refrigerator at or near 4°C until shipping in eskies containing ice bricks to Sydney for analysis. Nutrient samples were kept frozen where possible or at 4°C where not possible to freeze them.

It was recognised that the modified field and laboratory procedures are not feasible for long-term data collection and thus duplicate samples were collected in May 2009 for analyses by a commercial laboratory (ALS Environmental, a NATA-accredited laboratory) and commercial low-level detection limits were requested.

Results

Field and laboratory results are summarised in **Tables 5-9** to **5-11** by surface water category: freshwater streams, freshwater tree swamps and estuarine/marine, respectively. In general, freshwater stream locations (refer **Table 5-9**) were flowing at the time of sampling but this group contains some samples from pools (26A, 9A, 1A, 11 and 25A) whereas tree swamps (refer **Table 5-10**) represent stagnant water. The full water quality data set is available from RTA.

The 20th and 80th percentiles of measured parameters were calculated for categories with more than five data points and these are presented along with the median (50th percentile) value in **Tables 5-9 to 5-11**.

The *Environmental Protection (Water) Policy 2009* (Qld) (EPP (Water)) consists of a framework that identifies environmental values (EVs) and water quality objectives (WQOs) to enhance or protect EVs. However, WQO's have not yet been established for the Cape York region. Therefore, in conformity with the *Queensland Water Quality Guidelines* (DERM 2009a), the national guidelines (ANZECC) described below have been used for comparison purposes.

The results are discussed below and are compared with:

- Local data – other habitat categories in the Project area;
- Regional data – northern Australian tropical waters; and
- National guidelines – *Australian and New Zealand Guidelines for Fresh and Marine Water Quality* (ANZECC/ARMCANZ 2000).

The following data from northern Australian tropical waters has been summarised in **Table 5-12**.

- metal concentration data from a reference stream in the Gove bauxite deposit area and general parameter data from the wider Gove area (RTA data and Zaar *et al.* 1999);
- streams from baseline sampling in the Ely bauxite deposit area, north of Weipa (RTA data);
- post- first flush wet season flows in Magela Creek in the Alligator Rivers Region in the Northern Territory (data from Hart *et al.* 1987);
- rivers in the southern Gulf of Carpentaria and the Mitchell River, southern Cape York Peninsula (Hydrobiology 2004a); and
- Mary River catchment, Northern Territory (Shultz *et al.* 2002).

ANZECC/ARMCANZ (2000) proposes water quality guidelines designed to protect the EVs of aquatic ecosystems. The guidelines are not mandatory standards; rather, they provide a risk-based decision framework, wherever possible, to enable the development of guideline trigger values for application at local and/or regional scales. The guidelines provide default water quality trigger values and a process to derive guideline trigger values tailored to the local environment, where required. In cases where baseline water quality parameters exceed default trigger values, it is recommended that local or regional trigger values are derived based on a statistical analysis of the baseline dataset. In some instances, default guidelines have not been developed due to data deficiencies and low reliability or interim working levels have been proposed for comparative purposes.

pH

The streams and tree swamps were generally acidic. The 20th percentile field pH of both streams and tree swamps was 4.6 and the 80th percentile pH was 5.8 and 5.5 respectively. The pH of Project area freshwaters is typically at the lower end of the range of other freshwater tropical streams and typically below the ANZECC/ARMCANZ default trigger value of 6.

The pH of marine waters ranged from 7.0 to 7.7 and was within the ANZECC/ARMCANZ range of 7 to 8.5. Estuarine waters exhibited a wider pH range of 5.1 to 7.7 owing to the seasonal inflow of freshwater.

Electrical Conductivity

The electrical conductivity of freshwaters ranged from 12 to 136 microsiemens per centimetre (µS/cm). The median conductivity for freshwater tree swamps was 27µS/cm, similar to the median for freshwater streams (21µS/cm). The fresh surface waters of the Project area were typically at the lower end of the conductivity range found in other tropical streams, although higher than Ely stream water. The ANZECC/ARMCANZ default conductivity trigger values for freshwater ranges from 20 to 250µS/cm for upland and lowland rivers. The single backdune lagoon (site 16A at Pera Head), was intermediate in its characteristics, but became brackish in December 2008, when king tides breached the dune system at its mouth, and it remained brackish in March 2009 with a conductivity of 2,266µS/cm.

During the late dry season, conductivity in pools within streams that became isolated from other surface or ground waters (e.g. isolated deep clay lined pools in Winda Winda Creek (site 9A)) increased moderately from 26µS/cm (September 2007) to 80µS/cm (November 2007).

The water quality characteristics of the Project area reflect the nature of water flowing through and within bauxite terraces, with the ferro-alluminosilicate matrix of the laterite layers acting as a physical and chemical filter for particulates resulting in very clear, almost salt-free surface waters. The low conductivity of the Project area surface waters presents challenges both to the accurate measurement of its chemical characteristics and comparison with appropriate guidelines (refer **Section 8.5.1**).

Conductivity in estuaries ranged from 50 to 51,590µS/cm, reflecting the tidal influence. Conductivity was less variable in marine waters, ranging from 19,000 to 53,200µS/cm.

During December 2008, at a time when the upper Ward estuary (site WP8) was tidally influenced, there appears to have been groundwater upwelling along the bed of the upper estuary. In places this was strong enough to maintain a slight lowering (11µS/cm) of salinity near the bottom, the reverse of the situation in the lower estuary (WP14) which had a layer of slightly more brackish water at the surface (refer **Figure 5-7**). This demonstrates the influence of groundwater inflows into the estuaries on water quality, particularly in the late dry season when surface freshwater flows have ceased in some streams.

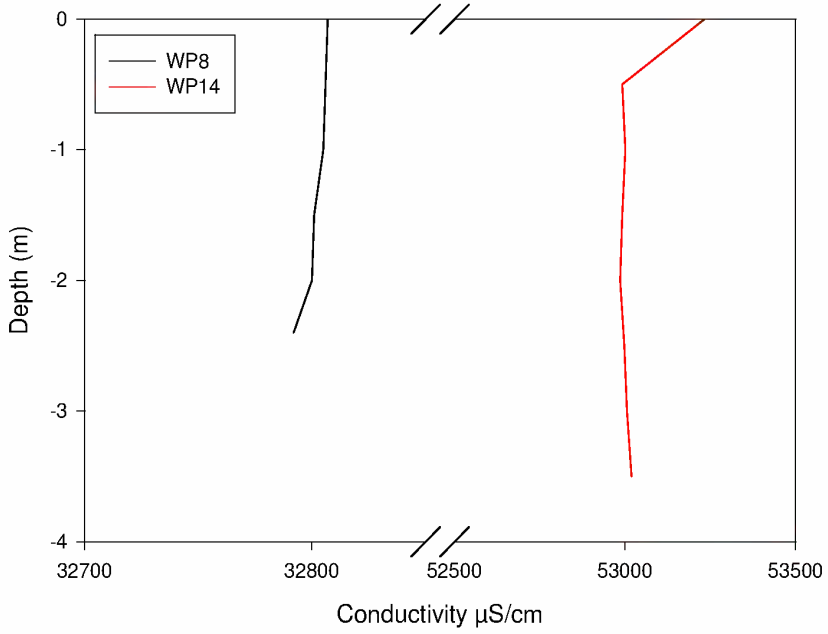

Figure 5-7 Conductivity Profiles in Upper (WP8) and Lower (WP14) Ward River Estuary

Turbidity

Freshwater turbidity was very low, with a median of 1.1NTU in tree swamps and 1.4NTU in streams. This is lower than most tropical streams, but comparable to that found in the Ely bauxite deposit area. The ANZECC/ARMCANZ range for turbidity is 2 to 15NTU in freshwater. The surface waters of the Project area are characterised by high clarity.

Turbidity in estuarine waters ranged from 1.2 to 5NTU, with a median value of 2.6NTU. Turbidity increased in marine waters, with a range of 5.9 to 16.5NTU and a median value of 9.5NTU. The ANZECC/ARMCANZ range for turbidity is 1 to 20NTU in marine waters and the Project estuarine and marine waters are within this range.

Nutrients

The ANZECC/ARMCANZ (2000) default guideline criteria for ammonium, total nitrogen and total phosphorus were exceeded by select freshwater and estuarine/marine samples and are discussed below.

A maximum concentration of 0.06mg/L total phosphorus, 1.1mg/L total nitrogen and 0.45mg/L ammonium was recorded for freshwater, which exceeded the ANZECC/ARMCANZ (2000) guideline for tropical lowland rivers of 0.01 total phosphorus, 0.2-0.3mg/L total nitrogen and 0.01mg/L ammonium.

Estuarine and marine waters had higher concentrations of total phosphorus, total nitrogen and ammonium when compared with project freshwater. The maximum concentration of total phosphorus estuarine/marine waters was 0.18mg/L. The maximum concentration of total nitrogen in estuarine/marine waters was 4.8mg/L and ammonium was 1.8mg/L.

The nutrient levels were generally at or near the level of resolution of the analyses for all other analytes in freshwater samples. Despite the generally low concentrations of solutes, surface waters contribute nutrient inputs into the drainage networks, thereby affecting downstream productivity (refer **Section 8.5.1**). Nutrient levels in the Project area freshwaters were generally as low as or lower than that of Ely, Magela Creek, Gove, and/or Mary River.

Dissolved Organic Carbon

The concentration of dissolved organic carbon ranged from 0.5 to 10mg/L in freshwater samples with a median of 1mg/L in stream samples and 2.5mg/L in tree swamp samples. The concentration of dissolved organic carbon in estuarine sample ranged from 0.5 to 5mg/L with a median of 2mg/L. Organic carbon can complex some trace metals, such as aluminium, copper, zinc and cadmium into non-biologically available forms (ANZECC/ARMCANZ 2000). Based on these results in the fresh surface waters of the Project area dissolved organic carbon is not considered an appreciable contributor to metal complexation.

Hardness

Freshwater hardness ranged from 0.4 to 9mg/L $CaCO_3$. Freshwater hardness was predominantly very low with a median of 1.4mg/L $CaCO_3$ in freshwater tree swamps and 1.3mg/L $CaCO_3$ in freshwater streams.

Hardness in estuarine waters ranged from 3.4 to 6,800mg/L $CaCO_3$, reflecting seasonal freshwater inflows, with a median value of 238mg/L $CaCO_3$. The range in marine waters was from 1,475 to 6,418mg/L $CaCO_3$, with a median value of 3,160mg/L $CaCO_3$.

The hardness for the Project area fresh surface waters was generally lower than for other tropical streams, but comparable to that for the Ely area, Gove and Magela Creek.

Hardness may affect metal toxicity in two ways: first, in terms of the competition for uptake sites between calcium and other metals; and second, as an indicator for the potential for inorganic complexation of metals in solution into forms of low bioavailability. Therefore, some metals have hardness dependent trigger values and the ANZECC/ARMCANZ (2000) guidelines provide a mechanism for adjustment of the trigger values for hardness. Weiner (2008) classifies soft waters as being waters with hardness below 75mg/L $CaCO_3$. The hardness of fresh surface waters in the Project area is less than 30mg/L $CaCO_3$ (with the exception of three outliers

December 2008 when king tides had caused saltwater intrusion into certain sites affecting both conductivity and hardness). All other hardness measurements were less than 10mg/L $CaCO_3$, with most below 3mg/L $CaCO_3$.

When the ANZECC/ARMCANZ (2000) hardness correction algorithms are applied to determine trigger values for relevant metals (cadmium, chromium (III), lead, nickel, zinc) in such soft waters the hardness modified trigger value is commonly below commercial laboratory detection limits. The applicability and limitations of hardness correction are discussed further in **Section 8.5.1**.

Metals in Freshwater

The maximum dissolved concentration of arsenic cadmium, chromium, copper, lead, manganese, nickel and zinc was less than the default ANZECC/ARMCANZ guideline trigger value in freshwater streams and tree swamps.

An ANZECC/ARMCANZ guideline for iron in freshwaters has not yet been developed and the Canadian criterion of 300µg/L has been adopted in the interim. Freshwater dissolved iron concentrations were usually below 300µg/L with the 80th percentile of stream samples being 65µg/L and tree swamps 32µg/L. The maximum concentration of dissolved iron in some freshwater stream and tree swamp samples exceeded the 300µg/L. Iron is a parameter that may be affected by natural or anthropogenic geochemical changes in water, as discussed further below in relation to seasonality.

The dissolved concentration of manganese in freshwaters did not exceed the ANZECC/ARMCANZ guideline of 1900µg/L. The median concentration of dissolved manganese in surface waters ranged from 0.94µg/L in streams to 0.36µg/L in tree swamps.

Aluminium concentrations for freshwater sites exceeded the ANZECC/ARMCANZ low reliability trigger value of 0.8µg/L (applicable to waters with pH below 6.5). The median concentration of dissolved aluminium ranged from 17.6µg/L in freshwater streams to 41µg/L in tree swamps.

Generally, the dominant metals in surface waters of the Project area are aluminium and iron. The concentration of dissolved aluminium, iron and manganese in surface water is seasonal. While for many sites concentrations of aluminium were above the default trigger values in all months, much higher values and greater variability was found for samples from the late dry season in November 2007 and December 2008. The median concentration of aluminium in freshwater streams ranged from 55µg/L in December (before onset of wet season flows) to 12µg/L in January, after the onset of streamflows. Similarly, the median concentration of iron and manganese in freshwater streams ranged from 162µg/L and 5.1µg/L in December to 10µg/L and 0.98µg/L in January, respectively.

Iron is much more soluble in anoxic water, and rapidly oxidises and flocculates out of solution when exposed to air. The presence of elevated dissolved iron concentrations late in the dry season indicates that, where surface waters could be sampled at that time of the year, they were influenced by surface expression of groundwater close to the point of sampling. While surface water flow post- wet season ultimately results from expression of groundwater, before the last months of the year the combined flow of the expressed waters results in aerated streamflow, and the removal of iron from solution with distance (and time) from the point(s) of surface expression of groundwater. In the late dry season, few streams receive sufficient inflows to form a continuous flow of water in any reach, resulting in a greater dominance of recently expressed groundwater in the existing surface waters, with higher dissolved iron. Therefore, the relatively higher dissolved aluminium concentrations in the late dry season reflect the higher proportion of recently expressed groundwater in the remaining surface waters.

For the perennially flowing sites 7A, 5A and 1A in the eastern branch of Norman Creek, the seasonality of dissolved aluminium and iron was much less marked, because longitudinal surface waters flows and aeration were maintained.

When iron flocculates out of solution the floc tends to adsorb other metals and remove them from solution. Although defined as dissolved, the water sample fraction that can be filtered

through 0.45µm filters can contain ultra-fine colloidal particles, particularly in the early stages of formation of iron and aluminium flocs. Much of the reported higher metal concentrations in the late dry season sampling may be associated with such colloidal material, and may be of limited bioavailability for most metals. Over time, these colloids would form flocs that settle, removing the metals from the water column.

The concentration of dissolved nickel, copper and zinc increases late in the dry season. The median concentration of dissolved nickel in freshwater streams ranged from 0.013µg/L in January to 0.06µg/L in August–September. The median concentration of dissolved copper in freshwater streams ranged from 0.005µg/L in January to 0.07µg/L in November. The median concentration of dissolved zinc in freshwater streams ranged from 0.078µg/L in January to 0.72µg/L in November.

The water quality guidelines note there is no good evidence for the toxicity of aluminium associated with colloidal material (ANZECC/ARMCANZ 2000, Section 8.3.7.1). Hydroqual (2006) states that some studies have suggested polymerisation or precipitation of aluminium at the gill surface may be responsible for some observed respiratory effects of aluminium. Rosselund *et al.* (1990) reported that precipitated Al-complexes can irritate the gills of fish and cause inflammation, oedema, swelling and sometimes irritation of the secondary lamella. Therefore, filterable aluminium should be regarded as being of potential ecotoxicological significance, even if colloidal material is included.

Metals in estuarine and marine waters

The concentration of dissolved aluminium in most estuarine and marine samples exceeded the low reliability default ANZECC/ARMCANZ trigger value for marine water of 0.5µg/L. The median concentration ranged from 2.5µg/L in marine waters (three samples only site WP14) to a median of 4.0µg/L in estuarine samples.

The median concentration of dissolved iron in marine and estuarine waters was 1µg/L and 13µg/L, respectively. There is no ANZECC/ARMCANZ marine guideline for iron.

The total and dissolved concentration of other metals analysed did not exceed applicable ANZECC/ARMCANZ guidelines in estuarine or marine samples.

Hydrocarbons

As the Project area is relatively undisturbed, hydrocarbons were not anticipated to be present in fresh, estuarine or marine waters but sampling was carried out to assess baseline conditions. During August–September 2007, ten locations were sampled for total petroleum hydrocarbons, benzene, toluene, ethylbenzene and xylenes. All results were below the corresponding laboratory detection limits.

Summary

These results suggest the Project area freshwater streams are not unusual in terms of conductivity and hardness compared with streams in other bauxite areas (e.g. Ely and Gove). However, they have lower solute concentrations and lower hardness compared to other waters in northern Australia. The Project area streams and tree swamps have naturally elevated dissolved aluminium concentrations.

5.2 Surface Water – Potential Impacts and Mitigation Measures

5.2.1 Water Supply

The Project's principal water requirements are for process water, haul road watering, vehicle wash-down, dust suppression and potable supplies. The average water demand for the Project is summarised in **Table 5-13** in both GL per annum and L/s.

Table 5-13 Average Annual Water Demand

Production Rate	Location of plant	Process	Haul Roads	Other*	Total Demand
		Average Annual Demand (GL)			
15Mdptpa	Boyd	15.4	0.5	0.5	16.4
30Mdptpa	Boyd	15.4	0.5	0.5	16.4
	Norman	15.4	0.7	0.5	16.6
	Total	30.8	1.2	1.0	33.0
50Mdptpa	Boyd	25.6	1.1	0.8	27.7
	Norman	33.8	1.4	0.9	36.1
	Total	59.5	2.5	1.7	63.7
		Average Annual Demand (L/s)**			
15Mdptpa	Boyd	535	17	17	570
30Mdptpa	Boyd	535	17	17	570
	Norman	535	24	17	576
	Total	1069	42	35	1146
50Mdptpa	Boyd	892	38	28	958
	Norman	1174	49	31	1253
	Total	2066	87	59	2212

* vehicle wash-down, dust suppression, potable

** L/s values are based on average of 8,000 hours of operating time per annum

The Project potable water requirements are small: 15ML per annum at 15Mdptpa rising to 30ML per annum at 50Mdptpa. A reverse osmosis potable water treatment plant would be used to treat raw water to a standard that meets the *Australian Drinking Water Guidelines* (NHMRC 2004).

The Project's sources of supply are recycled water from tailings storage facilities, surface water (water storage dam and direct pumping from stream), deep artesian groundwater and water recovered from slots adjacent to the tailings storage facilities. The average water supply for the Project is summarised in **Table 5-14** in both GL per annum and L/s.

Typically water would be drawn in order of preference from tailings recycle, recovery slots, surface water dam (Dam C), and artesian bores. Some supplementary surface water would be drawn directly from the Ward River to minimise the risk of inadequate supply from Dam C. The artesian demand would therefore fluctuate depending on whether there is above or below average rainfall runoff into the dam. The average annual artesian demand at 50Mdptpa would be 11.9GL per annum, with fluctuations up to 15GL per annum. RTA has an existing artesian Water Licence for 9GL per annum which allows abstraction from bores located on ML7024. RTA proposes to apply to increase the artesian allocation to cover the fluctuations in artesian demand. It is proposed that a five-year moving average of 12GL per annum be established, with a peak abstraction of 15GL in any one year. The impact of abstraction on the artesian aquifer has been modelled and is discussed in **Section 5.4.2.**

The impacts on streamflow of the proposed water storage dam and of direct pumping from Ward River are discussed in **Section 5.2.3.** The water supply infrastructure for the SoE Project would not be connected to the water supply infrastructure for the existing Weipa operations.

Table 5-14 Average Annual Water Supply

Production Rate	Location of plant	Recycle	Artesian	Dam	Slots*	River	Total Supply
		Average Annual Supply (GL)					
15Mdptpa	Boyd	4.7	3.1 (5.2 Peak)	7.8	0.8	0	16.4
30Mdptpa	Boyd	4.7	3.2 (5.8 Peak)	7.3	0.8	0.4	16.4
	Norman	4.7	2.8 (4.8 Peak)	6.5	0.8	1.9	16.7
	Total	9.4	6.0 (10.6 Peak)	13.8	1.6	2.2	33.1
50Mdptpa	Boyd	9.6	5.6 (7.1 Peak)	11.6	0.8	0	27.6
	Norman	12.5	6.4 (8.5 Peak)	13.8	0.8	2.5	36.0
	Total	22.1	11.9 (15 Peak)	25.4	1.6	2.5	63.5
		Average Annual Supply (L/s)**

5.2.2 Site Water Management

Water Management System

Schematic diagrams of the proposed water management systems are shown in **Figure 5-8** and **Figure 5-9**. The locations of water management infrastructure are shown in **Figure 2-7** and **Figure 2-8**.

The process water ponds have been designed to contain three days supply of water for the beneficiation plants, dust suppression and other industrial uses. Water would be recycled from the tailings storage facilities and the mine industrial area drainage slots and used preferentially as process water. More than 33% of the water used in the beneficiation plants will be recycled from these sources.

Water would be recycled from the tailings storage facilities, via the decant sump, to the process water pond. Water from the heavy and light vehicle wash bays would be treated in oil water separators prior to recycling.

Stormwater runoff from product stockpiles and the wharf would be directed through sediment ponds. Provision would be made to recycle some of this water.

Treated effluent from the Boyd and Norman Creek sewage treatment plants (STPs) would also be recycled. Treated effluent from the construction camp STP would be used for irrigation of landscaping near the camp during the construction period. Management of STPs is discussed further in **Section 13.3.7**.

A reverse osmosis potable water treatment plant would be used to treat raw water from Dam C to a standard that meets the *Australian Drinking Water Guidelines* (NHMRC 2004).

The process water ponds and tailings storage facilities are constructed as "turkeys' nests", meaning they only capture the rainfall that falls directly on the dam impoundment. Neither of these dams contain contaminants in concentrations that are hazardous (refer **Section 13.3.4**).

The hazard category of the tailings storage facilities has been rated in accordance with the DME/DEH (1995) *Site Water Management* guidelines. For the purposes of determining a design storage allowance, a conservative approach has been adopted and a "significant" hazard category assigned. The relevant design criteria from the DME/DEH (1995) *Site Water Management* guidelines are shown in **Table 5-15**. The design criteria would be reviewed whenever revised criteria are updated by the Department of Environment and Resource Management. Further information on management of tailings is provided in **Section 13.3.4**.

Table 5-15 Tailings Storage Facility Design Criteria

Location	Design Storage Allowance*	Spillway Critical Design Storm	Mandatory Reporting Level
Boyd tailings storage facility	0.02 AEP, 2 month wet season plus other inputs for the 2 month wet season, to be available on 1st November each year	0.001 AEP	72-hour 0.01 AEP
Norman Creek tailings storage facility	0.02 AEP, 2 month wet season plus other inputs for the 2 month wet season, to be available on 1st November each year	0.001 AEP	72-hour 0.01 AEP

AEP = Annual Exceedance Probability

* Even though the tailings are low toxicity, a conservative approach has been adopted and a "significant" hazard category assigned. The design criteria would be reviewed whenever the guidelines are updated by DERM.

The Australian National Committee on Large Dams (ANCOLD 2000) provides hydrologic design criteria for spillways based on downstream flood hazard. Dam C represents a low to significant incremental flood hazard category and, as such, the spillway should be designed to pass a 1:1,000 ARI storm event as a minimum. A 1:1,000 ARI storm event is considered a rare event (IE Aust 2001). The dam spillway would be designed to pass the peak flow from a 1:2,000 ARI flood event. The spillway would be at a low gradient (<3%) and be designed to facilitate fish passage during spillway flow events.

The process water ponds are "low" hazard category (DME/DEH 1995) and therefore would be designed for a spillway critical design storm of 1:100 year ARI. The process water ponds would be designed to operate a freeboard equivalent to a 24-hour 1:100 year ARI rainfall event.

Stormwater Management

The Mine Industrial Area drainage slots and the stockpile sediment ponds would receive stormwater runoff. These ponds would be sized to a volume equivalent to the runoff volume from a 1:10 ARI 24-hour rainfall event, plus 20% for sediment storage. The water from these ponds may be recycled, either via the process water pond or via the tailings storage facility.

Stormwater runoff generated within active mine areas is predominantly contained within the internally draining mine pits. The post-mining landscape effectively provides internally draining sumps that contain stormwater runoff, which then infiltrates through the pit floor and walls. In the event that the active pit or post-mining topography is not an internally draining pit, stormwater runoff would be directed via a sediment pond.

The Mine Access Road alignment follows elevated portions of the landscape wherever possible to enable all weather access; however, box culvert causeways would be required at certain watercourses. The Norman Creek access road and certain internal mine haul roads would also require box culvert causeways for a number of watercourse crossings. Sediment traps would be included as part of the drainage designs at points where haul roads cross watercourses. Further information on road drainage is provided in **Section 2.7.2**.

The following principles would be applied in the management of stormwater discharge:

- the *Engineering Guidelines for Queensland for Soil Erosion and Sediment Control* (IE Aust 1996) would be followed;
- land disturbance would be restricted to that necessary for the works;

- topsoil would be salvaged for use in rehabilitation;
- outflow would be passed from the sediment dams via engineered spillways to adjacent waterways;
- stormwater and runoff from upstream catchments would be diverted away from active mining and disturbed areas;
- drains would be protected to prevent scouring if necessary;
- sediment dams would be de-silted and cleaned periodically;
- hazardous materials would be stored in bunded areas or stored such that contaminated runoff is not generated; and
- traffic would be confined to maintained tracks and roads.

Erosion and Sediment Control

Erosion rates from active mining areas are higher than from unmined areas. In the wet season, increased erosion is expected to occur during mining operations from activities such as soil stripping, mining, and haul road construction. However, due to pit layout and topography, rainfall runoff would be predominantly retained within the mined areas.

Some elevated sediment concentrations are expected to occur in stormwater runoff from ore processing and stockpile areas.

An Erosion and Sediment Control Management Plan would be prepared prior to construction.

Areas disturbed by mining activities and infrastructure are to be rehabilitated to a stable landform with a self-sustaining vegetation cover. After overburden and soil are returned to mined-out pits the overall slope of the landform would be similar. Where mining leaves batters on the edges of the pit, these would be recontoured to a maximum slope of 20% (1 in 5). The final landform would not have any out-of-pit dumps of excavated wastes or soil. Rehabilitation methods are described further in **Section 3.10**.

Sediment laden runoff from ship loading activities has the potential to cause turbidity in the vicinity of the proposed port. Runoff and sediment collected from catch trays, belt scrapings, and the sealed maintenance area on the wharf would be pumped back to the wharf drainage sump on shore. Management measures to control product spillage are described in **Section 14.4.7**.

The water quality of natural surface drainage systems would be maintained by preserving riparian vegetation corridors. The buffer system, which is described in **Section 7.9.2**, would exceed the minimum requirements of the *Regional Vegetation Management Codes* (Qld) as they relate to clearing set-back distances from watercourses and wetlands (DERM 2009a). The retention of vegetation buffers around and adjoining surface drainage lines and wetland features provides effective management of elevated sediment load risks that would otherwise impact aquatic ecosystems (refer **Section 8.15.2**).

5.2.3 Surface Water Supply

Water Supply Dam

A water supply dam (Dam C) would be constructed on a freshwater tributary of Norman Creek (refer **Figure 1-3**). In determining that Dam C was the best option for water supply for the Project, alternate water sources were considered and a wide range of supply combinations utilising various proportions of these sources were investigated (refer to **Section 1.6.8**). Originally, two dams were considered, with the second dam being located on the Ward River. Following consultation with Traditional Owners and further feasibility studies, this was amended to only one larger dam (Dam C) on a freshwater tributary of Norman Creek.

Dam C would have a maximum storage capacity of 29GL and could be constructed in either two stages or a single stage. If constructed in two stages, the first stage would provide 10.9GL storage capacity and, later, the wall would be raised to provide 29GL storage capacity. The dam

would be constructed in a single stage (29GL capacity) should expansion of production above 15Mdptpa be anticipated to occur quickly, or should an initial production capacity of 22.5Mdptpa be adopted. This is the subject of ongoing feasibility studies. This EIS has assessed the impact of the dam at minimum, intermediate and maximum production rates of 15, 30 and 50Mdptpa. Details of both Dam C stages are summarised in **Table 5-16**.

Table 5-16 Water Supply Dam Summary

	Dam C	
	At 10.9GL capacity	**At 29.0GL capacity**
Total catchment area (km^2)	259.0	
Dam catchment area (km^2)	77.3	
Dam catchment as % of total catchment	29.8	
Maximum dam volume (GL)	10.9	29.0
Dam surface area (km^2) (at spillway)	3.6	6.5
Dam wall height (m) (at spillway)	8.0	12.0
Freeboard above spillway (m)	2.75	2.75

Dam C would be a conventional earth-fill dam. A cross section of Dam C is shown in **Figure 5-10**.

The Australian National Committee on Large Dams (ANCOLD 2000) provides hydrologic design criteria for spillways based on downstream flood hazard. Dam C represents a low to significant incremental flood hazard category and, as such, the spillways should be designed to pass a 1:1,000 ARI storm event as a minimum. A 1:1,000 ARI storm event is considered a rare event (IE Aust 2001). The dam spillways would be designed to pass the peak flow from a 1:2,000 year ARI flood event.

The spillways would be at a low gradient (<3%) and be designed to facilitate fish passage during spillway flow events. The conceptual design for the Dam C spillway and fish passage is shown in **Figure 5-11**. RTA would collaborate with TOs and the DEEDI (Fisheries Services) to ensure the most appropriate and best final design is selected for the circumstances. The final design would be submitted to DEEDI for approval under the *Fisheries Act 1994* (Qld). The dam would have a low level outlet pipe equipped with a valve to allow environmental flow releases when required.

Dam C supplies both the Boyd beneficiation plant and the Norman Creek beneficiation plant. The artesian borefield can supply water to both plants.

The impact of Dam C on downstream flow was modelled using a daily rainfall–runoff model (Boughton's AWBM) embedded in a GoldSim model that takes into account inputs (catchment runoff, direct rainfall) and outputs (pumped withdrawals, evaporation, seepage, spillway overflow and environmental releases).

The GoldSim model applies stochastic (Monte Carlo) trials to assess flows in streams and yield in dams of various sizes. For each trial or model realisation, rainfall was generated stochastically from the SILO rainfall recorded for the region using the Transition Probability Matrix (TPM) model. The record generated in the Monte Carlo approach has the same statistical character as the actual record (i.e. the parameters attaching to each record such as variance and standard deviation remain unchanged), but it would include instances of extreme behaviour such as long periods of low rainfall which are not captured using methods based on an average rainfall value method.

The TPM model allows a supply system to be tested over an extremely long period, which includes a wide spectrum of potential extreme conditions. It has been refined to incorporate climate change. Instances of extreme behaviour, as well as long periods of either higher or lower than average rainfall, have been incorporated into the model through use of recorded Southern Oscillation Index (SOI) data. The use of the data allows the generation of rainfall to be influenced by different consequences of the SOI that produce El Nino conditions, La Nina conditions or neither.

The GoldSim model was used to estimate dam inflow, spillway overflow and environmental releases. The downstream flow (spillway overflow plus environmental releases) was compared to the inflows into the dam to evaluate the effect of the dam on the hydrological regime. For the purposes of modelling, environmental releases were assumed to be 5% of daily dam inflows. The effect of rainfall variation was assessed by estimating the 10th and 90th percentile flows. The modelled effect of Dam C on flow immediately downstream of the dam and on annual flow from the whole Norman Creek catchment under production rates of 15 Mdptpa, 30 Mdptpa and 50Mdptpa is summarised in **Tables 5-17, 5-18** and **5-19** respectively**.**

Annual	220.68	187.45	84.9%	75.9%	84.1%	89.1%

The key findings are:

- the effect of Dam C at 15Mdptpa, 30Mdptpa and 50Mdptpa production rates is to reduce mean annual flow immediately downstream in the Norman Creek tributary to 78.3%, 67.2% and 49.5% of original flow respectively; and
- considering the whole Norman Creek system catchment discharge (i.e. discharge into the estuary), the mean annual input into the estuary would be 93.5%, 90.2% and 84.9% of original flow respectively.

In summary, Dam C leads to an appreciable annual decline (>20%) in flows immediately downstream on that particular branch of the Norman Creek. However, when the catchment is considered as whole, the overall decline is less than 15% and well within the range of normal year-to-year variation.

The change in monthly flow in the Norman Creek tributary immediately downstream is shown at production rates of 15Mdptpa, 30Mdptpa and 50Mdptpa in **Figures 5-12 to 5-14.** The change in monthly flow into the Norman Creek estuary is shown in **Figure 5-15**.

The modelling shows that the onset of wet season flow immediately downstream of the dam is delayed by about a month as it fills following the dry season. However, there is little delay effect on the estuaries downstream due to contributing flows from other sub-catchments.

The effect of Dam C on the timing of downstream flow during the onset of the wet season was examined in relation to the timing of bank full flow. The bank full flow on the Norman Creek was estimated to have an ARI of 1:2.5 years (refer **Section 5.1.1**), which is equivalent to 8,300L/s at the dam site. GoldSim model output for typical flows with and without Dam C at 15Mdptpa, 30Mdptpa and 50Mdptpa are shown in **Figures 5-16 to 5-18.**

A statistical analysis shows that the onset of bank full flow downstream of Dam C is delayed on average only one day at 15Mdptpa, six days at 30Mdptpa and nine days at 50Mdptpa. The small time delay that the dam causes in downstream bank full flow is due to the nature of the rainfall–runoff relationship for the bauxite plateau:

- the surface runoff component of incident rainfall is very small (<1%) and therefore flows are unresponsive to incident rainfall unless the catchment is saturated already;
- the catchments must wet-up before there is any substantial baseflow into streams;
- the baseflow rises quite smoothly over time as the wet season progresses and is not highly variable like surface runoff in a "hard" catchment. Unlike a "hard" catchment, there is no conventional early wet season "first flush" or "pulses", rather a fairly sustained increase in flow over January, February and March to an April peak, followed by a decline, with cessation of flow around September (on average);
- the key factor is that the dam is typically already full by the time bankfull flow rates would normally be reached (mid-February on average), hence such inflows just pass over the spillway; and
- to the extent that timing of overbank flow may have an environmental influence, the installation of the dam would, on average, have negligible impact.

The ecological implication of the effect of Dam C on downstream flows is discussed in **Section 8.14.1.**

Dam C would be fitted with a low level outlet pipe which would permit the controlled release of environmental flows when required. Sufficient water would be reserved for environmental flows to enable continued releases in the driest months (August to October) of a volume equivalent to 25% of dam inflows. The pipe would be sized to enable peak discharge of up to 1,000L/s, if required. When dam inflows cease, environmental flow releases would cease. Once the dam is full following the onset of the wet season, the spillway would typically overflow on a regular basis. If environmental flow releases are required during the wet season, they would commence after the dam is full.

Impact of Dam C on Flood Events

Wet season inundation of floodplains resulting of overtopping of the main channel banks is a seasonal characteristic of the area. Dam C would not increase the risk of flooding as it would reduce the peak flow (as shown in **Figures 5-12 to 5-14**) during rain events.

Dam C has had a dam failure impact assessment in accordance with the *Guidelines for Failure Impact Assessment for Water Dams* (DNRW 2002). There are no buildings or public roads downstream of Dam C that would be at risk of flooding.

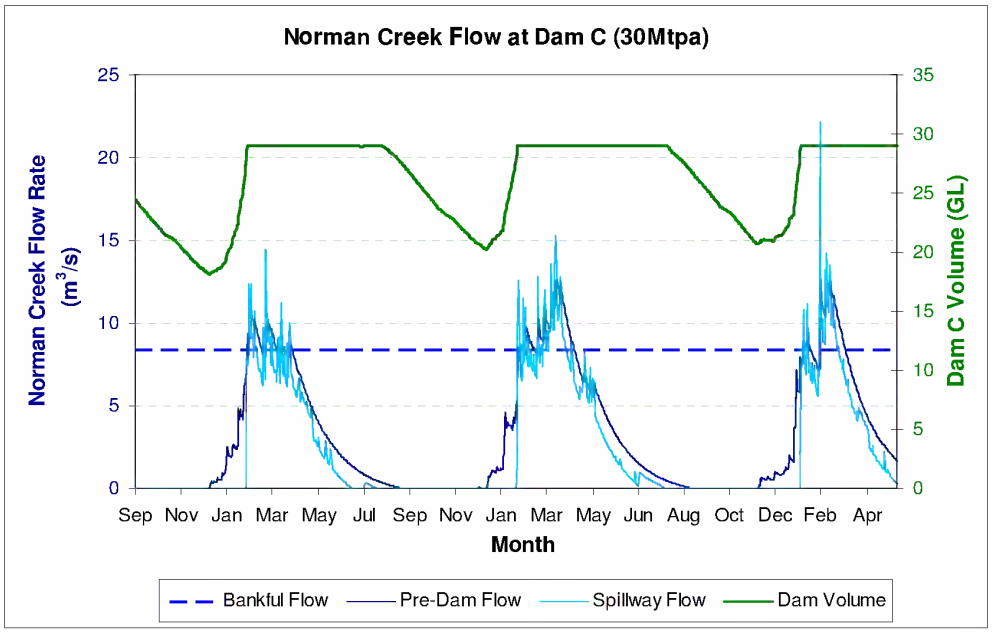

Figure 5-18 Norman Creek Flow at Dam C (50Mdptpa)

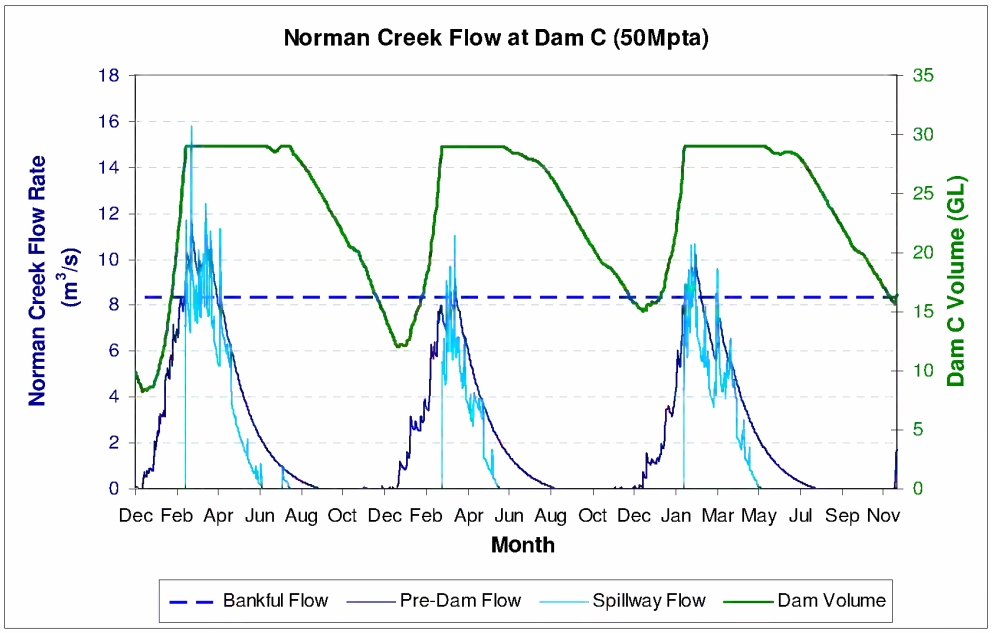

Direct Pumping

To maintain the reliability of the overall surface water supply at production rates between 30Mdptpa and 50Mdptpa and supplement the Dam C supply, some water would be pumped directly from the lower reaches of the Ward River (refer **Figure 1-3** for location of pump). The proposed pump station layout is shown schematically in plan view in **Figure 5-19** and cross section view in **Figure 5-20**. An in-stream weir or dam structure is not required. Water could be pumped via a pipeline corridor to either the Norman Creek or Boyd beneficiation plants.

The annual volume of water pumped from the Ward River would be capped at 1% of mean annual river flow at the pump station (2.67GL). In addition, no pumping would occur when Ward River flow was less than 1,000L/s and the rate of pumping at all times would be less than 20% of the river flow rate.

The GoldSim daily water balance model was used to estimate Ward River flow at the pump station and the pumped volumes. The downstream flow (river flow minus pumped volumes) was compared to the upstream flow to evaluate the effect of the pumping on the hydrological regime. The effect of the pumping on downstream monthly flow is summarised in **Table 5-20**.

July is the only month when pumped volumes exceed 10% of monthly river flow and this reduction is well within the normal seasonal monthly flow variation. The natural 10th percentile flow for July (0.96GL) is 80% less than mean flow (4.84GL). The effect of pumping at the 30Mdptpa and 50Mdptpa production rates is to reduce mean annual flow immediately downstream of the pump station by a very small amount (0.8% and 0.9% of original flow respectively). The overall impact of pumping on the Ward River hydrological regime is minor. The ecological implications of pumping on downstream flow are discussed in **Section 8.14.**

The proposed 6.5Mdptpa Aurukun Bauxite Project is within the catchment of the Ward River estuary (GHD 2007a). If the Aurukun Bauxite Project surface water demands were proportional to the 25Mdptpa Norman Creek beneficiation plant surface water demands, the demand for that project would be to 4.2GL per annum. If this demand was met from a dam on a tributary of the Ward River, the cumulative overall decline in mean annual discharge to the Ward River estuary would be very minor (<1%) and well within natural seasonal variation.

Monitoring and management commitments related to surface water supplies are described in Section 3.5 of the draft Environmental Management Plan (EM Plan) (**Section 21**).

5.2.4 Mining and Catchment Hydrology

To assess the effect of mining on the discharge from catchments subject to mining, rainfall–runoff characteristics of undisturbed, active mine and rehabilitated areas need to be estimated. The AWBM rainfall–runoff model was used to determine the water balance characteristics of the undisturbed catchment and of open mining areas. A study of recharge characteristics of undisturbed, mined and rehabilitated land at Weipa by Volker and Crees (1993) found there were no long-term major changes to the recharge of the shallow aquifer once vegetation was fully re-established. Hence, for the purposes of estimating impacts on catchment discharge, water balance characteristics for immature rehabilitation (<15 years old) and mature rehabilitation (≥15 years old) were interpolated between the undisturbed and fully disturbed AWBM cases. These characteristics are summarised in **Table 5-21**.

Table 5-21 SoE Project AWBM Water Balance Characteristics

Water Balance Component		Undisturbed	Open Mining Area	Immature Rehabilitation	Mature Rehabilitation
Evapotranspiration	mm	735	615	724	747
	%	42.6%	35.3%	41.6%	42.9%
Surface Runoff	mm	10	23	5	3
	%	0.6%	1.3%	0.3%	0.2%
Baseflow	mm	843	905	820	801
	%	48.0%	52.0%	47.1%	46.0%
Deep baseflow/recharge	mm	153	198	192	190
	%	8.8%	11.4%	11.0%	10.9%

The active mining area exhibits the largest change from the "undisturbed" situation. Internal in-pit surface runoff increases due to compaction from mining equipment traffic. However, although such runoff ponds in low spots, not much spills to the external catchment as the geometry of the pit provides a large sump. Rather, the extra in-pit runoff infiltrates and leads to increased baseflow. Without vegetation, annualised evapotranspiration declines.

In the "immature" rehabilitation situation, the rainfall partitioning pattern shifts partway back toward the "undisturbed" situation and this trend continues with the "mature" rehabilitation. However, the mature rehabilitation situation does not quite return completely to the "undisturbed" state because the residual post-mine topography still "traps" a little extra rainfall.

For each main catchment within which mining is planned, the annual discharge of the catchment was estimated for the following situations:

- undisturbed;
- maximum footprint of mining (i.e. largest footprint of open mining area and previously rehabilitated area); and
- post-mine closure (i.e. when all rehabilitated disturbed areas are mature).

The catchment discharge is the sum of the surface runoff and baseflow and is dominated by the baseflow component.

A summary of the annual catchment discharges is presented in **Table 5-22.**

The Ina Creek catchment has the largest proportion of area mined but the overall change to average annual discharge is very small (–1.4% at maximum mining impact; –2.2% post-closure). There are only very small changes to the discharge from the overall Norman Creek system (–1.0% at maximum mining impact; –1.8% post-closure) and overall Ward River system (–0.2% at maximum mining impact; –0.5% post-closure).

The proposed Aurukun Bauxite Project is located in the catchment of the Ward River estuary. While there are uncertainties as to whether this project would proceed, the operation of both projects simultaneously could give rise to a cumulative impact. In the absence of publicly stated areas of disturbance, estimations of mining disturbance associated with the Aurukun Bauxite Project were calculated using publicly available information on bauxite reserves. It is predicted this mining disturbance would total approximately 9,300ha. This would increase the potential aggregate mining disturbance in the Ward River estuary catchment to 14,900ha but would have a very minor change on the annual discharge from the overall Ward system (–0.6% at maximum mining impact; –1.2% post-closure).

The Ward River catchment makes up a minor part (3.8%) of the catchment of the Archer Bay Aggregation along with the Watson and Archer Rivers. The Project will not have any impact on the Watson River or Archer River and therefore the impact on discharge to the Archer Bay Aggregation would also be very minor, if any.

The modelling indicates the overall impact of mining on catchment discharge is very much less than the normal year-to-year variation driven by rainfall variation. This is consistent with the calibrated rainfall–runoff model which shows that surface runoff is extremely low and hence changes to surface drainage patterns have little impact on overall discharge into streams.

Impact of Mining on Flood Events

Wet season inundation of floodplains resulting of overtopping of the main channel banks is a seasonal characteristic of the area. There are no buildings or public roads downstream of the mining areas that would be at risk of flooding. The main impact of seasonal flooding is restricted access for vehicles rather than flood damage.

Mining would not increase the risk of flooding as the geometry of pits provides a large sump, resulting in infiltration rather than runoff to the external catchment.

Monitoring and management commitments related to catchment hydrology are described in Section 3.5 of the draft Environmental Management Plan (EM Plan) (**Section 21**).

5.2.5 Surface Water Quality Impacts

The environmental values of waters to be protected are defined by the EPP (Water) as:

- biological integrity of a slightly modified aquatic ecosystem;
- suitability for recreational use;
- suitability for minimal treatment before supply as drinking water;
- suitability for agricultural use; and
- suitability for industrial use.

Proposed mining activities may result in impacts to surface water quality. The two potential impacts are sedimentation and contamination, which are discussed below.

Clearing vegetation cover for mining activities and associated infrastructure may result in elevated sediment loads in catchment runoff during some stages of mine development. The potential impacts of increased sediment in surface water on aquatic ecology are discussed in **Section 8.15**. As less than 1% of incident rainfall results in direct surface runoff (refer **Section 5.1.1**) and mining pits retain overland flow, the risk is considered low. However to mitigate risk, clearing and soil stripping would be scheduled following the wet season when the ground is moist and pit development would be underway during the following wet season. In addition, turbidity would be regularly monitored in surface waters (refer **Section 5.5.1**) to provide an early indicator of any potential impacts.

Mining activities may introduce contaminants to surface waters via the following:

- hydrocarbon spills;
- sewage;
- ore spills;
- mining activities altering the hydrology and thus the geochemistry of an area resulting in a change of metals concentrations; and
- mining, processing and handling. Increased metals via recycled process water from the beneficiation plant, tailings liquid, and runoff from ore stockpiles.

The potential impacts of contaminants in surface waters on aquatic ecosystems are discussed in **Section 8.15**. The process and potential risks are discussed below.

Hydrocarbons (fuel and lubricants) would be transported in road tankers via barge to the mine infrastructure areas. Small volumes would be stored on-site in accordance with Australian Standard *AS1940* (refer **Section 19.1**). Bauxite product spillage into the marine environment could occur during routine loading operations. Bauxite is non-hazardous and the risk of impact to marine ecology is considered to be low. Mitigation measures are proposed in **Section 14.4.7** to reduce the likelihood of spills.

The management of sewage and design of STPs are described in **Section 13.3.7**.

Mining activities may alter the geochemical (e.g. manganese and iron) makeup of surface waters by modifying the volume of contributing groundwater and surface waters. However, generally the mining pit floor is above the groundwater table (refer **Section 5.3.2**) and thus the risk to alteration of groundwater is considered minimal. The primary mechanism for this impact would be the effect of the dam on surface water flow volumes; however, releases from Dam C would mimic the natural cycle as described in **Section 5.2.3** and thus the risk is considered minimal.

Crude ore from the Project area, ore and tailings solids from existing Andoom and East Weipa operations, tailings liquid, water from tailings recovery slots, shallow aquifer groundwater, and runoff from existing product stockpiles were analysed (Rio Tinto 2009b; refer **Section 13.3.4** and **Section 8.15.1** for data). The results are summarised below in terms of potential contaminant impacts to surface water:

- The results suggest bauxite stockpiles are unlikely to be a significant contributor of aluminium to surface water ecosystems via runoff. Tailings liquid and some tailings seepage waters may contain aluminium concentrations greater than 80th percentile calculated for any freshwater site in the Project area, but within the range found in late dry season sampling of site waters.
- The following metals were not detected in tailings liquid at concentrations greater than the reporting limit: arsenic, boron, cobalt, copper, lead, nickel, selenium, zinc and mercury. This, combined with the lack of enrichment in the ore (Geochemical Abundance Index less than three) indicates these elements are not considered potential constituents of concern for the Project area.
- Tailings solid and ore samples were collected for leach analyses using two analytical methods. Based on these results, leaching from either is not anticipated to have an adverse effect on surface or ground waters.

A range of metals would be regularly monitored in surface waters (refer **Section 5.5.1**) to provide an early indicator of any potential impacts.

Monitoring and management commitments related to surface water quality are described in Section 3.5 of the draft Environmental Management Plan (EM Plan) (**Section 21**).

5.2.6 Regulatory Requirements

The *Water Act 2000* (Qld) regulates the use of surface waters and the interference with watercourses, lakes or springs. Pre-existing rights to build weirs or dams and take surface water for the Project are held under section 1037A of the *Water Act 2000* due to the *Commonwealth Aluminium Corporation Limited Agreement Act 1957* (Qld) (Comalco Agreement Act).

The Cape York Peninsula Moratorium Area has been declared under the *Water Act 2000*. It covers most of northern Cape York, including the Project area south of Boyd Point. The Moratorium restricts the type and volume of new Water Licences that can be issued under the *Water Act 2000.* The Moratorium recognises and does not affect the existing rights under the Comalco Agreement Act.

Certain watercourses would be crossed by roads, pipelines and conveyors. Riverine Protection Permits are required for any activities that destroy riparian vegetation, or excavate or place material in a watercourse to the extent that such activities are not authorised under an environmental authority (mining activities) or the *Water Regulation 2002* (Qld).

Dam C has had a dam failure impact assessment in accordance the *Guidelines for Failure Impact Assessment for Water Dams* (DNRW 2002). The dam does not have a population at risk located downstream of the dam wall and would not be a referrable dam under the *Water Supply (Safety & Reliability) Act 2008* (Qld).

Approval is required under the *Fisheries Act 1994* to construct a waterway barrier that obstructs fish movement. Such operational works are assessable development under the *Sustainable Planning Act 2009* (Qld). The dam spillway would include provision for fish passage and approval for the design would be required from DEEDI.

5.3 Groundwater

5.3.1 Regional Hydrogeology

Environmental Values

The EPP (Water) seeks to achieve the objective identified by the *Environmental Protection Act 1994* (Qld): to protect Queensland's waters while allowing for development that is ecologically sustainable. The EPP (Water) provides a framework for identifying EVs for Queensland waters and deciding and stating water quality guidelines and water quality objectives to enhance or protect the environmental values (EVs). The EVs relevant to groundwaters within the Project area are described in Section 6 subsection 2 of the EPP (Water) and include:

- biological integrity of an aquatic ecosystem;
- suitability for agricultural use; and
- suitability for industrial use.

Hydrogeology

This section describes the key sources of groundwater in the Western Cape region. The geology of the Project area is discussed in **Section 3.2**. The geology of the Project area is represented by the following geological units, which are listed in descending stratigraphic order:

- Coastal dunes
- Estuarine and delta deposits
- Ferruginous duricrust, including bauxite (the Aurukun Surface which is derived from laterised Bulimba Formation). This formation is part of the Wyaaba beds
- Bulimba Formation
- Rolling Downs Group
- Gilbert River Formation
- Garraway Beds
- Permian Basement Rock.

The contact between the bauxite and sandstone Bulimba Formation is a transitional zone consisting of kaolinite clay.

The groundwater bodies in the area have been differentiated as shallow aquifer and artesian aquifer resources. The artesian resources are hosted within the Gilbert River formation and Garraway Beds, and the shallow aquifer resources are those occurring within the formations above the Rolling Downs Group. A conceptual hydrogeological cross section for the superficial formations from east to west across the Project area is shown in **Figure 5-21**.

Groundwater dependent ecosystems in terms of regional ecosystems (REs) are detailed in **Table 8-3**.

Shallow Aquifers

The superficial geology associated with the shallow aquifer is shown in **Figure 3-2**.

The coastal dunes and estuarine and delta deposits do not provide a viable groundwater resource, as extraction is difficult due to the fine-grained nature of the sediments. Furthermore, the saline conditions and risk of saltwater intrusion are key factors against development of the coastal aquifers (CSIRO 2009).

The Ferruginous duricrust (bauxite) consists of medium to coarse ferruginous gravel in clayey matrix. This formation is highly permeable and is usually unsaturated, with the watertable residing in the underlying Bulimba Formation (CSIRO 2009).

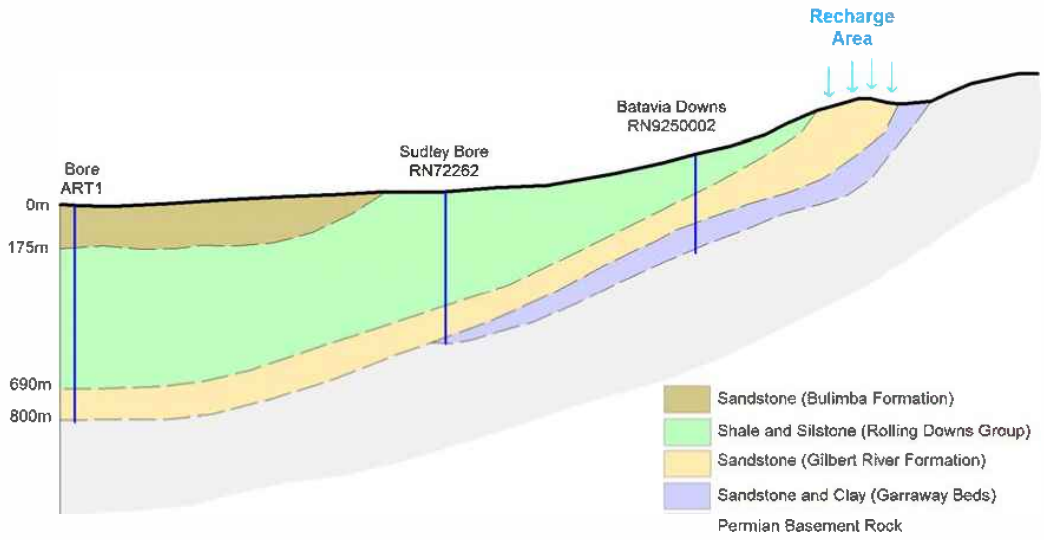

Figure 5-21 Cross Section through Artesian Host Formations

The bauxite overlies a kaolinite clay layer, which is part of the Bulimba Formation and contains kaolinite clay, to layers of fine clayey sand, to fine sands. This unit is generally of low permeability and is characterised as an aquitard, with some poor aquifer units of moderate permeability present. The kaolinite clays typically contain macropores which allow preferential flow.

The Bulimba Formation hosts a high yielding shallow aquifer which is an important resource over the Weipa Peninsula. It contains groundwater suitable for industrial and domestic use. Aquifers are typically constrained to old stream channels which trend easterly and meander through a matrix of clayey, less transmissive sediments and hence are not continuous and not always in hydraulic connection with one another. Recharge occurs where the Bulimba Formation outcrops and also potentially from underlying Great Artesian Basin (GAB) aquifers. Discharge occurs as baseflow to creeks, which helps maintain flow into the dry season (CSIRO 2009).

The shallow aquifers in the Project area are not as uniform as those used to supply existing RTA mining operations north of the Embley River and tend to be poorly developed and discontinuous.

The shallow aquifers are separated from the artesian aquifers by the 500m thick mudstones of the Rolling Downs Group.

Artesian Aquifers

The Gilbert River Formation is part of the GAB aquifers and is the main artesian groundwater resource in the region. The Gilbert River Formation aquifer is present across the entire Western Cape region, west of the Great Dividing Range. It comprises fine- to coarse-grained quartzose sandstone with pebble conglomerate and siltstone. Within the Project area this formation is artesian and is confined by the mudstones of the overlying Rolling Downs Group. The confining layer has low hydraulic conductivity and holds groundwater within the artesian aquifers under pressure. It is capable of supporting a large rate of abstraction.

The Garraway Beds underlie the Gilbert River Formation in the Project area. The Garraway Beds are similar to the Gilbert River Formation in lithology and artesian groundwater is also present in this unit. In relation to water resources management, the Gilbert River Formation and Garraway Beds are considered equivalents and are managed as one unit.

5.3.2 Shallow Aquifer

The shallow aquifer in the SoE Project area has been investigated through groundwater level monitoring and aquifer parameter tests. Investigative boreholes were installed in 2006 (25 bores) and 2007 (19 bores) in the Project area. A sub-set of bores has been selected for ongoing monitoring. The location of bores is shown in **Figure 5–22.** Four monitoring bores were equipped with dataloggers to monitor water level continuously (MB01, MB02, MB03, MB04) and the rest were manually measured.

The bauxite layer is present typically as a laminate overlying the kaolinite layer within which poorly developed and discrete aquifers are present. As a consequence, the shallow aquifers are not as uniform as those used to supply operations on the Weipa Peninsula. Aquifer parameter testing was carried out using airlift pump out tests and falling head tests. Low yields were recorded at all of the bores tested with the exception of MB04 and SOE10 where discharges of 0.5L/s and 1.0L/s respectively were measured over 30-minute trials. The low yields mean the shallow aquifer is not proposed to be used as a water supply source for the Project.

The hydraulic conductivities measured in falling head trials vary between 0.007 and 1.9m/d across the range of monitoring bores tested. Given the shallow aquifer depths, these conductivities indicate minimal transmissivities, which result in low groundwater flows and poor yields in the vicinity of the bores tested.

Localised semi-permanent baseflow into streams and tree swamps was observed, even at the end of the dry season. This indicates that although the extent of the shallow aquifers might be limited in places, the aquifer parameters such as storativity and transmissivity are highly variable, and are capable of supporting high baseflows at specific locations, including tree swamps.

This is consistent with the explanatory notes for the Weipa 1:250 000 scale geological map sheet SD/54-3 from the Bureau of Mineral Resources, Geology and Geophysics, which suggests permeabilities across the area may be influenced by the original depositional conditions. Buried stream channels running east–west can be expected to provide zones of higher permeability.

Piezometric contour maps of the shallow aquifer were created based on dry season and wet season groundwater level measurements (refer **Figure 5-23** and **Figure 5-24** respectively).

The contour mapping indicates a general groundwater flow direction is from east to west. It should be noted that the shallow aquifer behaviour depends on highly variable parameter distributions and physical extent.

There is a large seasonal influence on the level of the water table. The difference between wet season (March 2008) and dry season (November 2007) levels is illustrated schematically in **Figure 5-25.** This cross section is from Boyd Point through the Boyd Bay mining area and it traverses two Norman Creek tributaries. The bauxite horizons are based on resource drilling. The wet season water table is below the base of the bauxite for the majority of the transect distance. The dry season water table level is always below the base of the bauxite.

The maximum and minimum water table levels recorded in each groundwater monitoring bore are shown in relation to the bauxite layer in **Table 5-23**. This data shows that the water table rises above the base of the bauxite infrequently.

The seasonal response of groundwater level to rain in the continuously monitored bores (MB01, MB02, MB03 and MB04) is shown in **Figures 5-26** to **5-29**.

Figure 5-26 Groundwater Level in Response to Rainfall – MB01

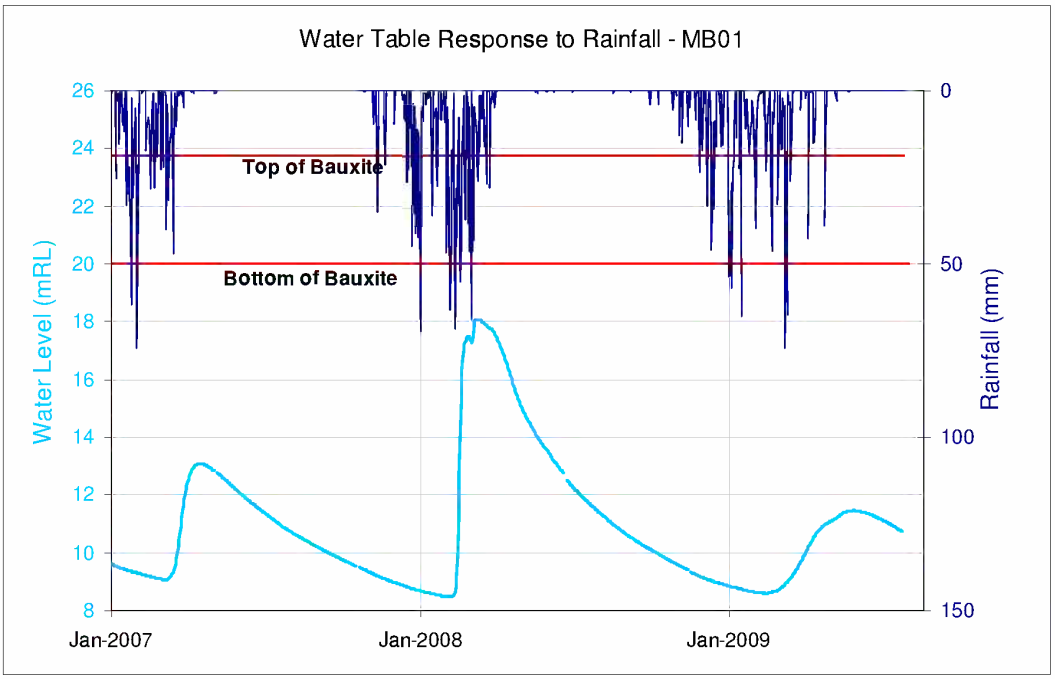

Figure 5-27 Groundwater Level in Response to Rainfall – MB02

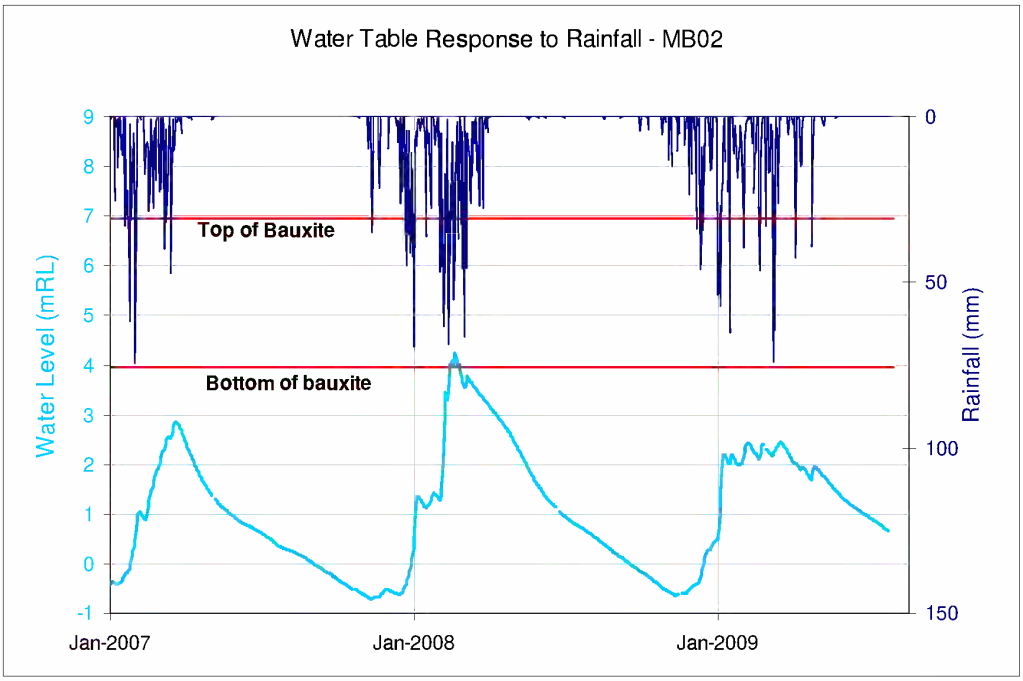

Figure 5-28 Groundwater Level in Response to Rainfall – MB03

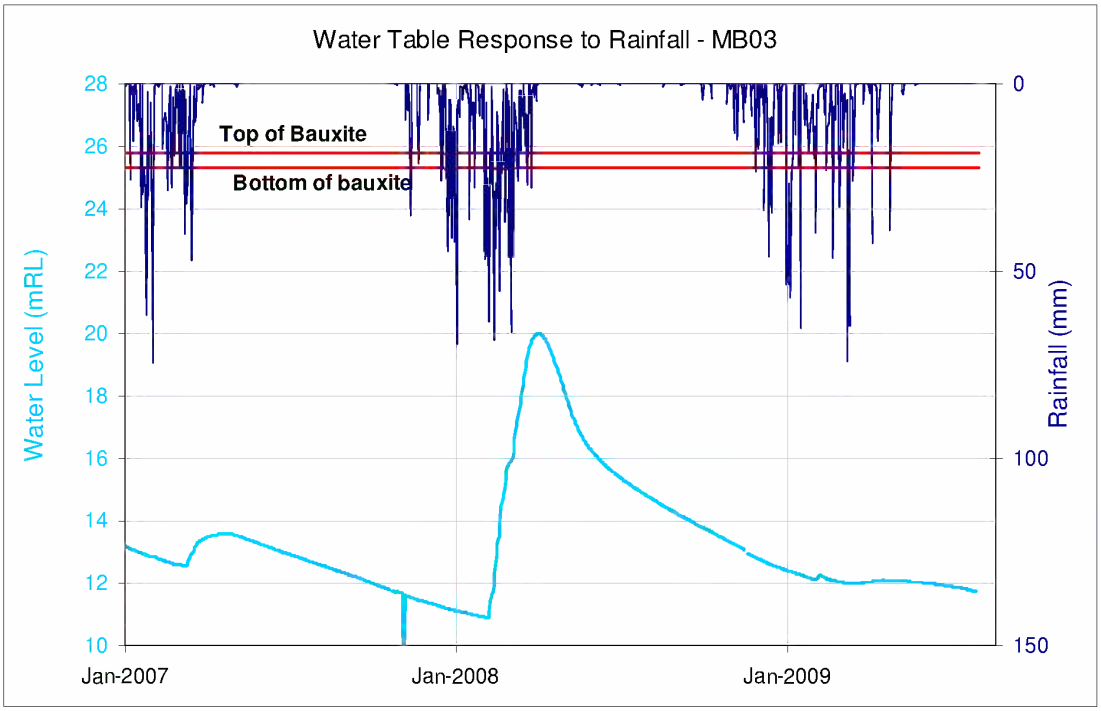

Figure 5-29 Groundwater Level in Response to Rainfall – MB04

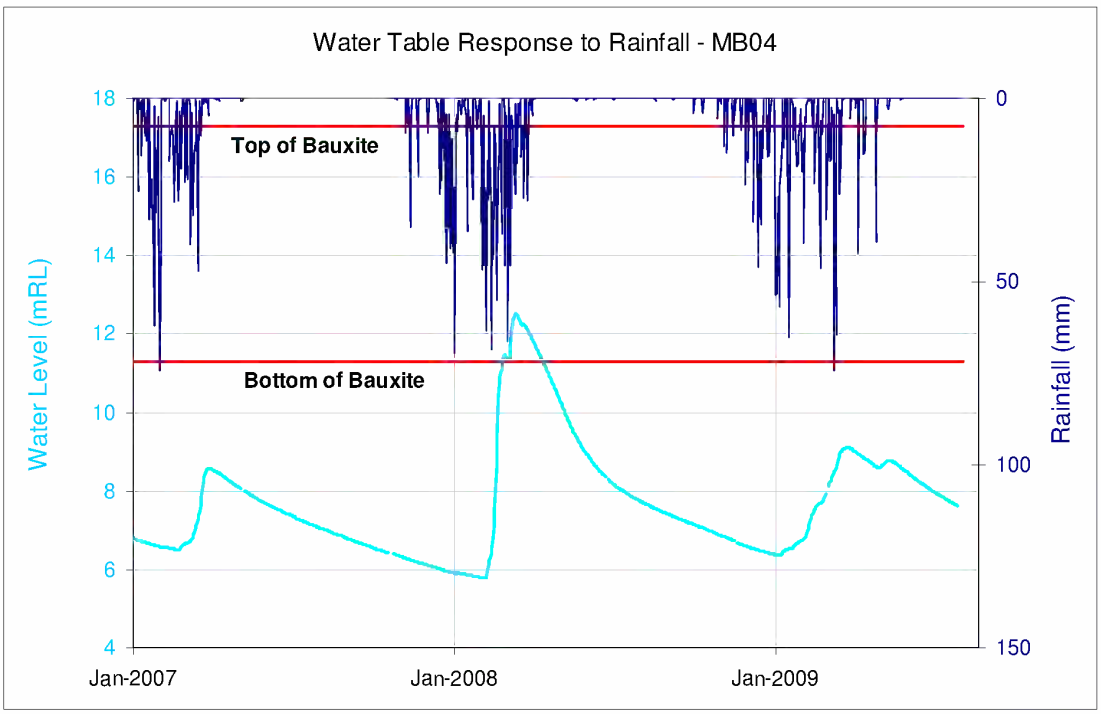

The 2007–2008 year was one of average rainfall (1,758mm) and the water table rose above the base of the bauxite temporarily, at the height of the wet season, in two of the four monitoring bores. The 2006–2007 and 2008–2009 years had below average rainfall. The response of the water table to rainfall is very similar to the response of streamflow to rainfall and shows:

- the "soil" water store has to "wet up" before there is a rise in the water table;
- once that happens, there is a rapid response to incident rainfall; and
- peak wet season water table levels vary with incident rainfall, but the end of dry season water table levels are less variable and tend to return to a similar level each year.

The available data on groundwater levels indicates the kaolinitic layer below the bauxite is generally hosting the shallow aquifer during the dry season. Hence, in situations where streamflow extends well into the dry season, it is unlikely this is due to baseflow originating from the bauxite.

5.3.3 Shallow Groundwater Quality

This section describes existing shallow groundwater quality conditions in the Project area. To provide a spatial representation of groundwater quality across the Project area, 13 monitoring bores were selected for sampling. Locations are shown in **Figure 5-22**. All bores were sampled at the end of the dry season in November 2007. Two bores were sampled again in June 2008.

Prior to sampling each bore, the water level was measured, appropriate bore volumes were purged and physicochemical conditions were measured using a multi-parameter water quality meter. Water samples were collected for laboratory analysis by Australian Laboratory Services (ALS) of physicochemical parameters, total dissolved solids, total suspended solids, cations, anions, and a suite of total and dissolved metals. All samples were field filtered for analyses of dissolved metals with the exception of SoE06 and SoE02 due to excessive sediments – these were later filtered by the laboratory upon receipt.

Two of the June 2008 samples (MB03 and MB04) were selected for further, ultra-trace sampling by the CSIRO. The purpose of this ultra-trace sampling was to obtain results that would be comparable with those obtained for the surface water

Laboratory results are summarised in **Table 5-24**.

Generally, the pH of water in all bores was acidic to slightly acidic, with a range of 3.9 to 6.5. Such acidic groundwater is typical of leached, tropical environments that have a relatively rapid recharge through rainfall and a low residence time, such as the Project area.

Generally, all bores contained freshwater, with exceptions noted below. Bore SOE01 was saline with a field EC measurement of 21,600µS/cm. This bore is located about 3.5km from the coast upstream along Norman Creek, a section that is still tidally influenced. Bores MB05, SoE02, SoE06, SoE03 and 57 were brackish with a measured EC of 635 to 1,330µS/cm.

In freshwater bores sampled, hardness ranged from <1.0 to 6mg/L $CaCO_3$. The soft water is consistent with Project area fresh surface waters where hardness ranged from 0.4 to 9mg/L $CaCO_3$. Hardness ranged from 14 to 168mg/L $CaCO_3$ in brackish groundwaters with a maximum of 54,530mg/L $CaCO_3$ in the saline groundwater of bore SoE01. These ranges are comparable to Project area surface waters with corresponding salinities.

Mercury was not detected at concentrations greater than the laboratory reporting limit in any samples. The concentration of dissolved arsenic, chromium and lead was less than the laboratory reporting limit or very low. The following maximum concentrations in groundwater samples were recorded: arsenic of 3µg/L, chromium of 0.5µg/L and lead of 1.0µg/L.

* T = Total F = Filtered

Note: Location MB05 is not shown on **Figure 5-22**, located west of 60

The concentration of dissolved cadmium in groundwater was less than the laboratory reporting limit in samples from eight locations and reported at low levels in samples from four locations, with a maximum of 0.27µg/L. A concentration of 13.4µg/L dissolved cadmium was reported in the sample from location 57. This is one of the samples that was not filtered until the sample arrived at the laboratory and the result is suspected to be anomalous.

The concentration of dissolved iron in brackish samples was generally greater than that of fresh groundwaters. The concentration of dissolved iron in brackish groundwater ranged from <2 to 1,030µg/L, which is also greater than the range for Project estuarine surface waters (0.5 to 86µg/L). The concentration of dissolved iron in fresh groundwater ranged from <2 to 107µg/L, which is less than the range of Project area fresh surface water streams (2 to 553µg/L).

The concentration of dissolved manganese in fresh groundwater ranged from <0.5 to 11.7µg/L, comparable to the range of Project area fresh surface waters (0.02 to 80 µg/L). The concentration of dissolved manganese in brackish groundwater ranged from 8.7 to 867µg/L, greater than the maximum estuarine surface water value of 8.7µg/L.

The concentration of dissolved aluminium ranged from <5 to 287µg/L in samples from fresh shallow groundwater bores and 10 to 186µg/L in samples from brackish groundwater bores, both consistent with the range recorded for Project area fresh surface waters.

The maximum concentration of dissolved copper, nickel and zinc in all groundwater samples was greater than that of surface waters. The concentration of dissolved copper in all groundwater samples ranged from <0.5 to 16µg/L, compared with a maximum surface water value of 0.43µg/L. The concentration of dissolved nickel in fresh groundwater ranged from <0.5 to 1.5µg/L, slightly greater than the maximum surface water value of 0.28µg/L. The concentration of dissolved nickel in brackish groundwater ranged from 1.8 to 39µg/L, greater than the maximum estuarine surface water value of 0.47µg/L. The concentration of dissolved zinc in fresh groundwater ranged from 6 to 73µg/L, greater than the maximum surface water value of 7.1µg/L. The concentration of dissolved zinc in brackish groundwater ranged from 27 to 260µg/L, greater than the maximum estuarine surface water value of 3.4µg/L.

The values of parameters measured in the groundwater generally tend to reflect those recorded for the surface waters with the exception of higher concentrations of copper, nickel and zinc in the groundwater. However it should be noted that the most groundwater samples were collected during one event at the end of the dry season (November 2007) when the residence time of groundwater would be at its longest. These results have been compared with medians and ranges from the surface water program which generally covered multiple sampling events over wet and dry seasons.

5.3.4 Artesian Aquifer

The hydrology and current uses of the artesian aquifer in the vicinity of the Project area are described in the sections below.

Hydrogeology

Typically, water-bearing formations in the Project area are located at depths of between 750 and 1,000m below ground level. Groundwater moves in a westerly direction from what are known as "recharge beds" or "intake beds" to the Gulf of Carpentaria (CSIRO 2009). Artesian conditions occur from the coastal margin inland to areas where topography lies below 30 to 40m above sea level. Experience of similar aquifer conditions in the Weipa area, and test pumping in the Aurukun area, indicates the aquifer transmissivities tend to lie in the range 180 to 300m^2/d, and storativities in the range ~10^{-4} (dimensionless).

Large supplies (>60L/s) of medium quality groundwater can be obtained from the Gilbert River Formation aquifer from bores that intersect the entire sandstone sequence (CSIRO 2009). Shallow bores that intersect the unconfined Gilbert River Formation typically provide yields of 1 to 5L/s of groundwater (DNRM 2005a).

The GAB aquifers are recharged primarily by direct infiltration of rainfall where the GAB sandstone outcrops along the eastern margin of the region (the recharge area) – along the

flanks of the Great Dividing Range, particularly along watercourses. During the wet season stream leakage recharges the unconfined aquifers through which the streams are incised.

Springs

The Great Artesian Basin Resource Operations Plan (GAB-ROP) (DNRW 2007) defines three spring types being recharge, watercourse and discharge springs. The GAB ROP specifies criteria to protect the flow of water to springs and includes The Springs Register, which lists springs that support significant cultural and environmental values.

The majority of the Western Cape region, including the Project area, is represented in the GAB ROP by the Cape Management Area. The Project area is located within the Cape 1 Management Unit. The Cape Management Area serves to protect the groundwater resources of the GAB sediments in the Carpentaria Basin north of the Holroyd River. Spring locations derived from the DERM spring register for the Cape Management Area are shown on **Figure 5-30**. There are no registered springs within the Project area.

Recharge springs are quite common in the recharge areas on Cape York Peninsula, with numerous listed within the Cape Management Area. Recharge springs result from overflow or the rejection of recharge from the overfilling of aquifers. These springs provide an important source of water for maintaining surface water flow during the dry season. The Jardine, Wenlock, Archer, Coen, Holroyd and Dulhunty rivers all receive groundwater baseflow from the Gilbert River Formation aquifer (CSIRO 2009).

Watercourse springs are also found on Cape York Peninsula and are listed within the Cape Management Area. These are defined in the GAB-ROP as a part of a watercourse where water enters the watercourse through its bed or banks to become baseflow in the watercourse.

Discharge springs are not listed on The Springs Register as occurring within the Cape Management Area. These are defined as spring's supplied by underground water from a confined aquifer.

It should be noted, that an Environmental Protection and Biodiversity Conservation (EPBC) Act Protected Matters search was conducted of the pre-defined Cape York Natural Resource Management (NRM) region (accessed on 25/03/2011). The search identified the potential occurrence of discharge springs within the Cape York Management Area. The discharge springs are identified through association with the threatened ecological community '*The community of native species dependent on natural discharge of groundwater from the Great Artesian Basin'*. The listing advice for the community identifies that these springs are only associated with discharge springs and are an endangered ecological community.

It is likely that the Protected Matters database includes information from the Communities of National Environmental Significance database mapping (Environment Australia, 2003) which identifies one spring group in the Cape York Peninsula.

However, although the Protected Matters search identifies this community as potentially occurring in the Cape York NRM region, the GAB ROP does not identify any discharge springs within the Cape Management Area. Available evidence, detailed below also supports that GAB discharge springs do not occur within the Cape Management Area.

The *Great Artesian Basin Resource Study* (Cox and Barron 1998) separates this mapped Cape York spring group from the remainder of the known discharge spring groups at the time of publication, and associates these springs with recharge areas on the Cape York Peninsula. An update to this plan (GABCC 2010) provides a quantification of spring complexes within Queensland. Sixteen spring complexes are identified within the Cape Management Area, and all 16 are classified as active recharge springs. In addition, the *Recovery plan for the community of native species dependent on natural discharge of groundwater from the Great Artesian Basin* (Fensham *et al* 2010), also state that the "GAB discharge springs occur from the southern end of Cape York Peninsula to Lake Eyre in South Australia, spanning tropical semi-arid and temperate arid climates".

Discharge springs are therefore not associated with the Cape Management Area or the Project area. It is therefore unlikely that the threatened ecological community '*The community of native species dependent on natural discharge of groundwater from the Great Artesian Basin'* would occur in the Project area.

Existing Groundwater Use

The major water use from the Gilbert River Formation in the Project area and surrounds is for industrial and mining purposes associated with the RTA's existing operation north of the Embley River. Artesian groundwater is used to supplement process water supplies but would require significant treatment to make it suitable for sustained potable use.

RTA extracts artesian groundwater from borefields at both East Weipa and Andoom operations. Currently in use are three production bores at East Weipa and seven production bores at Andoom. The locations of existing production bores are shown on **Figure 5-30**. RTA takes water from these bores under an existing Water Licence, under the *Water Act 2000,* which allows abstraction of up to 9GL per annum. There are no other large users of artesian groundwater on Cape York.

RTA has installed monitoring bores within the artesian aquifer both on-site and off-site at various locations throughout the Cape York region. The Sudley Station and Batavia Downs monitoring bores are located off-site on cattle stations and are both used for stock watering.

The small number of stock and domestic bores that access GAB aquifers in the Western Cape region are restricted to areas of outcrop to the east, where only shallow bores are required (DNRM 2005a). Towards Aurukun, test bores have been drilled in the past and constructed and used in aquifer tests, but development of this aquifer for potable use has not proceeded owing to water quality constraints.

Existing Groundwater Monitoring Network

A Water Licence condition is that taking of water by RTA must not lower piezometric levels in monitoring bores located at Bramwell, Batavia Downs Homestead or Weipa Crossroads by more than five metres. To meet Water Licence conditions and internal RTA objectives, a borefield monitoring network has been installed at Andoom and at various locations throughout the Cape York region (refer **Figure 5-30**). The monitoring bores and their status are listed in **Table 5-25**.

Table 5-25 Artesian Aquifer Monitoring Bores

Bore ID	Status
ART 4 Bore	Former production bore at East Weipa, now monitoring bore
ART 5 Bore	Former production bore at Andoom, now monitoring bore
Sudley Station Bore	Artesian, east of Project area
Batavia Downs Bore	Sub-artesian, east of Project area
Weipa Crossroads Bore	Sub-artesian, east of Project area
Bramwell Station Bore	Sub-artesian, east of Project area

The majority of monitoring bores were pre-existing production bores which were retrofitted with either pressure gauges and dataloggers or downhole level sensors and dataloggers. The Weipa Crossroads bore and the Bramwell Station bore were constructed by RTA specifically as monitoring bores. Logging of production bore data is carried out through the telemetry system. Submersible data loggers with long-term storage capabilities have been installed at the non-production bores.

5.3.5 Artesian Groundwater Quality

Five artesian monitoring bores were sampled in September 2006; results are detailed in **Table 5-26**, including one bore from the existing Andoom borefield (Art 7).

In general, artesian water quality is variable across the sampling sites and is summarised below.

- pH ranged from 4.7 to 8.3.
- Artesian water is generally brackish with EC ranging from 1,800µS/cm (Art 7) to 16,000µS/cm; however, 330µS/cm was recorded at Batavia Downs.
- The concentration of cations and anions are variable across locations as the concentration of calcium ranged from 7 to 1,060mg/L and magnesium ranged from 0.2 to 300mg/L.
- Artesian water sampled from Sudley, Batavia Downs and Andoom was of low hardness (<50mg/L$CaCO_3$); however, hardness was 460mg/L $CaCO_3$ and 1,060mg/L $CaCO_3$ in water from Weipa Cross Roads and Bramwell Station, respectively. Elevated hardness corresponds with chloride, sodium and total dissolved solids concentration in water. The use of artesian water must be monitored as high chloride has an undesirable impact on the bauxite refining process.
- The concentration of dissolved iron ranged from <100 to 2,000µg/L.
- The concentration of dissolved manganese ranged from 40 to 1,500µg/L.

Table 5-26 Artesian Water Quality

Parameter	Units	Sudley Station	Weipa Crossroads	Bramwell Station	Batavia Downs	Art 7 – Andoom
pH	pH	8.2	4.7	6.9	7.1	8.3
Electrical Conductance	µS/cm	2,800	8,000	16,000	330	1,800

Manganese – Total	µg/L	60	140	2,100	70	40

5.4 Groundwater – Potential Impacts and Mitigation Measures

5.4.1 Shallow Aquifer

Mining may have the potential to affect the shallow aquifer in two ways:

- alterations to the surface drainage regime by the creation of internally draining post-mining landform may lead to changes in the shallow aquifer response; and
- removal of a portion of the lateritic bauxite strata that may host the aquifer.

The AWBM modelling of mining impacts has shown (refer **Section 5.2.4**) that mining has a temporary impact on the partitioning of surface runoff and baseflow and that, as rehabilitation matures, the overall hydrological regime at a catchment scale returns toward an "undisturbed" situation. The main reason change due to mining has a small impact is that direct surface runoff from the bauxite plateau is a very small proportion of incident rainfall (<1%); hence, redirection of surface flow does not greatly alter aquifer recharge characteristics.

The removal of bauxite would only have the potential to change discharge from the shallow aquifer in situations where the bauxite is an appreciable source of baseflow. Typically in the Project area, the water table is within the bauxite only at the height of the wet season, if at all. In the dry season the water table generally falls to 4 to 8m below the base of the bauxite. Streamflow during the dry season tends to be maintained by baseflow originating predominantly from kaolinitic strata. The overall effect of mining on the baseflow and deep baseflow component of the water balance is very small (**refer Section 5.2.4)**.

Monitoring and management commitments related to the shallow aquifers are described in Section 3.5 of the draft Environmental Management Plan (EM Plan) (**Section 21**).

5.4.2 Artesian Aquifer

RTA proposes to install an artesian borefield that accesses the Gilbert River Formation artesian aquifer, as part of the Project. The artesian water would form one component of the water supply for the Project (refer **Section 5.2.1**). RTA has an existing artesian Water Licence for 9GL per annum which allows abstraction from bores located on ML7024. RTA has applied to increase this artesian allocation to cover the increase in artesian demand arising from the Project. RTA proposes that the Water Licence be based on a five-year moving average of 12GL per annum, with a maximum of 15GL in any one year.

The general location of the proposed artesian borefield is shown in **Figure 5-30**. It is expected that no more than 12 artesian bores would be required to achieve the planned abstraction rates.

From experience of discharge rates at East Weipa and Andoom, it is expected the individual bores would be capable of delivering 80 to 100L/s with built-in standby redundancy. The exact locations of the bores would be determined at design stage to ensure the bores are sufficiently well spaced to prevent interference. The assumed design bore availability is 7,800 hours per year.

The potential drawdown impacts in the artesian aquifer at various stages over the life of the Project were assessed using the FEFLOW modelling package. The proposed abstraction scenarios, the model code, development and calibration and the potential drawdown impacts at existing production and monitoring bores are discussed below.

Groundwater Modelling

Assessment of two proposed abstraction scenarios was carried out using the FEFLOW modelling package, an industry-standard software for simulation of groundwater behaviour. All modelling was undertaken by Golder Associates Pty Ltd. The model was developed on behalf of RTA, and is in active use as part of the operational planning of Andoom and East Weipa. It is regularly updated in response to new field information from ongoing pumping tests and with data extension from updated monitoring records.

Abstraction Scenarios

The potential impacts of artesian groundwater abstraction were modelled under two different scenarios:

- a constant 12GL per annum over the 40-year mine life (the "12 GLpa scenario")
- 12GL per annum for the first 13 years and then 18GL per annum for the remainder of the 40-year mine life (the "18GLpa scenario").

The 12GL per annum scenario was used to determine the maximum potential impact under the proposed licensed abstraction regime. The 18GL per annum scenario was modelled to obtain an indication of the upper bounds of aquifer sustainability.

Table 5-27 lists the abstraction scenarios tested in the FEFLOW model. For each scenario, the same initial conditions apply. It was assumed that simulation Year One coincides with start of operations in 2013. The start of operations was nominally set at 2013 for the purposes of modelling. The initial conditions were simulated for 2012 based on historical data and from simulation of predicted usage between 2009 and 2012. That is, the model predicted the most likely and representative conditions expected to prevail by 2012 – these were then applied as the initial conditions for the tested scenarios. Mean recharge conditions were applied throughout each scenario simulation. The model was run in each trial for a further 70 years beyond the abstraction period to estimate the progress of the aquifer recovery following mine closure.

Table 5-27 Abstraction Scenarios

Scenario	Year 1 – Year 13		Year 14 – Year 40	
	Andoom/Weipa Borefield Abstraction (GLpa)	SoE Borefield Abstraction (GLpa)	Andoom/Weipa Borefield Abstraction (GLpa)	SoE Borefield Abstraction (GLpa)
12 GLpa	6	6	0	12
18 GLpa	6	6	0	18

Model Code

FEFLOW (version 5.3), is a finite element groundwater modelling package developed by WASY Institute for Water Resources Planning and Systems Research in Berlin, Germany. It has the following attributes:

- capability to simulate seepage flow in conditions dominated by irregular geological structure;
- ability to represent complex boundary conditions;
- capability to present distributions output in a range of different formats;
- ability to incorporate transient physical changes to the host aquifer, including excavation or the placing of tailings, for example; and
- an enhanced capability to represent 3D geometry accurately provides the following as primary computed results;
- hydraulic head distributions;
- pressure distributions; and
- flow distribution.

These can be reproduced for steady-state or transient conditions at any point within the simulated extent of the aquifers.

Model Mesh

The model mesh is shown in **Appendix 5B Figure 1**. It is bounded by the Great Dividing Range in the east. The north, south and west boundaries are set at a distance far enough away so as not to be affected by significant drawdown.

Recharge

It is believed the majority of the recharge occurs in the Great Dividing Range area via fractured sandstone in the Gilbert River Formation during rainfall events, particularly along watercourses. It is likely that higher recharge to the aquifer occurs in the Wenlock River area, and this is reflected in the model boundary conditions.

Recharge was based on data for the nearest rainfall gauge to the recharge area, which is located at Moreton Telegraph station. The average annual rainfall for this station is 1,390mm.

This record is conservative when compared to the continuous daily rainfall record derived from the Bureau of Meteorology SILO website's Data Drill database corresponding to a location in the Dividing Range recharge area. The Data Drill record at this location indicates an average annual rainfall value of 1,560mm. Data Drill accesses grids of data derived by interpolating the BoM's station records calculated by splining and kriging techniques.

Aquifer Properties

The initial aquifer hydraulic properties adopted in the model were based on values estimated from all available test pumping program results from production bores at East Weipa and Andoom. These parameters were then refined within acceptable bounds during the subsequent calibration process.

The model parameter distributions are generalised and extend over a wide area. Although they should not necessarily be expected to reflect the detailed conditions at single production bores or monitoring bores exactly, the storativities in the model were found after calibration to lie in the order of 10^{-6} to 10^{-4}, which is consistent with the pumping test results found using the Theis equation. Specific yield values are applied in the model to represent unconfined conditions where they occur during simulation.

The initial model parameter distributions were based on transmissivity values predicted from pumping tests. These distributions were then refined in a calibration exercise, and yielded results in the borefield area for transmissivities that lie in the range 180 to 300m^2/d. The pumping test results, when analysed using the Theis equation, tend to predict higher values (typically in the range 300 to 500m^2/d) for the individual production well sites because they are localised values estimated using analytical approaches to estimation. These analytical approaches are substantially different to the finite element modelling approach, which provides generalised values over a larger area. The outputs from the analysis of the individual tests are shown in **Appendix 5B Figures 2** to **9.**

Initial Conditions

Simulation starts from aquifer conditions based on the expected state of the aquifer at Year 1 (i.e. approximately 2013). To derive these conditions, the model is run from the time of the earliest aquifer development in the Weipa area, which took place around 1971. A steady-state model was developed in the first instance to simulate the original heads prevailing at 1971. It was then run for the period between 1971 and 2008 using the best estimates and known discharge details for the bores in both the Andoom and East Weipa borefields during this period. Finally it was run for predicted extraction rates for the period from 2008 to 2012. Hence the resulting simulation of aquifer conditions provides a representative starting point for the transient trials that investigate long-term borefield usage.

Boundary Conditions

The applied boundary conditions included recharge at the Great Dividing Range and a no flow boundary heads to the west. Geophysical information received recently indicates the Gilbert

River formation, which is host to the aquifer, pinches out in the Gulf of Carpentaria at a depth in excess of ~1,000m, about 150 to 180km to the west of Andoom.

No flow boundaries are applied at the northern and southern margins of the model domain, coinciding with groundwater flow lines which are assumed to be approximately aligned to an east-west direction.

Steady-State Calibration

The steady-state calibration carried out to simulate the natural conditions assumed prior to the East Weipa borefield development in 1971 considered recharge entering the aquifer in the Great Dividing Range area, and refinement of the aquifer parameters that have been collated from available pumping test information.

The aquifer parameters and the recharge applied over the exposed extent of the Gilbert River sandstone was varied in parameter estimation software (PEST).

The model boundary conditions include nodes corresponding to locations along the riverbed alignment, to represent the Wenlock River over the outcrop area. Potential river losses would recharge the artesian aquifer. These losses are predicted by the model on the basis of the relative groundwater head and river level, and the estimated river permeability.

Model calibration trials indicate the average direct rainfall recharge rates are approximately 1.1mm/year over the area.

Observed heads applied in the calibration were taken from representative estimates for East Weipa bores ART1 to ART4, based on bore construction completion records. The calibrated steady-state head distribution for the natural conditions prevailing prior to development in 1971 is shown in **Appendix 5B Figure 10.**

Transient Calibration

Transient calibration of the model was carried out using the steady-state initial conditions described previously based on relevant recorded data. Comparisons were made between available observed head data from monitoring and production bores for the wider area representative of transient conditions. Representative output for these calibrations are plotted as time series plots for the period subsequent to 1971, and are shown in **Appendix 5B Figures 11 to 18.**

As part of the calibration exercise to simulate the pumping test conditions, the model was used to estimate local and regional aquifer parameters being determined by the test.

Long-term time series plots, which show comparisons with field values monitored at different times over the 26-year period, indicate the model shows reasonable agreement with field conditions.

A summary of the parameter extents for hydraulic conductivity and storage used in modelling is provided in **Appendix 5B Figures 19 and 20** respectively.

The monitoring program, which is now well-established as part of the management of the Andoom borefield, is important for providing information on the resource with representative data on the state of both temporal and spatial conditions. This information is essential for calibration of the model and would provide a valuable check on model performance over time.

Modelling Simulation Results

The predicted relative drawdown for each scenario at the existing East Weipa and Andoom borefield and the monitoring bores is discussed below.

The existing Water Licence requires that drawdown does not exceed 5m at Bramwell Station, Batavia Downs and Weipa Crossroads monitoring bores. The FEFLOW model was used to predict relative drawdown for each abstraction scenario and determine whether current Water Licence conditions would be met.

The drawdown for each scenario described in **Table 5-27** is defined here as the difference in simulated aquifer head relative to simulated baseline conditions where no abstraction takes place; i.e., a baseline scenario is simulated in which there is no abstraction. The results of each scenario are then compared to this baseline, with the difference between the two data sets being the relative drawdown. The drawdown calculated in this way will then represent the direct influence of the proposed abstraction scenario only.

The predicted relative drawdown for each abstraction scenario at various time steps is shown in **Table 5-28**. Drawdown hydrographs for these locations over the full simulation period are provided in **Appendix 5B Figures 21 to 26**.

The drawdown contours for the 12GL per annum scenario at the end of mine life (Year 40) are shown in **Figure 5-31.** Predicted drawdown contour maps related to other years for 12GL per annum scenario are presented in **Appendix 5B Figures 27 to 31** and **Figures 32 to 36** for the 18GL per annum Scenario.

Table 5-28 Predicted Drawdown

* Water Licence compliance monitoring bore

The existing Water Licence requires that drawdown does not exceed 5m at Bramwell Station, Batavia Downs and Weipa Crossroads monitoring bores. The modelling results show that for both the 12 and 18GL per annum scenarios the maximum drawdown occurs in about Year 50 (2063). The predicted drawdown contours for the 12GL per annum scenario at Year 40 (refer **Figure 5-31**) shows that, at about the year of maximum drawdown, drawdown was less than 5m at the Water Licence compliance monitoring bores. The modelling results for those three monitoring bores show that, for the proposed licensed abstraction of 12GL per annum, the maximum drawdown occurs at Batavia Downs bore (3.75m at Year 50, refer **Appendix 5B Figure 24**). The maximum drawdown at the other two monitoring bores was less than 2m (refer **Appendix 5B Figure 23** and **Appendix 5B Figure 26**).

The modelling results indicate that under the proposed licensed abstraction regime the existing Water Licence condition relating to maximum relative drawdown would be met. The modelling also predicted that the existing Water Licence condition relating to maximum relative drawdown would also be met for a 18GL per annum scenario, with the maximum drawdown of 4.95m occurring in 2063 (year 50) at Batavia Downs. The results indicate that the aquifer could sustainably support abstraction rates greater than the proposed rate of 12GL per annum.

Datum/Projection: GDA94/MGA Zone 54 Date: 14/07/2010

The Rolling Downs Group separates the shallow and artesian aquifers with a 500m thick confining layer of low hydraulic conductivity. Abstraction of artesian groundwater is not expected have any impact on the shallow aquifer.

Spring Factors

Section 39 of the GAB-ROP (DNRW 2007) prescribes conditions that must be met for the chief executive to make a decision about a Water Licence, if the decision is associated with a management unit connected to a spring, and the water is for purposes other than domestic and stock watering. A decision associated with abstraction from a management unit connected to a spring is subject to the cumulative spring factor not exceeding 400mm head of water. The GAB-ROP (DNRW 2007) prescribes how the spring factors are to be calculated.

The proposed artesian groundwater abstraction from existing and proposed new bores would take water from the Gilbert River Formation, which is connected to watercourse and recharge springs. The spring factors for the closest recharge and watercourse springs have been calculated to demonstrate that cumulative spring factor limit of 400mm is not exceeded for any of the existing or proposed new bores.

Table D-1 and Table D-2 of the GAB-ROP (DNRW 2007) must be used to determine the spring factor for each spring:

- Table D-1 is used to associate regions to transmissivity groups (TG); and
- Table D-2 provides multiplying factors according to the TG, distance and spring type to calculate cumulative spring factors.

Table D-2 is reproduced as **Table 5-29**.

Table 5-29 Spring Factor Multipliers from GAB-ROP

780	0	0	0	0	0	0

Spring factors are calculated by multiplying the annual take of water in megalitres by the relevant spring factor multiplier determined from Table D-2. Where the actual distance between a spring and the bore is not shown in Table D-2, the spring factor multiplier can be determined on a pro-rata basis using the distances in Table D-2 that are the closest to the actual distance (DNRW 2007).

Spring Factor Calculation Results

Springs in the Cape 1 management unit are designated as either watercourse or recharge springs (not discharge springs) according to the definitions for spring types given in the GAB-ROP (DNRW 2007). Table D-1 of the GAB-ROP (DNRW 2007) indicates the relevant TG for the Cape 1 management unit is TG-50.

The watercourses and springs on the DERM spring register closest to the existing and proposed borefields are presented in **Table 5-30** with their respective calculated spring factors**.** The spring factors for the closest watercourse and recharge springs were calculated by multiplying the spring factor multiplier by the abstraction rate for the two abstraction rate scenarios (12,000ML and 18,000ML per annum).

Table 5-30 Spring Factors

Spring Type	Spring ID	Distance from Closest Borefield (km)	Closest Borefield	Spring Factor Multiplier (from Table D-2)	Spring Factor (mm Head of Water) (spring factor x abstraction rate)	
					12 GL/a	18 GL/a
Recharge	V512	110	Andoom	0.0003	3.6	5.4
Recharge	V511	107	Andoom	0.0004	4.8	7.2
Recharge	V499	113	Andoom	0.0002	2.4	3.6
Recharge	V498	112	East Weipa	0.0002	2.4	3.6
Recharge	V495	126	SoE	0	0	0
Recharge	V497	138	SoE	0	0	0
Watercourse	Palm Creek	84	Andoom	0.008	96	144
Watercourse	Oliver River	100	Andoom	0.0006	7.2	10.8
Watercourse	Wenlock River	87	Andoom	0.007	84	126
Watercourse	Wenlock River	94	East Weipa	0.004	48	72
Watercourse	Archer River	129	SoE	0	0	0
Watercourse	Coen River	154	SoE	0	0	0

The calculated spring factors represent the highest possible cumulative spring factor for each spring because the spring factors are calculated on the assumption that all the water is abstracted from the closest bore. The calculated spring factors are all well below the spring factor limit of 400mm head of water, demonstrating the spring factor requirement is met in all cases.

5.4.3 Regulatory Requirements

Water Licence Requirements

RTA has an existing artesian Water Licence under the *Water Act 2000* for 9GL per annum which allows abstraction from artesian bores located on ML7024, which access the Gilbert River Formation and Garraway Beds aquifers. RTA has applied to increase this artesian allocation to cover the increase in artesian demand arising from the Project. RTA proposes that the Water Licence be based on a five-year moving average of 12GL per annum, with a maximum of 15GL in any one year.

The decision to grant or amend a Water Licence is made by the chief executive administering the GAB-ROP (DNRW 2007), currently through the agency of DERM. The criteria used in deciding applications are outlined in Section 210 of the *Water Act 2000*.

Water Resource (Great Artesian Basin) Plan 2006

A primary purpose of the *Water Act 2000* is to advance sustainable management and efficient use of water and other resources by establishing a system for the planning, allocation and use of water. One of its main provisions is the development and implementation of Water Resource Plans for river basins in Queensland.

The Project area is located within the plan area of the *Water Resource (Great Artesian Basin) Plan 2006*, which will be referred to here as the GAB WRP. The GAB WRP applies to artesian water in the plan area and hence to the proposed increase in artesian allocation for the Project. The stated objectives for the GAB WRP are that water is to be allocated in a way that seeks to achieve a balance in the following outcomes:

- to protect the flow of water to springs and baseflow to watercourses that support significant cultural and environmental values;
- to provide for the continued use of all water entitlements and other authorizations to take or interfere with water;
- to reserve water in storage in aquifers for future generations;
- to ensure a reliable supply of water from the plan area; and
- to make water available for new users.

The GAB WRP deals with principles and objectives of the planning and management of water resources in the GAB. Details of how water management would be implemented to achieve those objectives are the subject of the GAB ROP (DNRW 2007).

Granting unallocated water from the State reserve

A new artesian allocation, or an increase in existing allocation, must be made from the State reserve. Section 25 of the GAB WRP states that unallocated water from the State reserve may only be granted for a project of State significance, a project of regional significance, or for town water supply purposes. The SoE Project was declared a project of State significance in November 2008 and is eligible for being considered for an allocation from the State reserve (which is limited to 10GL under Section 26 of the GAB WRP).

Section 18 of the GAB WRP states that in dealing with unallocated water the chief executive must consider, amongst other things, the impact the proposed taking of water may have on the flow of water to springs or baseflow to watercourses, artesian water pressure and subartesian water levels. The potential impact of the proposed taking of artesian water for this Project on groundwater levels is discussed in **Section 5.4.2**.

Protection of flow to springs and baseflow to watercourses

Section 12 of the GAB WRP states that Water Licences in the plan area must be consistent with the criteria for the protection of the flow of water to springs and baseflow to watercourses stated in the GAB ROP (DNRW 2007). Criteria to protect the flow of water to springs are detailed in Section 3 of the GAB ROP (DNRW 2007). The two relevant criteria for the SoE Project are:

- for a management unit connected to a spring, the chief executive must not make a decision about a Water Licence that would increase the amount of water that can be taken from within 5km of that spring; and
- for a decision about a Water Licence associated with a management unit connected to a spring, the chief executive may make a decision about a Water Licence if the decision does not result in the cumulative spring factor for the spring exceeding 400mm of water head.

The distances for those recharge springs and watercourse springs within the Great Dividing Range that have the closest location to the existing and proposed borefields all greatly exceed 5km. The calculated spring factors (refer **Table 5-30**) are all well below the spring factor limit of 400mm head of water, demonstrating that the spring factor criteria are met in all cases.

Installation of artesian borefield

Development of bores required to extract water from an aquifer is an assessable development under the *Sustainable Planning Act 2009* (Qld). The Comalco Agreement Act permits 12 artesian bores under section 32(b) (or more with Minister's consent). It is expected that no more than 12 artesian bores would be required to achieve the planned abstraction rates.

5.5 Monitoring

5.5.1 Surface Water

A surface water monitoring program is proposed to provide an early indicator of potential impacts identified in **Section 5.2.5** for parameters identified in **Section 8.15.1**. Locations and parameters were assigned based on catchment, location within the catchment and proposed activities up and down gradient. Locations, rationale and parameters are summarised in **Table 5-31**. Locations would be monitored monthly until a statistical baseline is established (consistent with ANZECC requirements) and then quarterly thereafter. Locations are shown on **Figure 5-32**.

In addition, quarterly vertical salinity profiling of Norman Creek and Ward River upper estuaries is proposed to evaluate if the Project has had any impact on the freshwater–saltwater interface.

Aluminium, iron and manganese concentrations may potentially be affected by geochemical changes arising from Project impacts (e.g. dam seepage) or natural causes. Turbidity may be affected by mining activities. It is proposed to set Project-specific trigger values for these parameters.

Project-specific trigger values were adopted in accordance with the decision tree processes defined in ANZECC (2000) guidelines. Trigger values can be set as tabulated default trigger values, provided in ANZECC (2000) or as site-specific trigger values obtained from baseline concentrations. Site-specific trigger values based on data from the Project area are preferred over default values (which are usually used when site data is lacking).

It is proposed to set Project trigger values for dissolved aluminium, iron, manganese and turbidity based on the 80th percentile of the baseline data set for freshwaters. If, during operations, the median concentration of aluminium, iron, manganese or turbidity exceeds the Project trigger value, an investigation would be carried out to determine the possible cause.

For estuarine waters, it is proposed to set Project trigger values for aluminium based on the 80th percentile of the baseline data set for estuarine waters. If, during operations, the median concentration of aluminium exceeds the Project trigger value, an investigation would be carried out to determine the possible cause.

A trigger value is not proposed for pH as any fluctuations in pH would give rise to fluctuations in aluminium, iron and manganese and these are more appropriate environmental indicators. Dissolved oxygen would be monitored up and down gradient of the water supply dam to evaluate potential impacts. A trigger value is not proposed for electrical conductivity as bauxite mining would not contribute to any increase in salt levels in the environment. Lead, chromium, copper, nickel and zinc are not considered constituents of concern at the Project area (**Section 8.15.1**); however, concentrations may fluctuate with seasonal changes, particularly at the end of the dry season, and thus they would be monitored to confirm concentrations remain in normal ranges. All other metals are not considered constituents of concern at the Project area (**Section 8.15.1**). Concentrations of these metals were less than the laboratory reporting limit or very low, and the low concentrations do not fluctuate seasonally; therefore they would not be monitored.

Table 5-31 Proposed Surface Water Monitoring Program

Monitoring Location	Rationale	Type*	Parameters
Norman Creek estuary (10A)	Norman Creek Catchment. Upper Estuary. Down gradient of mining years 1–13.	E	EC, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Norman Creek (4)	Norman Creek Catchment. Freshwater. Up gradient of mining years 1–13.	F	EC, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Norman Creek (2A)	Norman Creek Catchment. Freshwater. Adjacent to area of mining years 1–13.	F	EC, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Norman Creek (11)	Norman Creek Catchment. Freshwater. Within mining years 1–13 and down gradient of tailings storage facility.	F	pH, EC, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Norman Creek upstream Dam C (5A)	Norman Creek Catchment. Freshwater. Up gradient of Dam C.	F	pH, EC, temperature, dissolved oxygen, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Norman Creek downstream Dam C (1B)	Norman Creek Catchment. Freshwater. Down gradient of Dam C.	F	pH, EC, temperature, dissolved oxygen, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Coconut Creek (14A)	Ward River Catchment. Freshwater. Up gradient, control location	F	EC, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Ward River upstream (22)	Ward River Catchment. Freshwater. New location on lease boundary	F	pH, EC, temperature, dissolved oxygen, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Ward River downstream (25A)	Ward River Catchment. Freshwater. Down gradient of mining.	F	pH, EC, temperature, dissolved oxygen, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Ward River at pump station (23)	Ward River Catchment. Freshwater. Down gradient of mining.	F	pH, EC, temperature, dissolved oxygen, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Winda Winda / Triluck Creek estuary (21)	Winda Winda / Triluck Creek Catchment. Lower estuary.	E	EC, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Triluck Creek (19)	Down gradient of future mining (years 14–40) Triluck Creek Catchment. Lower freshwater.	F	EC, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Winda Winda Creek (9a)	Winda Winda Catchment. Upper freshwater. Accessible and contains water during dry season.	F	EC, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Ina Creek (26A)	Ina Creek Catchment. Freshwater. Down gradient of future mining (years 14–40)	F	EC, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Ina Creek (31)	Ina Creek Catchment. Lower freshwater. Down gradient of mining area.	F	EC, turbidity, Al, Cr, Cu, Fe, Pb, Mn, Ni, Zn.
Boyd Point (Marine)	Marine. North of port. Adjacent to reef habitat.	M	Hydrocarbons, turbidity.
Pera Head (Marine)	Marine. South of port. Adjacent to sensitive habitat.	M	Hydrocarbons, turbidity.

F = freshwater streams, E = estuarine, M = marine, S = swamp

Streamflow gauging stations would be installed upstream and downstream of Dam C, as well as in two Norman Creek sub-catchments (one to be mined and one non-mined "control"). When the Ward River pump station is installed, a stream gauging station would be installed on the river in the vicinity of the pump.

5.5.2 Shallow Aquifer

A network of shallow groundwater bores would be maintained. Some of the existing bores are likely to be discontinued and replaced by new bores more closely aligned with the mine plan and positioned up-gradient and down-gradient of mining pits. Exact locations would be determined once the detailed mine plan is developed. Water levels would be measured manually on a monthly basis (subject to access).

5.5.3 Artesian Aquifer

RTA proposes to continue the current monitoring and reporting requirements under the existing Water Licence:

- quantity of water abstracted from production bores;
- artesian groundwater quality and changes in water quality;
- artesian groundwater levels and changes in groundwater levels; and
- drawdown levels in the recharge area (through monitoring bores at Bramwell Station, Batavia Downs and Weipa Crossroads).

As part of the original Water Licence application, RTA submitted to DNRM predictions of the impact of artesian groundwater abstraction on the artesian groundwater levels in the region. These predictions were derived from a numerical model. The current Water Licence requires RTA to regularly undertake the following:

- comparison of actual impacts on artesian groundwater levels to impacts predicted from modelling; and
- assessment of the need to update the model used to predict impacts on artesian groundwater levels and description of any updates made.

The current and proposed monitoring requirements in relation to abstraction quantities and groundwater levels are presented in **Table 5-32.**

Table 5-32 Monitoring Regime

Bore Type	Parameter	Frequency
Production	Instantaneous discharge rate	Continuous
Production	Accumulated usage	Continuous
Production	Discharge pressure	Continuous
Production	Groundwater head	Weekly
Monitoring	Groundwater head	Weekly

Logging of production bore data is carried out through the telemetry system and data from monitoring bores east of the Project area is captured in installed data loggers. The current bore monitoring regime would continue.

The FEFLOW model developed for the Project would continue to be regularly updated in response to new field information from ongoing pumping tests and with data from updated monitoring records.

Groundwater quality analyses of artesian water are required to be undertaken at least annually. This monitoring regime would continue. It is expected the groundwater quality analyses would include the following parameters: pH, electrical conductivity, colour, turbidity, total dissolved solids, total suspended solids, magnesium, manganese, calcium, sodium, potassium, fluoride, chloride, sulphide, iron, sulphate, carbonates, alkalinity and hardness.

Monitoring data and reporting would continue to be provided to the regulatory authorities that administer the *Water Act 2000* on a regular basis.

The monitoring program would be reviewed regularly and updated as required.

Environmental Impact Statement

for South of Embley Project

Section 6
Marine

6 MARINE

This section describes the existing physical and biological marine environment including water quality and sediment properties in the vicinity of the SoE Project area, the associated environmental values, and any potential impacts associated with the Project.

The general study area, used to describe the existing marine environment and predict the environmental impacts from the Project, includes:

- Albatross Bay (including rivers and creeks) bound by Jantz Point in the north and Pera Head in the south, and extending further south to Thud Point (refer **Figure 1-1**);
- Embley and Hey River estuaries; and
- an area extending 17km westward, offshore from Boyd Point.

This area includes all marine components of the Project including the proposed port site, the proposed spoil ground offshore of Boyd Point, the existing Albatross Bay spoil ground, the location for barge and ferry facilities at Hornibrook Point and Humbug Wharf in the Embley River, and the location for the proposed barge/ferry terminal in the Hey River.

The State Coastal Plan describes how the coastal zone is to be managed as required by the *Coastal Protection and Management Act 1995* (Qld). Within the State Coastal Plan, Regional Coastal Management Plans specify the policy framework at the regional level and identify key coastal sites requiring special management within the region. Of the 11 coastal regions identified for Queensland, four Regional Coastal Management Plans have been finalised and three are under development. Development of Gulf of Carpentaria and Cape York Peninsula Coast regional plans has not yet commenced.

Following public consultation and review of the 2002 State Coastal Management Plan, the draft Queensland Coastal Plan was released for public comment on 25 August 2009 and closed on 30 November 2009. Submissions made during this period are currently being considered. The Queensland Coastal Plan will replace the State Coastal Plan once finalised.

6.1 Physical Environment and Coastal Processes

6.1.1 Bathymetry

The bathymetry (seabed topography) from Boyd Point to Thud Point was surveyed by 3-D Marine Mapping Pty Ltd during August 2006. In the vicinity of the proposed port development between Boyd Point and Pera Head, the mapping identified an upper-beach perched below high cliffs. The existing beach profile and proposed wharf jetty structure are presented in **Figure 6-1**. The nearshore bathymetry contours indicate that depth increases rapidly offshore. The seabed falls from –3m to –12m at Lowest Astronomical Tide (LAT) over the first 500m, levelling to –16m approximately 2km from shore. Detailed bathymetry beyond 2km from shore, for the extent of the departure channel, has not been completed and is not proposed. Navigation charts indicate a uniform grade. Description of the seabed and bathymetry in the vicinity of key offshore areas, including the new spoil ground, entrance channel and Nine Mile Reef, is based predominantly on drop-camera video inspection.

The nearest substantial sensitive seabed features include reefs and outcrops at Boyd Point 2.8km north-east of the proposed port area and Pera Head 2km south-west. Isolated reefs also occur south of Pera Head to Thud Point (refer **Figure 6-18**). Satellite imagery indicates there may be numerous small reef outcrops between Thud Point and Aurukun; however their presence have not been verified via bathymetric survey due to their distance from the proposed Port site and very low likelihood of impact from turbid plumes generated by dredging.

Seabed features in the departure channel area have been investigated using drop camera video and essentially comprise open seabed with infrequent low density aggregations of soft corals or sponges.

The proposed new spoil ground located 17km (central point) offshore from Boyd Point is located in approximately 23m water depth to LAT and is locally characterised by a flat, unvegetated, soft sediment seabed. The spoil ground is proposed to have a radius of 0.5 nautical mile (nm). Drop camera video survey within and adjacent to the spoil ground did not identify any small scale features, such as patch reefs. The nearest substantial seabed feature to the proposed spoil ground is Nine Mile Reef which is located approximately 6km to the south-south-west.

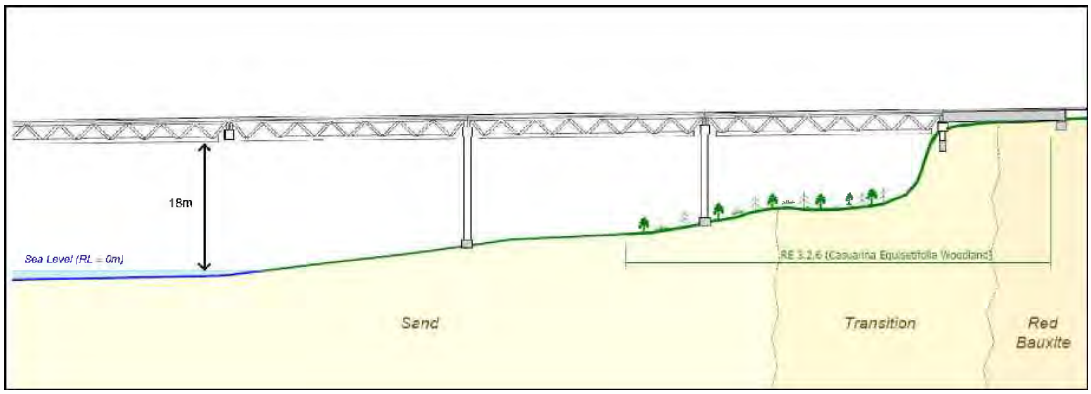

Figure 6-1 Beach Marine Profile and Proposed Jetty Structure.

6.1.2 Existing Coastal Processes and Hydrodynamics

Coastal processes and the hydrodynamics around the proposed port development area were assessed in the study using numerical models and analysis of collected field data. Currents, water levels, wave heights, plumes, and sediment transport were predicted with numerical models and compared against recorded data where practical. The predicted results were also used to ascertain the level of impact on the marine environment from proposed development in the coastal zone.

Full hydrodynamic modelling was undertaken using MIKE21 software (Danish Hydraulic Institute (DHI), a two-dimensional depth-integrated hydrodynamic modelling program. This software is an industry standard for modelling marine environments.

A large-scale hydrodynamic model of the Gulf of Carpentaria (referred to as the Outer model) and a fine-scale model around the proposed port development site (referred to as the Inner model) were developed (refer **Figure 6-2** and **Figure 6-3**). Bathymetry data from the following sources was used to assess coastal processes and hydrodynamics, sediment movement and turbidity effects from dredging at the proposed port and placement at the proposed new spoil ground:

- Australian Bathymetry and Topography Grid June 2005, Geoscience Australia;
- Australian Hydrographic Chart 410, Booby Island to Cape Wessel including the Gulf of Carpentaria. Scale 1:1,000,000 at Latitude 27°15';
- Australian Hydrographic Chart 376, Australia to Papua New Guinea. Scale 1:300,000 at Latitude 27°15'; and
- Hydrographic survey of the study site between Boyd Point and Pera Head to produce bed contours between –3 and –15m at one-metre intervals to LAT datum (3D Marine Mapping Pty Ltd).

Hydrodynamic modelling of dredging at Hornibrook ferry terminal, Humbug barge terminal and Hey River barge/ferry terminal and disposal at the Albatross Bay spoil ground was not undertaken given the relatively minor volumes to be dredged (i.e. approximately 19,000m^3, 10,700m^3 and 17,300m^3 respectively).

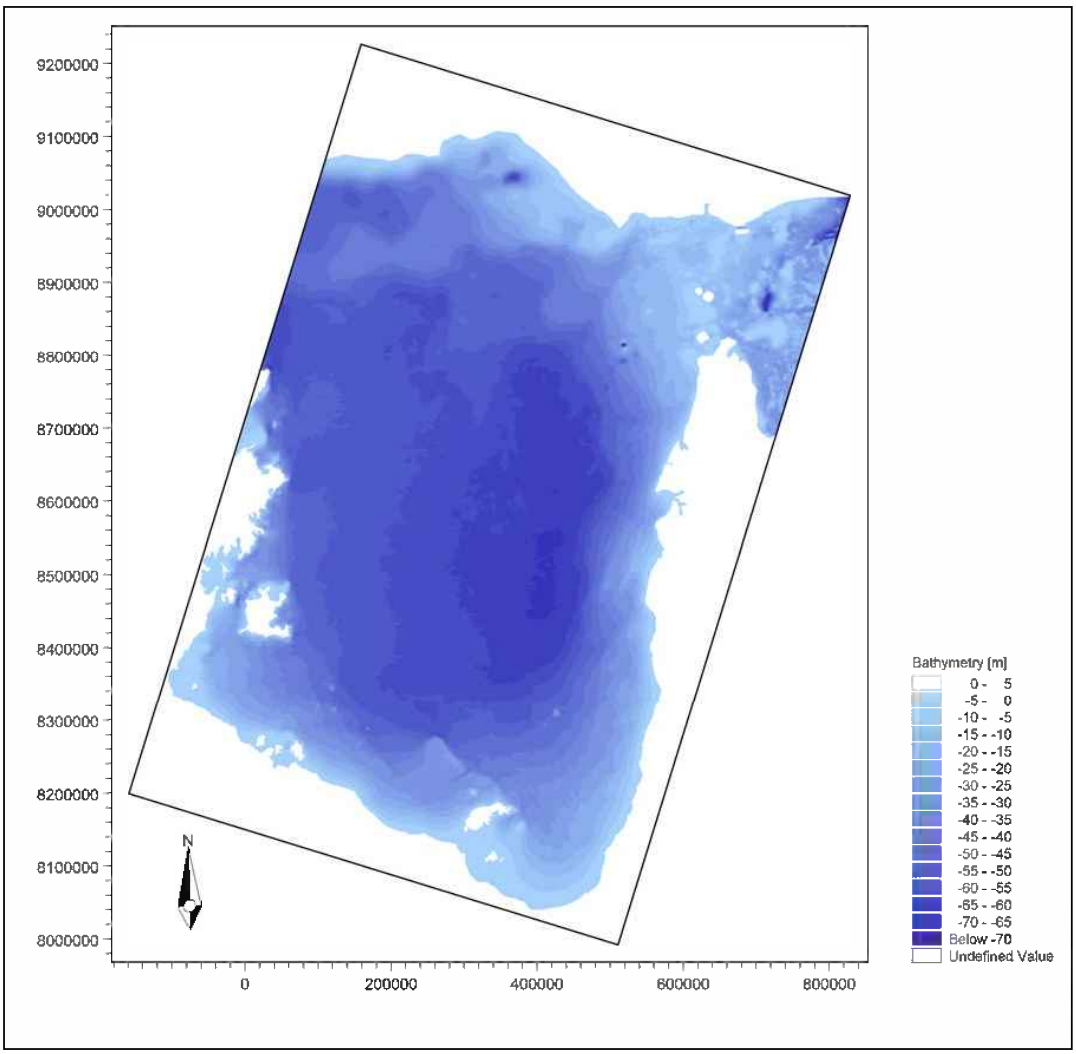

Figure 6-2 Gulf of Carpentaria Bathymetry and Model Boundaries

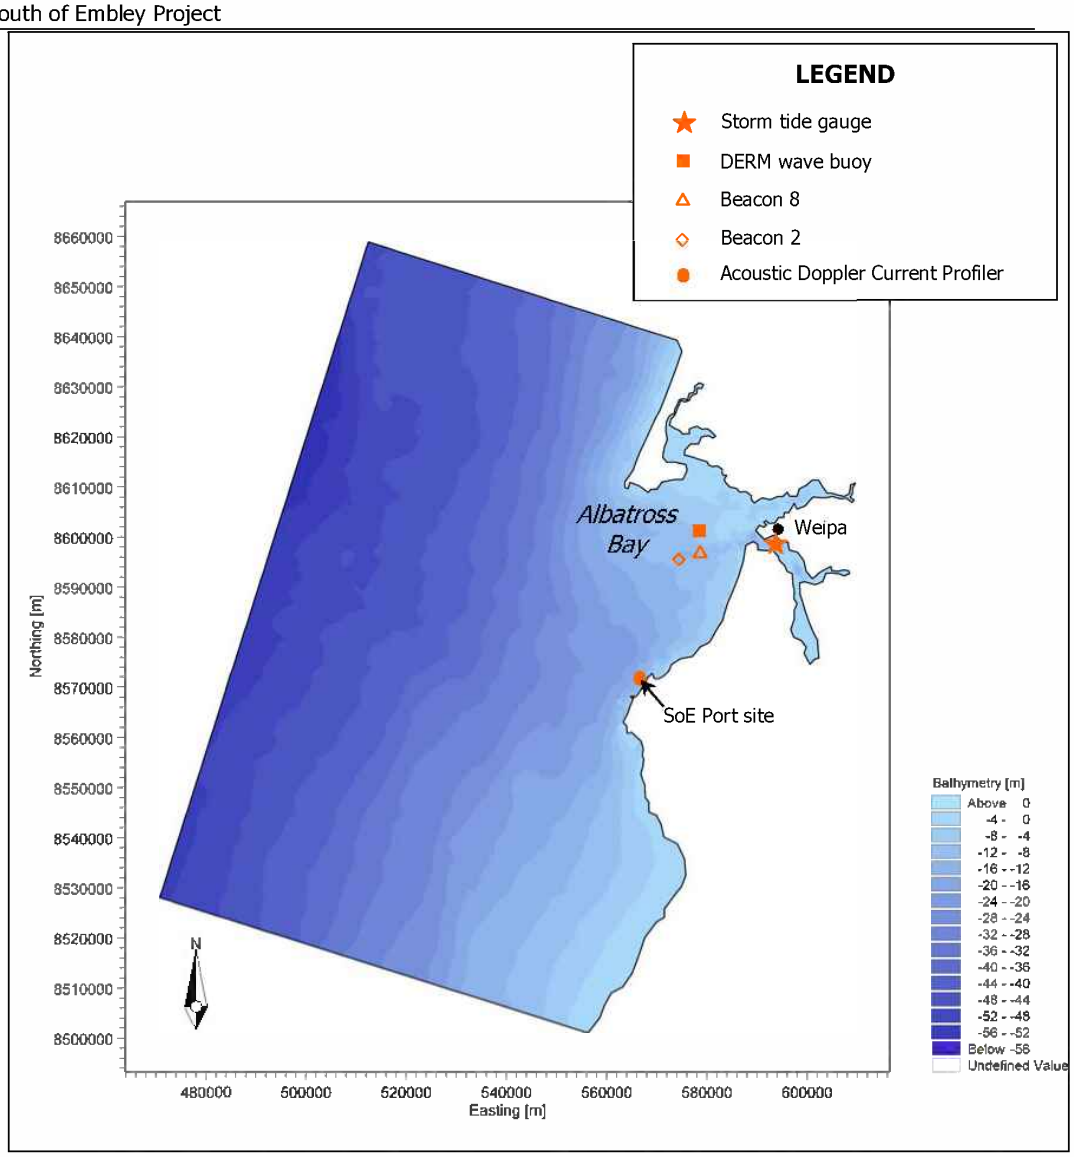

Figure 6-3 Inner Model Flexible Mesh Bathymetry and Model Boundaries with Observational Data Locations.

The Outer (Gulf) model has two open boundaries (refer **Figure 6-2**):

- the western boundary, which extends from Cape Wessel to the south-western tip of Dolak Island; and
- the eastern boundary, which extends from Shelbourne Bay to Bramble Cay.

Global tide model predictions, incorporating the major tidal constituents, were obtained at the outer model open boundary extents and are presented in **Figure 6-4**. The timing and magnitude of the tidal water level over the length of each open boundary was expected to show variation. This was represented in the model by applying a linear variation in predicted tide level between:

- Cape Wessel and Dolak Island for the western boundary; and
- Shelbourne Bay and Bramble Cay for the eastern boundary.

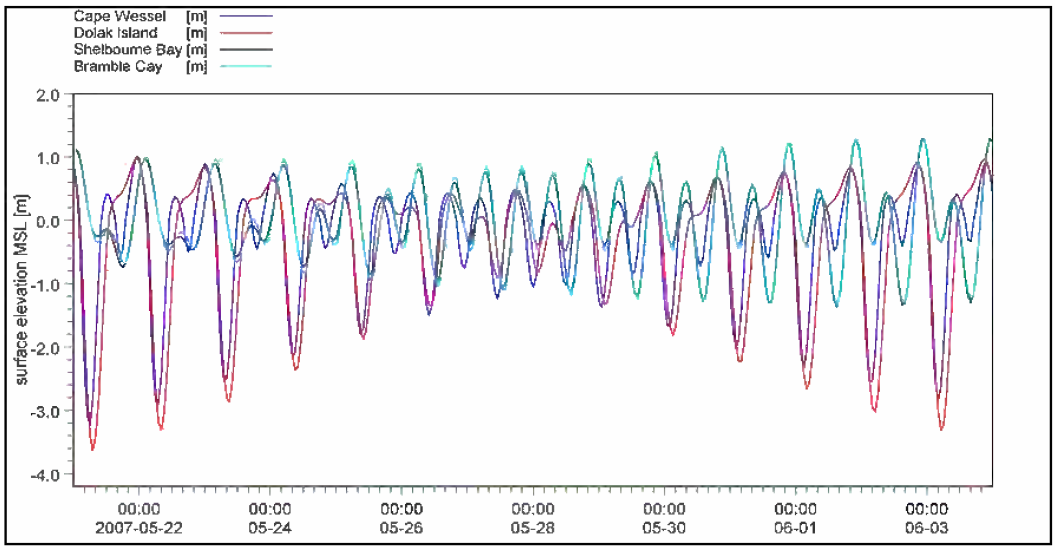

Figure 6-4 Global Tide Model Prediction at Outer Model Open Boundary Extents

Acoustic Doppler Current Profiler (ADCP) instrument deployment at the proposed port site (location indicated in **Figure 6-3**) provided measurements of current speed, current direction, and water level useful for hydrodynamic model verification. Additional water level data for the Weipa region collected by the Queensland Department of Environment and Resource Management (DERM, formerly the Queensland Environmental Protection Agency, EPA) was provided by Maritime Safety Queensland (MSQ). The data included both the Weipa storm tide gauge predictions and observations (May–June 2007) and a time-series (July–August 2003) of observational data from "Beacon 2", located toward the western extent of the existing Weipa shipping channel (refer **Figure 6-3**).

Three model simulations were performed, with each simulation covering a different observational data period. Outer model verification plots of MSQ observed/predicted versus simulated water levels are presented in **Figure 6-5** and **Figure 6-6**. Model verification at the Weipa storm tide gauge (May–June 2007) and at Beacon 2 (July–August 2003) was generally good in terms of the magnitude and timing of flood and ebb tide peaks, noting some over-prediction of peak water levels during neap tides. Small discrepancies between the observed and predicted water levels may be attributed to meteorological effects (e.g. atmospheric pressure or local wind effects) which are not typically included in the simulations during model development and/or the Outer model boundary conditions not incorporating the minor tidal constituents.

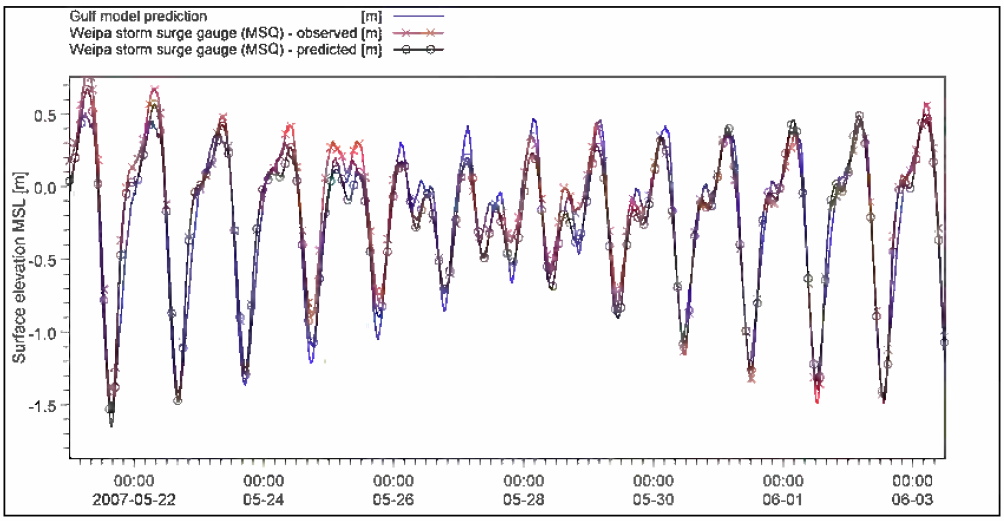

Figure 6-5 Outer Model Water Level Prediction Compared with Weipa Storm Tide Gauge

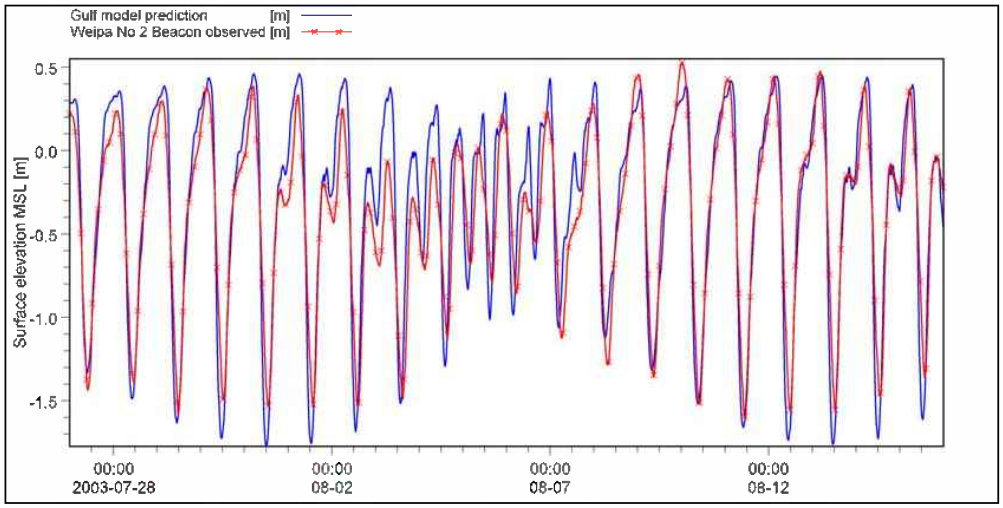

Figure 6-6 Observed Water Levels at Beacon 2 Compared with Gulf Model Prediction

Verification of the Inner model was achieved by comparing water level, and current speed and direction against measurements from the ADCP deployed at the Boyd Point site. Good agreement between measured and modelled hydrodynamics in the study area was found (refer **Figure 6-7**).

The Inner hydrodynamic finite-volume model (flexible mesh) was used in plume modelling and to quantify current speed and direction information to assess the potential impacts of turbidity, siltation, and sediment mobilisation as a result of dredging and disposal.

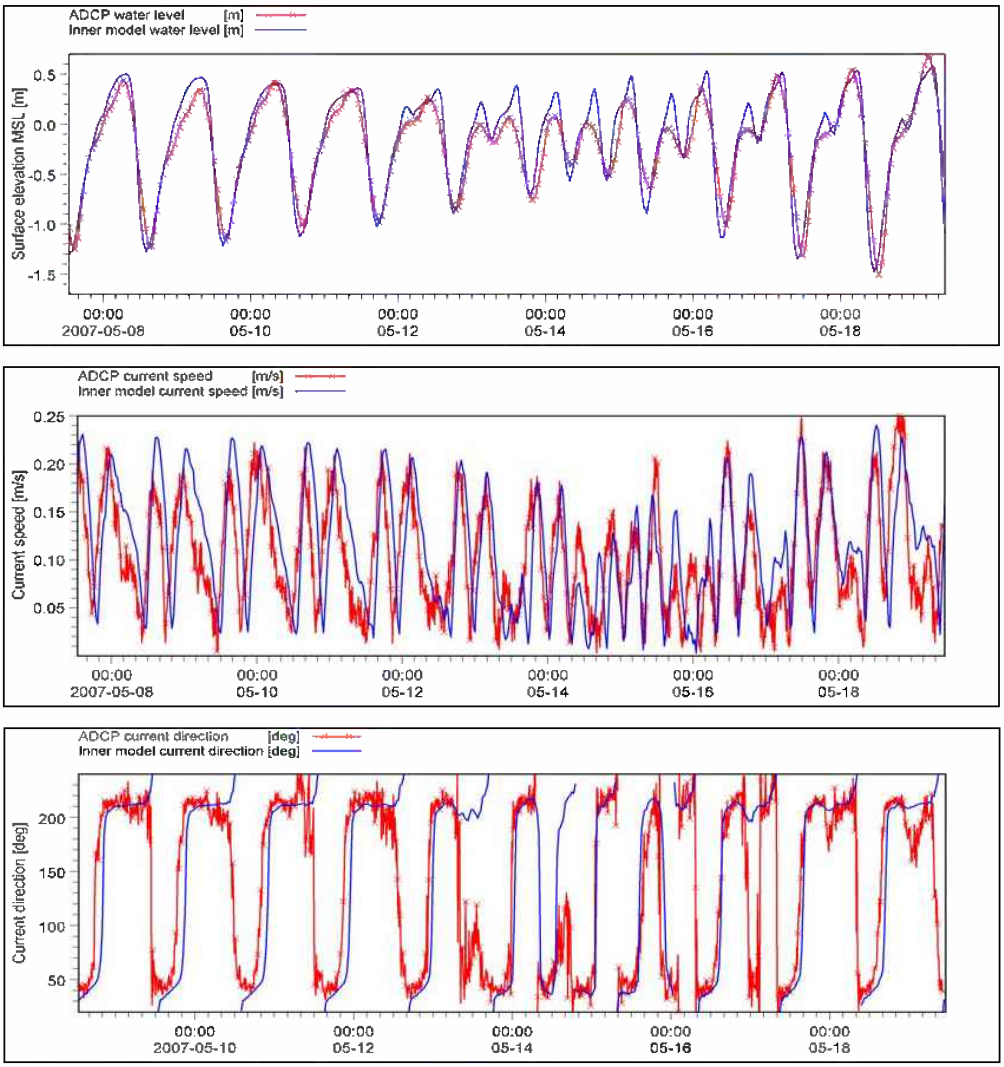

Figure 6-7 Measured (ADCP) Data Compared with Inner Model Prediction

Predicted peak flood (incoming) and ebb (outgoing) tide current vectors at the proposed port site are presented in **Figure 6-8** and **Figure 6-9**. Current vectors over the tide cycle indicate flow from the north-east or south-west depending on the tidal phase. Peak model currents are approximately 0.3m/s. ADCP measurements demonstrate the current speed is relatively uniform over depth.

The existing wave climate within the area is described in **Section 6.1.4** and the estimate of annual longshore sediment transport is reported on in **Section 6.1.5**.

The coastline between Boyd Point and Pera Head is relatively straight and has a bearing of 210º with respect to true north (i.e. 210°N). Above the water line the beach is relatively wide and contains a substantial volume of sand material. Nearshore beach slope immediately above and below the water line is steep inferring a reflective beach type (i.e. convex profile that reflects low wave energy).

Under existing coastal conditions, the shoreline either side of the proposed port development area appears to be uniform, inferring a balance of sediment supply in and out of the compartment.

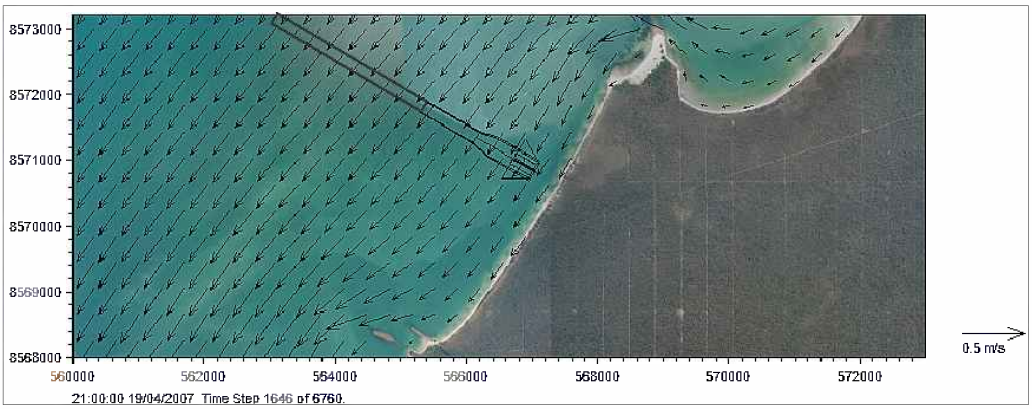

Figure 6-8 Predicted Peak Flood Tidal Currents at Proposed Port Dredging Area

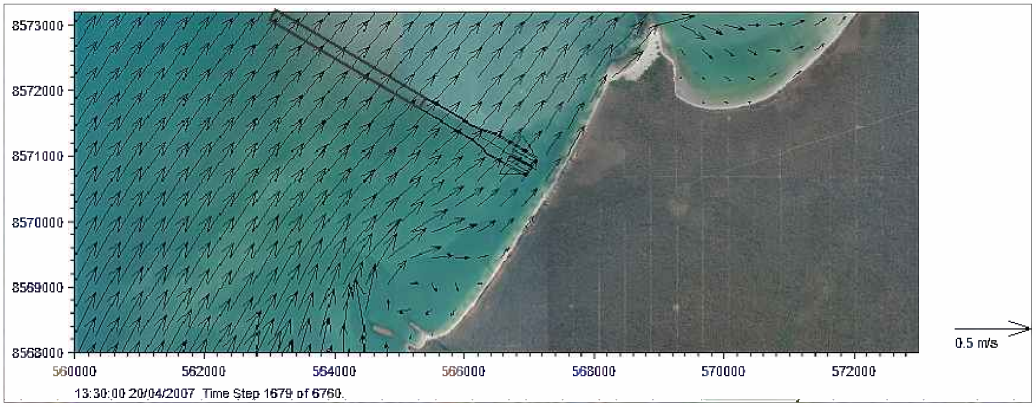

Figure 6-9 Predicted Peak Ebb Tidal Currents at Proposed Port Dredging Area

The supply of sediment to this part of the coast appears to originate from:

- nearby river systems such as the Embley and Archer River catchments;
- dunes and indurated sand and clay cliffs; and
- offshore marine sediments.

During severe storms, scarping or lowering of the existing beach profile is expected. The type of response will depend on the presence and depth of firmer underlying strata. During severe storms, when surge is combined with high tide, wave run-up will also erode the cliff at the back of the beach, transporting sediment into the littoral system.

Coastal process modelling was undertaken to assess the potential for shoreline change due to the construction of the proposed wharf and dredging. In particular, two aspects were analysed in detail to determine the influence on coastal processes:

- potential long-term changes to the alongshore profile and back-beach brought about by the required deepening of the inshore area through dredging and a qualitative description of the potential influence of the wharf trestle structure; and

- potential for upper beach profile sediments reaching the berths due to cross-shore transport during storm events.

A discussion of these potential impacts is provided in **Section 6.9.1**.

6.1.3 Currents and Tides

Weipa is the closest standard port to the Project area with sufficient tidal data for analysis. The tidal signal at Weipa is predominantly diurnal (daily cycles) with short periods of semi-diurnal tides at times of neap tides.

The tidal planes at the Weipa tide gauge located at Humbug Point (1.752m above LAT) are shown in **Table 6-1**. Heights are also shown in Australian Height Datum (AHD).

Table 6-1 Weipa Tidal Planes

Tidal Plane	Metres above LAT	Metres above AHD
HAT (Highest Astronomical Tide)	3.38	1.63
MHHW (Mean High High-Water)	3.0	1.2
MLHW (Mean Low High-Water)	2.2	0.4
MSL (Mean Sea Level)	1.85	0.10
MHLW (Mean High Low-Water)	1.5	–0.3
MLLW (Mean Low Low-Water)	0.7	–1.1

LAT = Lowest Astronomical Tide

AHD = Australian Height Datum

The tide prediction does not always fully explain the tidal observations at Weipa. Meteorological conditions acting over time can transfer additional energy to tidal signals, resulting in higher or lower water levels than the predicted values.

The tidal signal in the Project area is almost identical to Weipa, with a slight phase shift resulting in the high tide being slightly later than at Humbug Point.

Current data at the proposed port site was collected over the 2006–07 and 2007–08 periods. Measurements were taken with an ADCP located in 10 to 14m of water at Boyd Point. The ADCP recorded data at six-minute intervals and currents were measured at every half-metre depth over the water column. Little variation of current was observed with depth. Average peak spring tide currents were approximately 0.25 meters per second (m/s). Average peak neap tide currents were 0.15m/s. Currents are predominantly aligned with the coast, typically between 210 and 220°N during flood tides and between 30 and 40°N during ebb tides. The depth-averaged measured current speed and direction over a four-week period during April–May 2007 is presented in **Figure 6-10**.

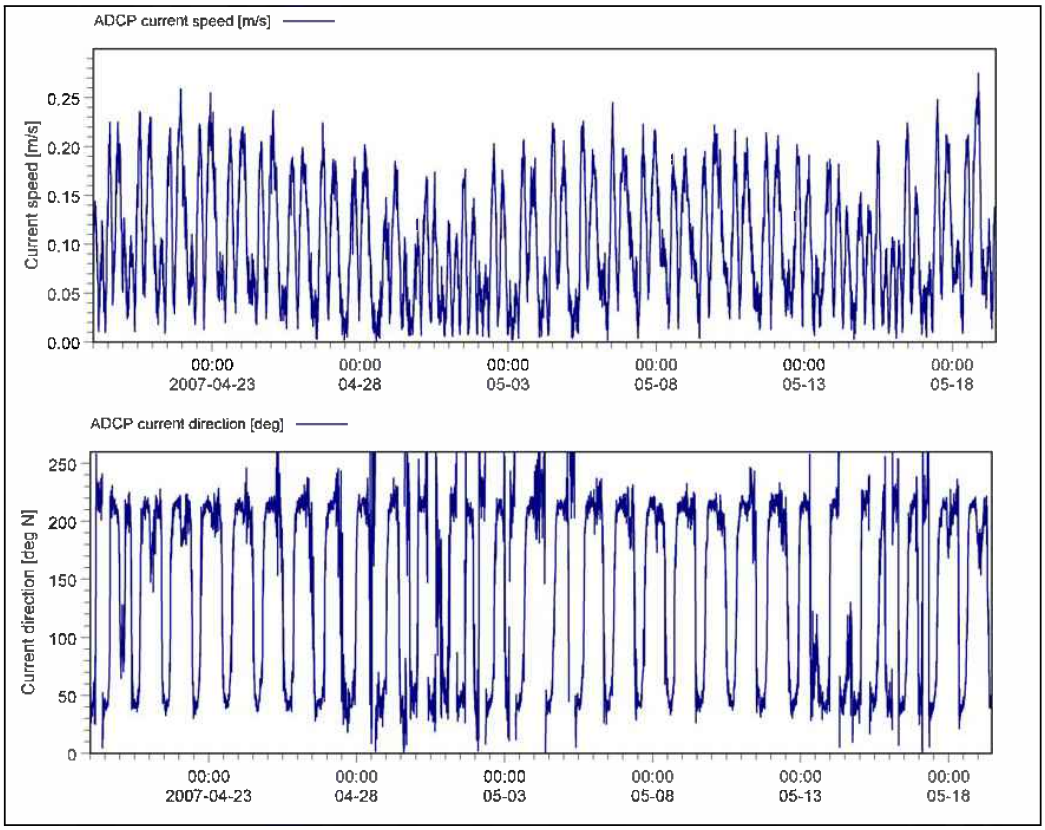

Figure 6-10 Depth-averaged Measured Current Speed and Direction at Study Site

6.1.4 Waves

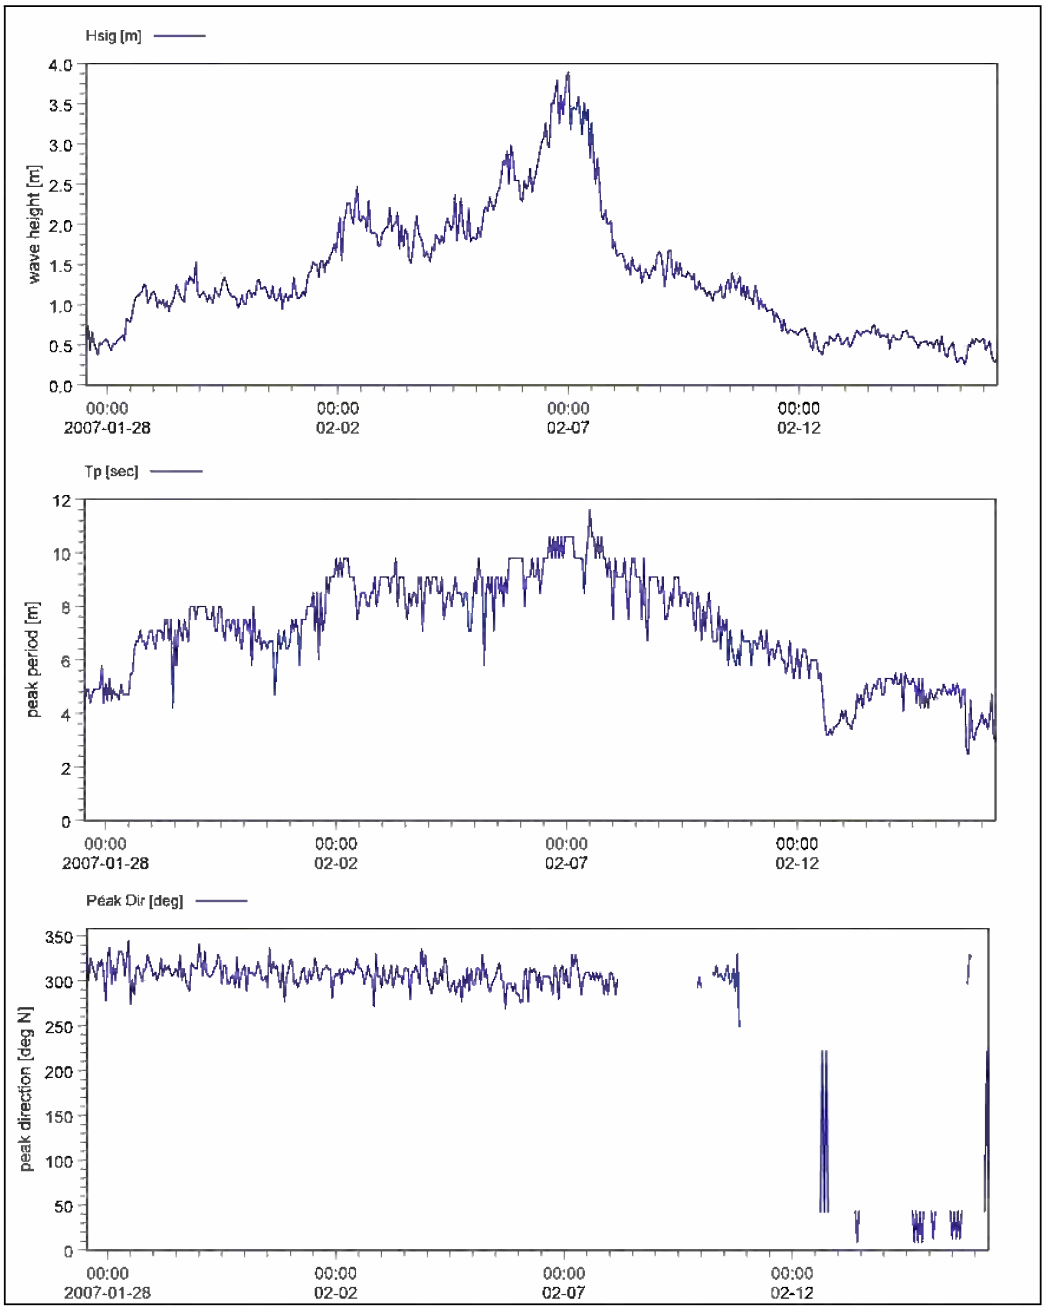
Smooth seas are frequently present at the Project site in the dry season (May to November). The westerly afternoon summer sea breezes are the only conditions favourable for generation of local seas.

Other than local seas, wave events are generated by the following during the wet season:

- tropical cyclones, tracking some distance away, that propagate waves towards Boyd Point;
- tropical cyclones that track over the proposed SoE Port site. The largest waves are produced if conditions are conducive to onshore winds; and
- monsoon winds that occasionally blow over long fetches that may commence in the Arafura Sea. Although these winds are not the same strength as cyclonic winds they still generate very active sea conditions in the Weipa area.

DERM has operated a long-term wave buoy site in Albatross Bay since 1978. Recorded summer data from this site indicates that significant wave heights (H_{sig}) are below 1m for more than 95% of the time. Hourly wave data statistics were also collected at the study site from August 2006 to March 2008. During this time two notable wave events occurred, one associated with Tropical Cyclone *Nelson* on 6 February 2007 and the other with ex-Tropical Cyclone *Helen* on 7 January 2008. The highest significant wave heights at the site during Tropical Cyclone *Nelson* were 3.5m from the north-west, characterised by peak energy wave periods (T_p) of ten seconds.

The wave measurements shown in **Figure 6-11** are associated with strong winds from the north-west that were generated by Tropical Cyclone *Nelson*'s low pressure system in the southern half of the Gulf of Carpentaria, as shown in **Figure 6-12**.



Note: Reliable directional data was not available after February 8, 2007

Figure 6-11 Boyd Point Wave Data Statistics during Tropical Cyclone Nelson

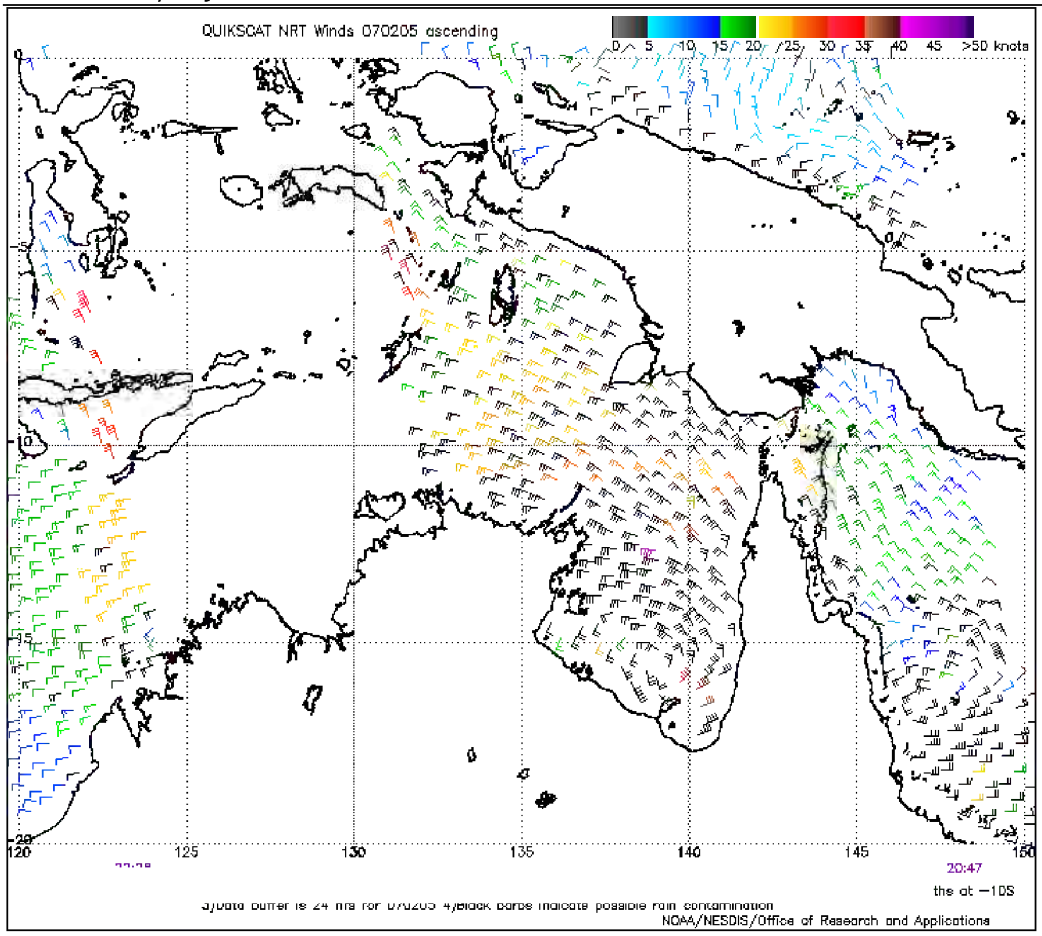


Figure 6-12 Tropical Cyclone Nelson Wind Field 5 February 2007

A Holland wind model and a SWAN (Simulating Waves Nearshore) wave model were used to simulate 15 historical events and to obtain a time series of wave parameters at the study site for inclusion into the coastal process models used to assess shoreline changes. A regular grid was developed, with a mesh resolution of 2km to suitably resolve the wind field. Wind fields used to generate waves acting on the study site can be of a regional scale and, to represent these, the model extents included the whole of the Gulf of Carpentaria, as shown in **Figure 6-13**.

Coastal processes were modelled by using wave height, period and direction information extracted from the wave model results at the proposed port site.

Modelled wave heights were compared with the actual DERM wave buoy measurements (non-directional) located in Albatross Bay. As shown in **Figure 6-14**, the relationship is reasonably linear. However, wave heights at the buoy site are limited by depth.

The relationship between modelled mean wave direction at the proposed port site and at the DERM wave buoy site is shown in **Figure 6-15**. Wave refraction in the shallower water of Albatross Bay accounts for differences in mean direction.

Figure 6-16 indicates that for the wave events modelled, directions were predominantly from the north-west, west, and south-west sectors. More of the large waves occur in the south-west and west sectors shown in **Figure 6-16**, resulting in higher sediment transport up the coast towards Boyd Point. As the alignment of the shoreline between Pera Head and Boyd Point is approximately 210°N, waves from the north-western sector tend to arrive at the shoreline square-on, resulting in minimal longshore movement.

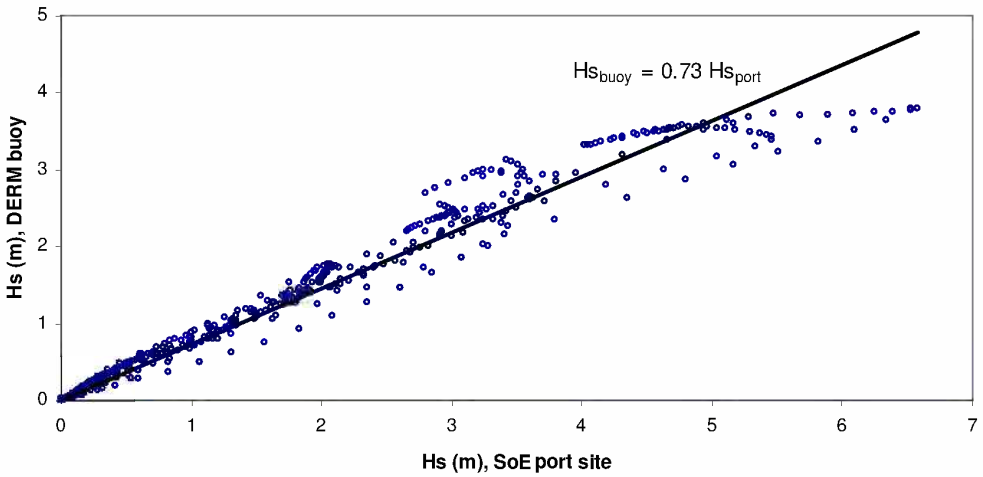

Figure 6-14 Modelled Highest Significant Wave Height at Proposed Port vs Measured at Buoy

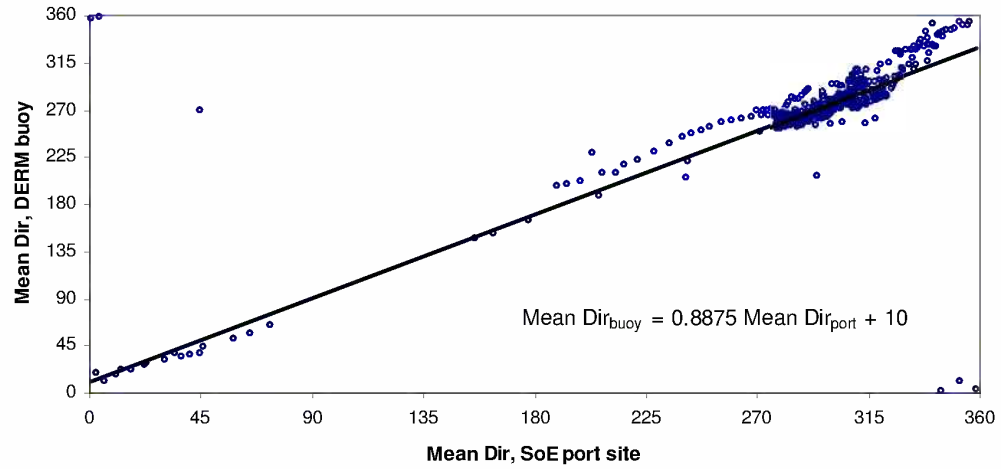

Figure 6-15 Modelled Mean Wave Direction at Proposed Port vs Measured at Buoy

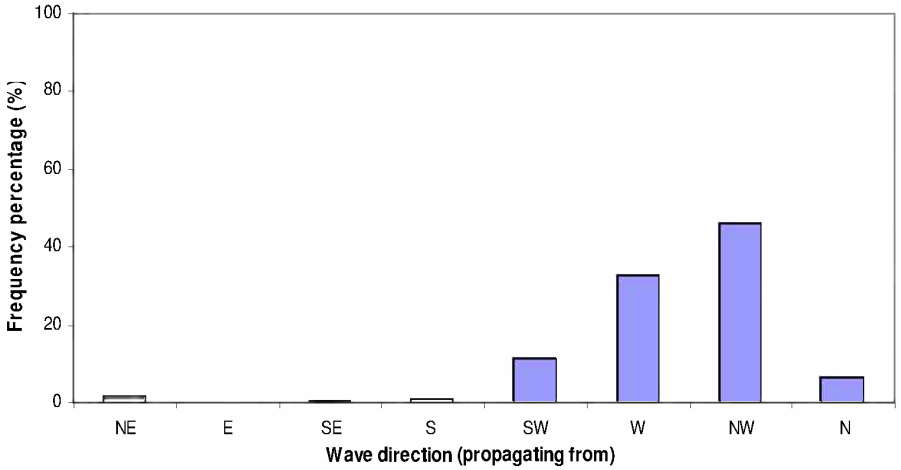

Figure 6-16 Modelled Wave Direction Frequency of Occurrence at Proposed Port Site

6.1.5 Sediment Movement

The beach either side of the proposed port site is relatively straight as shown in **Plate 6-1**. Longshore transport of beach sand occurs during storm events and the extent depends on wave height, direction, and storm duration. Calculations, using modelled wave data, show that over time there has been a net movement of approximately 12,000m^3 of beach sand per cyclone season transported towards Boyd Point. The largest single sand movement event of 86,000m^3 towards Boyd Point occurred during Tropical Cyclone *Dominic* in April 1982.

Mobilisation of fine sediments surrounding the dredge area is a function of the cohesive or non-cohesive nature of the material and the bed stresses that are able to be developed under prevailing current and wave conditions. The material within the dredge area mainly consists of cohesive sediments at least out to about 4km from shore where sediments increase significantly in sand content (refer **Section 6.5.4.2**). Once the current and wave conditions overcome the critical bed-shear stress, sediments will begin to move.

Normally the critical bed-shear stress is not greater than 0.3N/m^2 for a weakly consolidated mud and 1.2N/m^2 or greater for a moderately consolidated mud (mud is the combined silt and clay fractions).

Calculations show that the critical bed-shear stresses are exceeded when significant wave heights are larger than 1m during a neap tide, assuming the bed is weakly consolidated. During spring tides, the peak flood and ebb current forces alone are almost enough to initiate sediment motion and any additional wave action exceeds the critical bed-shear stress associated with fresh deposits of fine sediments. Larger waves will result in high concentrations of the fine bed material in suspension and higher turbidity of the waters around Weipa and the Project area. Changes in sediment movement as a result of the wharf trestle structure and berth dredging area are discussed in **Section 6.9.1**.

Plate 6-1 View at Beach Level Looking South (towards proposed port site)

6.2 Marine Protected Areas, Conservation Areas and Biodiversity Areas

Section 7.2 discusses protected areas, conservation areas and biodiversity areas from Cape York to the Project area. These relate largely to terrestrial habitats and wilderness areas which may include riverine and estuarine habitats including the Embley and Hey Rivers.

There are currently no similar protected, conservation or biodiversity areas specific to the marine environment. However, there is a current proposal by the Queensland Government to declare a fish habitat area (FHA) under the *Fisheries Act 1994* over the northern portion of Albatross Bay. Public consultation on the matter is currently being conducted. The area of Albatross Bay concerned is that north of 12° 36′ 00″ south. The existing Albatross Bay spoil ground and Port of Weipa entrance channel are south of the boundary of the proposed FHA.

The Australian Government is currently completing the marine bioregional planning process for the North Marine Region which covers more than 715,000 square kilometres of ocean covering the Gulf of Carpentaria, Arafura Sea and the Timor Sea as far west as the Northern Territory – Western Australian border. Within the region, five "Areas for Further Assessment" have been defined. "Areas for Further Assessment" are not the proposed boundaries for new marine reserves. Instead, they are intended to aid further analysis of information at a more detailed scale and assist in the design of new marine reserves. Based on ecological information and information obtained from key stakeholders on human activities within the "Areas for Further Assessment", the location and zoning arrangements of a new network of marine reserves will be developed. The Project area is not included within any of the five areas being further assessed.

6.3 Marine Habitats

Albatross Bay is recognised as containing environmentally important marine habitats (Baker and Sheppard, 2006). Key benthic marine habitat components and their associated environmental values in the vicinity of the Project marine infrastructure are discussed below and include:

- inshore and offshore reefs;
- mangroves;
- seagrass; and
- soft sediments.

6.3.1 Benthic Habitat Survey Methods

Benthic (sea floor) habitat surveys were completed within the Project area during October 2007, June 2008, November 2008, June 2009 and June 2010. A combination of towed video sled and drop camera video techniques were adopted for this study, allowing the survey of multiple sites in a short period, providing key information to describe the distribution and structure of benthic habitats. Towed video sled was used over low profile soft sediment habitats. Towed video transects covered a distance of 100m and had a field of view of approximately 0.5m width. Drop camera video was used over patchy reef habitat, seagrass areas and the proposed port entrance channel. The field of view was approximately 0.5m width. Vision was captured as the boat drifted, ranging from about 20m to 50m transect lengths. Detailed reef habitat surveys also utilised drop camera video methods at grid point (refer **Section 6.3.1.1**) and captured an area of 0.5m x 0.5m using a frame. In-water surveys were not undertaken due to potential safety risks posed by salt water crocodiles in the area. Refer to **Figure 6-17** and **Table 6-2** for survey locations and techniques.

6.3.1.1 Detailed Reef Habitat Surveys

Detailed drop camera video and towed video sled techniques were used between Pera Head and Boyd Point (inclusive) to systematically survey sponge, soft coral and fringing hard coral reef habitats in the immediate vicinity of the proposed port development during October 2007 and June 2008. These techniques assess the percentage of live benthic cover, provide diversity estimates via still imagery analysis and allow mapping of habitat distribution. Detailed sampling grids incorporating 125m spacing were applied over Pera Head and Boyd Point, facilitating the inspection of approximately 415 benthic survey sites. The *Coral Point Count with Excel Extensions* software (CPCe – Version 3.4) was used to analyse still images obtained from the video footage. Benthic community cover and diversity was assessed by randomly locating 20 points over each image. The underlying benthic biota from these 20 points was classified as follows:

- coral – massive coral, branching coral, tabulate coral, encrusting coral, foliose coral;
- gorgonian coral;
- hydroids;
- sponges;
- soft coral;
- algae – brown macroalgae, green macroalgae, red macroalgae, coralline algae, seagrass; and
- other biota – anemone, ascidians, holuthurians, sipunculid, bivalve, gastropod, zoanthid, nudibranch, bryozoan, crustacean, sea pen.

6.3.1.2 Dominant Reef Habitat Surveys

The distribution of dominant reef habitat types (hard coral or soft-coral – sponge) between Boyd Point and Thud Point were determined through site inspection following inference from available bathymetric charts, bathymetric survey commissioned by RTA and interpreted aerial photography. Slope analysis overlain with detailed contour information was also applied to assist in the delineation of reef patches. Drop camera video inspection was undertaken at Pera Head and Thud Point to assist in confirming the inferred presence of these reef areas. Detailed drop camera video surveys (described below) in 2007 and 2008 had already confirmed the extent of reef habitats at Pera Head and Boyd Point.

Drop camera video inspection was also undertaken from Nine Mile Reef approximately 6km south-south-west of the proposed disposal ground. This is the nearest substantial seabed feature to the proposed spoil ground.

Inspection of potential reef habitat south of Thud point was not undertaken due to the very low likelihood of turbid plumes extending inshore beyond Thud Point. This was confirmed through turbid plume modelling (refer to **Section 6.9.2.2**).

6.3.2 Inshore and Offshore Reef Habitats

While the vast majority of the Gulf of Carpentaria consists of open sandy and muddy habitats, some reef habitat occurs. Fringing and nearshore reefs occur on many parts of western Cape York and are recorded in parts of Albatross Bay, including much of the southern foreshore and Jantz/Duyfken Point (Baker and Sheppard 2006), but are generally poorly mapped.

The iron stone formations present along the western Cape York shoreline support the development of shallow fringing hard coral and soft benthos reef communities. Reef habitat similar to what is present within the Project area is located approximately 75km to the north of Albatross Bay, in the vicinity of the mouth of Port Musgrave (refer **Figure 1-1** for regional map). Dog Reef extends approximately 7km to the south of the mouth of Port Musgrave and

averages about 800m in width. It is a rocky algal reef system with patchy live hard and soft coral cover along its deepest fringe. Kerr Reef is situated approximately 16 km north-north west of the mouth of Port Musgrave, and supports a high live hard coral cover compared with inshore reef areas (Pers. obs. T. Koskela 2009).

There are also recently discovered deeper sub-tidal reefs in the Gulf of Carpentaria that are well below the surface and consist of a thin and patchy veneer of live corals (Harris *et al.* 2004). None of these deeper reefs are known to occur in the vicinity of the study area.

6.3.2.1 Proposed Port Area

Near shore fringing reef communities in the vicinity of the proposed port area occur at Boyd Point, Pera Head and between Pera Head and Thud Point. These comprise both reefs containing hard corals and low profile reefs containing soft coral – sponge assemblages. The reef habitats have established primarily over ironstone formations. Overall, reef systems between Boyd Point and Thud Point covered approximately 418ha (refer **Figure 6-18**), comprising 144ha of validated reef extent and 274ha of inferred reef. A breakdown of reef habitats is included in **Table 6-3**.

Three abiotic habitats – silty sand, coarse sand and rock – were identified around Boyd Point and Pera Head. Video results confirm the presence of fringing and submerged reefs located at Boyd Point, approximately 2.0km north of the proposed port, and Pera Head approximately 2.8km south of the proposed port. These reefs cover an area of approximately 49ha and 72ha, respectively. Results of percentage cover for sponges, soft corals and hard corals are presented in **Figure 6-19**. Percentage cover of reefs between Pera Head and Thud Point was inferred from the detailed Boyd Point and Pera Head survey on the basis that the reefs occupied similar inshore environments and appeared similar during drop camera video inspections.

Hard corals over the reef areas include species from the following genera: *Porites*, branching *Acropora*, *Turbinaria*, *Monitipora*, *Lobophyllia*, *Platygyra*, *Pavona* and *Favia*. Identification of corals to species level was not possible as this would have required scientific divers entering waters where saltwater crocodiles pose a safety threat. While hard corals are present, there is also abundant sponge and soft-coral fauna and marine algae.

Two small patches of submerged sponge and soft coral reef occur 150m south of the proposed port, and another two approximately 1km north-east of the proposed access channel. Together, these habitats total approximately 23ha. Sponge and soft coral assemblages adjacent to Pera Head are estimated at 48ha (refer **Figure 6-19**). Inferred extent of sponge – soft coral habitat between Pera Head and Thud Point is estimated to be approximately 117ha.

A summary of reef areas and extent of their dominant benthic assemblage (hard coral or sponge – soft coral) is provided in **Table 6-3**.

Table 6-3 Inshore Reef Areas and Extent of Dominant Benthic Assemblages

Location	Total area (ha)	Hard Coral (ha)	Sponge – Soft Coral (ha)
Boyd Point	49	49	0
Port area (between Boyd Point to Pera Head)	23	0	23
Pera Head	72	24	48
South from Pera Head to Thud Point (inferred)	274	157	117

Images of benthic habitats from Boyd Point reef, Pera Head reef, the port area, Thud Point reef and open benthic habitat within the departure channel area are provided within **Plate 6-2**.

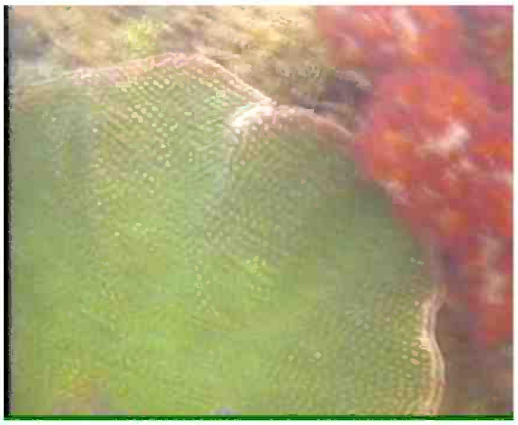
Boyd Point – Mixed branching soft corals, hard corals, rocks, sand and Sarcophyton (soft coral)

Boyd Point Reef Spur – Seawhips, soft corals, entrusting algae and zoanthids

Pera Head – Turbinaria hard coral, seawhips, rocks and entrusting algae



Pera Head – Turbinaria hard coral and soft coral

Pera Head – Branching soft corals, polyps out

Pera Head – Soft corals, rock and coarse sand substrate at base of reef slope

Shallow reef spur south of Pera Head – Montipora and Turbinaria hard corals.

Inner channel alignment – Sponges, bryazoans and encrusting algae

Port berth area – Open silty sand with sponge

Port berth area – Open silty sand

Sponge reef adjacent to Port development

Sponge reef adjacent to port development

There is a paucity of published information on lifecycles of nearshore corals in the Gulf of Carpentaria. Gilmour et al (2006) described a similar paucity of information regarding reef areas of the Pilbara in Western Australia, especially for mid and inshore reef corals. Gilmour et al (2006) note that, in contrast to mid to offshore reef corals, which commonly are broadcast spawners having gametogenic cycle a year, many of the species of inshore and coastal reefs do not mass-spawn or have variable modes of reproduction that are poorly described. This includes some of the most abundant coral species. Inshore corals of the genera *Porites, Pavona* and *Turbinaria* were identified to generally have colonies that are separate sexes and spawn heir gametes over protracted periods of several months, possibly at times other than the major spawning period. In addition, brooding corals, including corals from the families Dendrophyliidae, Faviidae, Acroporidae and Pocilloporidae, are also identified as common in inshore areas and characteristically have several gamete producing cycles over the warmer months. Gilmour et al (2006) concluded that there is a tendency for some of the most abundant species of corals not to spawn synchronously over a few nights each year, particularly on inshore reefs. This means that their patterns of reproduction are unpredictable and largely unknown. The situation discussed by Gilmore et al (2006) may reflect the situation of inshore reef areas of the Gulf of Carpentaria and therefore specific times of the year that corals within the Project area may reproduce are difficult to predict, although it may be concluded from the above research that mass spawning events do not take place within the Project area.

The importance of these reef systems (Boyd Point to Thud Point) in a regional context is considered to be high, as they support resources that are of conservation, cultural, commercial and recreational importance. In particular, near shore sponge and soft coral habitat provides a food resource for a range of turtle species in the area. The importance of inshore reef areas to marine fauna and fisheries is presented in **Sections 6.6** and **6.7** respectively.

6.3.2.2 Proposed Spoil Ground

Drop camera video survey within and adjacent to the proposed spoil ground did not identify any seabed features such as patch reefs. The proposed spoil ground location was selected primarily due to the absence of such features. The area is characterised by flat, unvegetated, soft sediment (refer **Sections 6.1.1** and **6.3.5**) that is considered to be of lower habitat value than reef or vegetated benthic habitats.

Nine Mile Reef is located approximately 6km south-south-west of the proposed spoil ground (refer to **Figure 6-18**) and is estimated to cover an area of approximately 287ha, based on available bathymetry information and video inspection. Its structure contains mixed sponge and soft coral assemblages developing a low profile reef system in depths approximately –22 to –25mLAT, arising from a silty sand substrate and occasional rock outcrops. Zoanthid colonies were observed at some locations clearly attached to the rock structure, their large polyps keeping fine silt deposition clear of their tissues.

Nine Mile Reef is accessed frequently by recreational fishers targeting species such as mackerel, cobia, tuna, finger mark and trevally.

6.3.3 Mangrove Habitat

Mangroves provide nursery habitat for species of fisheries significance including barramundi (*Lates calcarifer*), banana prawns (*Peneaus merguiensis*) and mud crabs (*Scylla serrata*). Mangroves provide a structurally complex habitat that can provide food and protection directly for juveniles and are a source of carbon that is exported by prevailing hydrodynamic processes to other areas, contributing widely to foodwebs elsewhere in the region.

The Albatross Bay mangrove assemblage is extremely diverse and is the most extensive system of mangroves on the eastern Gulf of Carpentaria. Thirty-six species of mangrove have been recorded on western Cape York and 30 of these are found in Albatross Bay (Duke, 2006). The mangrove assemblage of the Albatross Bay area is dominated by closed *Rhizopora*, *Avicennia* and *Ceriops* forests.

Mangroves are absent from the foreshores at and adjacent to the proposed port area (refer **Plate 6-3**), Hornibrook ferry terminal location (refer **Plate 6-3**) and Humbug barge terminal location.

Plate 6-3 Proposed Port Location (left) and Proposed Hornibrook Ferry Terminal Location (right)

The foreshore at the location of the proposed Hey River barge/ferry terminal has a thin mangrove fringe (1–2 trees wide), established over a mud and gravel shore at the base of a low pisolite plateau.

A maximum of 400m^2 of mangroves would be required to be removed to construct the Hey River barge/ferry terminal**.** At this location there is a narrow band of low-growing mangroves fringing the high tide zone. The mangrove species in the Hey River estuary include:

- *Rhizophora stylosa* (red mangrove);
- *Bruguiera gymnorhiza* (large-fruited orange mangrove);
- *Avicennia marina* (grey mangrove); and
- *Aegiceras corniculatum* (river mangrove).

The extent of mangrove clearing represents approximately 0.008% of RE 3.1.1a and 0.003% of the mangrove communities within the Project area (refer **Table 7.10**). The potential impacts on marine fauna associated with the removal of 400m^2 of mangrove habitat are discussed in **Section 6.9.3**.

6.3.4 Seagrass Habitat

Seagrass habitats in the Albatross Bay area provide nursery habitat for fish and macroinvertebrates such as tiger prawns (*Peneaus semisulcatus* and *Peneaus esculentus*). Seagrass beds also provide habitat for species of conservation significance such as Dugongs (*Dugong dugon*), Green Turtles (*Chelonia mydas*) and various species of pipefish (Order Sygnathiformes). Six species of seagrass have been recorded in Albatross Bay (Roelofs *et al.* 2003):

- *Halodule uninervis;*
- *Syringodium isoetifolium;*
- *Enhalus acoroides;*
- *Halophila decipiens;*
- *Halophila ovalis;* and
- *Thalassia hemprichii.*

Seagrass beds are typically present in the more sheltered areas of Albatross Bay, including the lower reaches of the Embley and Mission Rivers and Pine River Bay and are largely restricted to

shallow sand and mud banks of less than 4m below mean sea level (MSL) (Roelofs *et al.* 2003) or –2.2mLAT.

The Department of Employment, Economic Development and Innovation (DEEDI) (formerly the Department of Primary Industries and Fisheries) has been undertaking annual seagrass monitoring within the Port of Weipa since 2000. This monitoring is undertaken at three scales, with more intensive monitoring occurring near port and shipping infrastructure:

- mapping of seagrass distribution and community type within the entire Port of Weipa limits, including Albatross Bay and the Embley, Hey, and Mission Rivers and Pine River Bay. This survey is helicopter-based and occurs approximately every three years with surveys so far undertaken in 2000–2002, 2005 and 2008;
- annual mapping of seagrass distribution and confirmation of species composition in a defined Intensive Monitoring Area (IMA; refer **Figure 6-20**) which focuses on meadows in the vicinity of the port and shipping infrastructure in the Embley and Hey Rivers; and
- annual assessment of seagrass distribution, species composition and abundance in five core monitoring meadows (A2, A3, A5, A6, A7; refer **Figure 6-20** meadow for locations) primarily in the Embley River.

The most recent (2008) survey of the entire Port of Weipa (Chartrand and Rasheed 2009) identified approximately 3200ha of seagrass present primarily in aggregated patches, with continuous cover representing only about 10% of seagrass area. The mapped area was the lowest recorded over the five surveys completed since 2000.

6.3.4.1 Port Development Area Seagrass Distribution

The regular monitoring of seagrasses within the Port of Weipa does not extend to the southern areas of Albatross Bay in the vicinity of the proposed port development.

Extensive towed video and drop camera video surveys undertaken for the Project between Boyd Point and Thud Point and at the proposed spoil ground location confirmed that seagrass is absent from both these areas.

To the north of Boyd Point, a survey undertaken by Marine Ecology Consulting (cited in McKenzie and Yoshida 2009) identified relatively continuous sub-tidal meadows adjacent to Boyd Bay beach containing *Halophila dicepiens* and *Halodule uninervis*, about 4km north-east of the proposed port. Physical conditions, sediments and prevailing bathymetry were unlikely to support the occurrence of seagrass within the footprint of the proposed port development (Rasheed, Pers Comm. 2010). These assumptions support findings from several site-based surveys within the study area which did not find seagrass.

Other surveys undertaken between 1984 and 1988, and identified from the DEEDI Coastal Habitat Resources Information System (CHRIS) database, reported seagrass meadows south of Thud Point at Norman Creek and the Gulf beaches of Aurukun. These meadows are summarised as:

- sparse (1%) cover of *Halophila ovalis* adjacent to the mouth of Norman Creek, about 15km south of the proposed port; and
- 5% cover of *Halophila decipiens* located approximately 45km south of the proposed port area near Aurukun.

The location of the three identified patches of seagrass in Boyd Bay and south to Aurukun is indicated on **Figure 6-18**. The seagrass species identified are considered pioneering species and highly variable in their distribution over time.

6.3.4.2 Embley and Hey River Seagrass Distribution

In September 2009, it was estimated there were approximately 980 hectares of seagrass in 13 meadows within the bounds of the IMA within the Embley and Hey Rivers (McKenna and Rasheed 2010). This area was consistent with that of the previous four survey years where meadow coverage was the lowest recorded since monitoring began in 2000. Seagrass meadows

The extent and cover of the seagrass beds in Albatross Bay and estuaries can vary significantly on an annual basis with climatic conditions being the main driver of this variation. A review by Chartrand and Rasheed (2009) of seagrass density in the long-term monitoring meadows between 2000 and 2008 indicated declines in density for a number of meadows. These were particularly notable for intertidal *E. acoroides* meadows, with the largest of these meadows (A2) on the intertidal bank opposite Lorim Point reported to have been declining since 2000. The changes in biomass were largely a response to regional and local climate conditions, driven particularly by tidal exposure, temperature and solar irradiance, leading to "burning" – browning of the leaves and subsequent death. The most recent study in September 2009 identified an improvement in meadow A2 biomass over the 2008 record low but was still substantially below levels observed from 2000–2002. DEEDI considers *Enhalus* meadows in Weipa likely to be vulnerable to further cumulative impacts. While DEEDI considers the driver for *Enhalus* biomass change is tidal exposure, it does not discount that other natural and anthropogenic factors may contribute (McKenna and Rasheed 2010).

Additional detailed inspection for seagrass at the Hornibrook ferry terminal, Humbug barge terminal and Hey River barge/ferry terminal locations was undertaken during July 2009, as described below.

Hornibrook Terminal

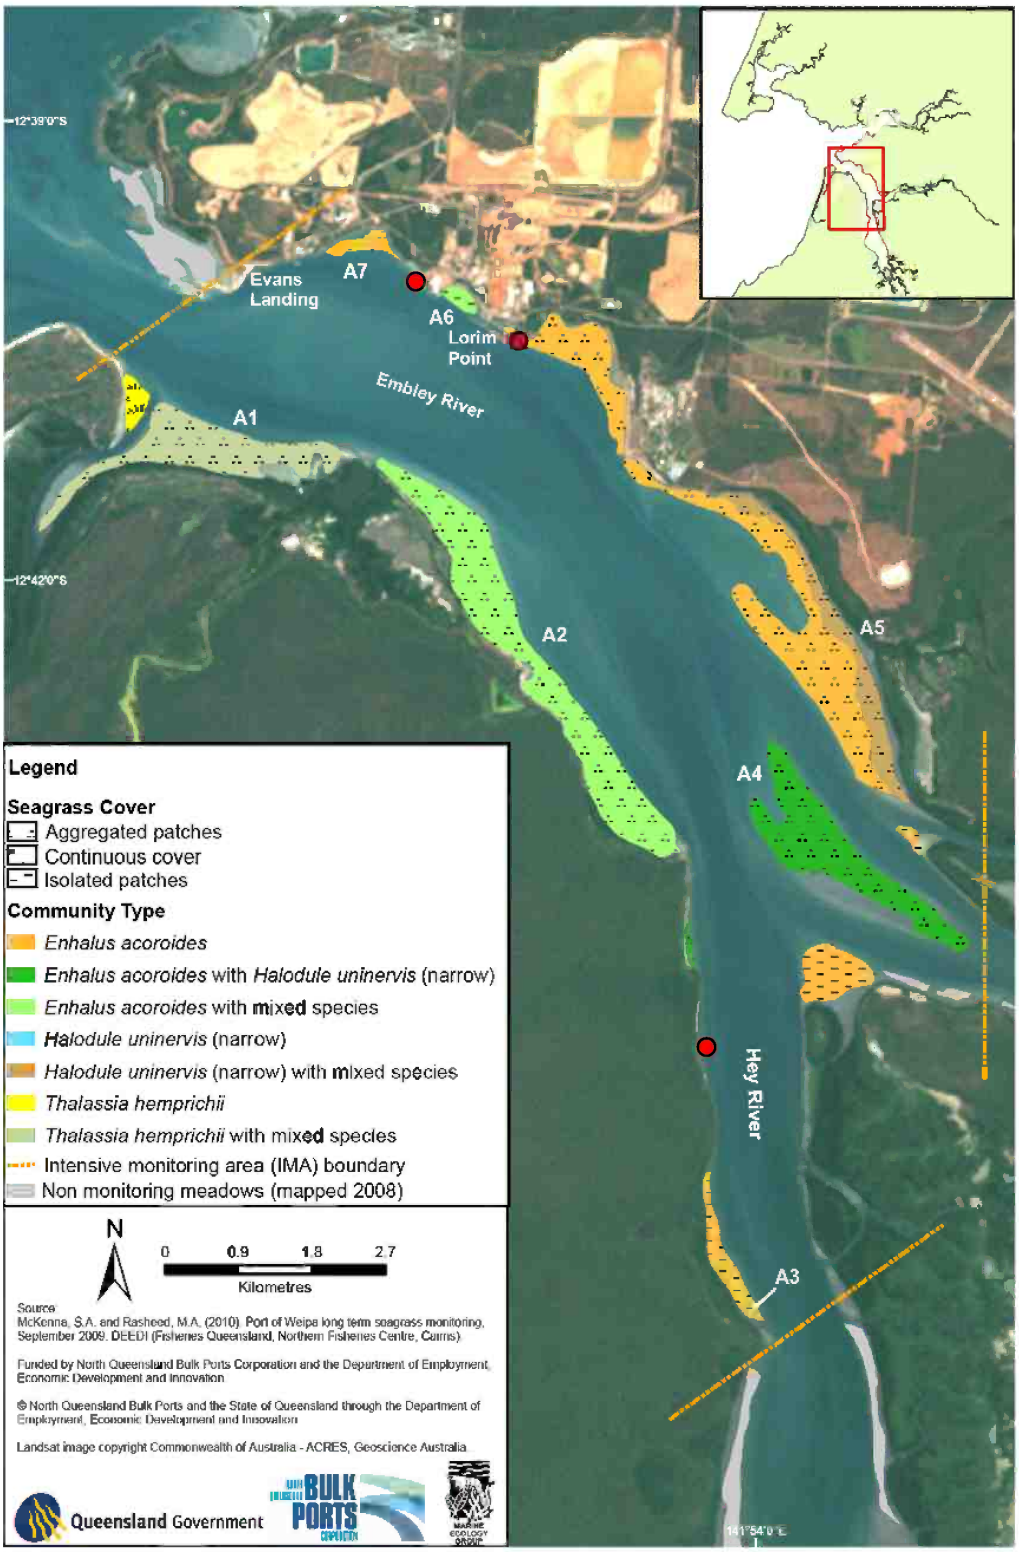
Surveys undertaken by DEEDI (e.g. Chartrand and Rasheed 2009, McKenna and Rasheed 2010) have mapped aggregated patches of *E. acoroides* at Hornibrook Point and landward of the Lorim Point Ship Loaders (refer **Figure 6-20**).

Drop camera video survey of the sub-tidal banks at Hornibrook Point was undertaken in July 2009 as part of the present study to identify the presence of seagrass within or immediately adjacent to the proposed Hornibrook ferry terminal dredging footprint. The survey did not identify seagrass within the dredging footprint or in areas landward of the Lorim Point Ship Loaders, however *E. acoroides* was identified approximately 50m east of the proposed terminal to a maximum depth of approximately 0.3mLAT (–2.1mMSL). The substrate within the dredge footprint area comprised bare, soft silts (refer **Plate 6-4**).

The absence of seagrass during the present survey is unlikely to be due to seasonal absence during the winter survey period since *E. acoroides* is not a highly seasonal or pioneering seagrass species. Further, no seagrass rhizome material was observed during sediment collection studies for contaminant assessment. The absence of seagrass is plausible given the most recent mapping prepared by DEEDI (McKenna and Rasheed 2010) indicated only aggregated patches of *E. acoroides* were present in the vicinity of Hornibrook Point and within the adjacent embayment to the east (refer **Figure 6-20**).

Humbug Terminal

Surveys of the proposed Humbug Terminal area and surrounds in July 2009 did not identify seagrass within or immediately adjacent to the proposed dredging footprint. However, visual inspection during early May 2010, coinciding with peak spring tides, did reveal isolated patches of *E. acoroides* in good condition within and adjacent to the proposed dredge footprint at low tide. The presence of isolated patches of *E. acoroides* is consistent with recent survey data reported by McKenna and Rasheed (2010) (refer **Figure 6-20**). While isolated seagrass was present, substrates at these locations were mixed, combining bare soft silts with patches of shell, sand and rubble. A range of other benthic biota was observed, including sponges, soft coral – seawhips, turfing algae, *Sargassum sp.*, and hydroids (refer **Plate 6-5**). A large patch



Note: Red dots indicate proposed barge/ferry terminal locations.

Figure 6-20 Seagrass Meadow Type and Cover – Embley and Hey River Estuaries, 2009

Plate 6-4 Bare Soft Silts within the Dredge Footprint

Plate 6-5 Coarse Sand and Shell Layer Winnowed from the Prevailing Current with Sea Whip (left) Hydroids Colonising Rubble Field Near the Intertidal Zone (right)

of exposed rubble was observed within the intertidal zone between Humbug Wharf and the Weipa sewage outfall, a distance of approximately 300m. A range of encrusting biota was associated with this rubble field.

Hey River Terminal

At the Hey River Terminal location, steep cliff lines, rocky beach and a thin mangrove fringe border a 20–30m wide intertidal habitat comprised of mixed mud, rock and rubble. Subtidally, shell, mud and sand substrates continue into deeper waters of the adjacent Hey River channel (refer **Plate 6-6**).

Seagrass monitoring between 2000 and 2009 (Chartrand and Rasheed 2009; McKenna and Rasheed 2010) in the vicinity of the Hey River Terminal location occasionally reports a very thin patch of isolated seagrass (refer **Figure 6-20**). The species composition of this seagrass appears to vary over the years, being recorded as absent in 2000, 2003, 2006–2007 and 2009, as *Halodule uninervis* with *Halophila ovalis* in 2001, as *E. acroides* with mixed species in 2002, and as *E. acroides* in 2004–2005 and 2008.

Preliminary drop camera surveys undertaken over the Hey River Terminal dredge footprint in October 2007 and November 2008 as part of the present study did not record any seagrass.

Additional detailed survey was undertaken in June 2009 (refer **Figure 6-45**) to confirm the absence of seagrass within the dredge footprint and adjacent areas. Based on the prevailing tidal conditions, drifting drop camera video inspection was undertaken along 12 transects encompassing the proposed footprint and adjacent areas to the north and south to a distance of approximately 300m at a spacing of approximately 50m. Depths of survey varied from approximately +0.3mLAT to –1.8mLAT, which is well within the primary depth range of seagrass reported for the Embley River estuary by Roelofs *et al* (2003) of shallower than –2.2mLAT (–4mMSL). No seagrass was recorded from the drift video transects undertaken at the proposed Hey River Terminal. Further, no rhizome material was observed in sediments collected when testing for contaminant assessment. Due to the timing of the study in winter months, it is possible that seasonally variable seagrasses were absent (e.g. *Halophila ovalis*). Overall though, it is considered that if any seagrasses do occur at the proposed terminal site from time to time, they are likely to contribute minimally to primary productivity in the area.

Inspection of the small cove and associated intertidal zone to the north of the proposed Hey River Terminal also failed to locate aggregated seagrass patches (*E. acoroides* and *Halodule uninervis*) as mapped in 2008 (Chartrand and Rasheed 2009) (refer **Figure 6-20**). Rather, this intertidal area was dominated by a dark rock and rubble substrate.

Isolated seagrass patches have been mapped approximately 1km to the east on intertidal banks at the junction of the Embley and Hey Rivers, and about 2km to the south along the shoreline (Chartrand and Rasheed 2009) (refer **Figure 6-20**). Confirmation inspection of these isolated seagrasses was not undertaken as it was considered unlikely that any impacts from the Hey River Terminal construction or operation would extend such distances.

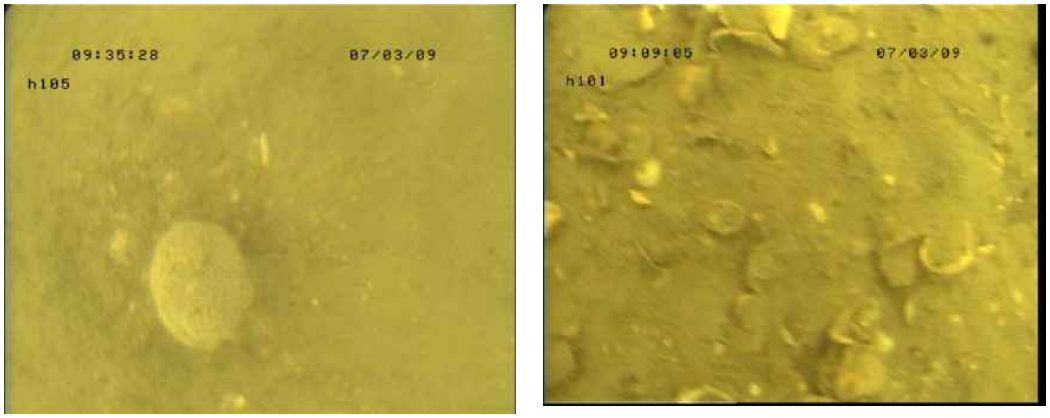


Plate 6-6 Hey River Terminal Area: Soft Coral (left). Mud and Shells Give Way to Gravel and Rocky Rubble Nearer the Intertidal Zone (right).

6.3.5 Soft Sediment Habitats

The study area contains extensive intertidal and sub-tidal soft sediment habitats. The development footprints for all marine infrastructure components of the Project (port area, proposed spoil ground, Albatross Bay spoil ground, Hornibrook ferry terminal, Humbug barge terminal and Hey River barge/ferry terminal) have been confirmed by field inspection as consisting primarily of soft sediment habitats that contain sparse epifauna typical of soft sediments, such as seapens and tube dwelling anemones, soft corals or sponges. **Figure 6-21** shows the types of unvegetated seabed at the proposed new spoil ground.

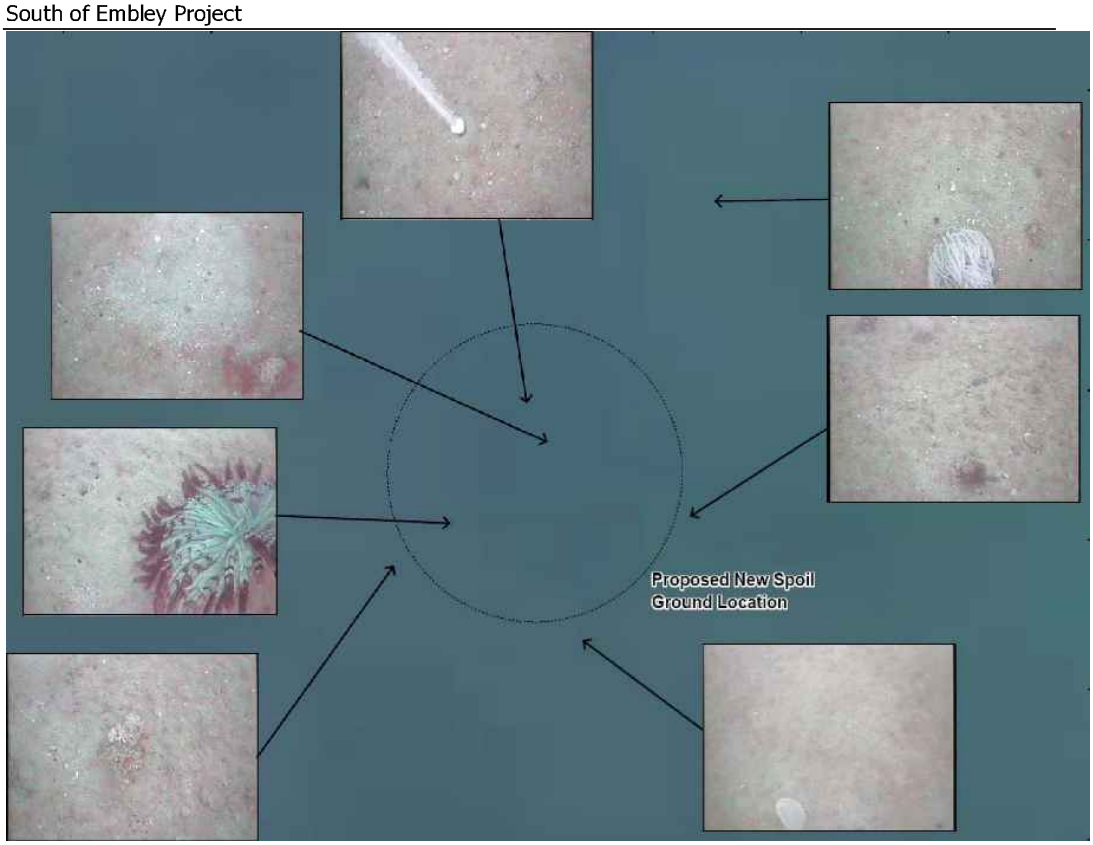

Figure 6-21 Seabed at the Proposed New Spoil Ground

While the environmental value of these habitats is generally considered less than that of vegetated habitats, primary production in these habitats can still be quite high through microscopic benthic algae, particularly in shallow water. These areas can also contain diverse and abundant assemblages of macrobenthic infauna. Soft sediments also provide habitat for a number of fish species that prefer shallow unvegetated habitats such as golden trevally (*Gnathanodon speciosus*), black spotted dart (*Trachinotus baillonii*) and whiting (*Sillago* spp.).

6.4 Water Quality

This section describes existing marine water quality conditions in the areas where the Project marine infrastructure would be located. The objectives of this section are to:

- identify background physicochemical and chemical water quality conditions at the proposed port area, barge/ferry terminals (Embley and Hey Rivers), existing Albatross Bay disposal ground and proposed new spoil ground offshore from Boyd Point;
- compare background water quality to applicable guideline criteria for the protection of aquatic ecosystems; and
- define key natural processes that act to drive water quality conditions within the study area, in particular the fate of suspended sediments.

6.4.1 Environmental Values and Water Quality Objectives

The *Environmental Protection (Water) Policy 1997* (EPP Water) is the principal legislative basis for water quality management in Queensland, and embodies the principles of the National Water Quality Management Strategy. The EPP Water includes a process for determining environmental values (EVs) (or uses) of waterways and corresponding water quality objectives

(WQOs) for different indicators of water quality. Protecting or achieving the identified WQOs for a waterway means the corresponding EVs and uses of that waterway will be protected. EVs and WQOs can be included in Schedule 1 of the EPP Water, and have been for the following areas:

- Moreton Bay/south-east Queensland;
- Mary River Basin/Great Sandy Region;
- Douglas Shire waters; and
- Trinity Inlet.

No EVs or WQOs have been determined for the Western Cape York area. The marine ecosystem in the Project area is effectively unmodified and, under the EPP (Water), is considered of high ecological value. The EV to be protected is the biological integrity of the aquatic ecosystem. In the absence of specified WQOs, the *Queensland Water Quality Guidelines* (DERM 2009a) recommends a range of other state or national guidelines. For aquatic ecosystem protection, the *Australian and New Zealand Guidelines for Fresh and Marine Water Quality* (ANZECC/ARMCANZ 2000) is recommended. Relevant ANZECC/ARMCANZ (2000) guideline values have been used for comparison with background water quality in the Project area.

6.4.2 Marine Water Quality Assessment Methods

Assessment of marine and estuarine water quality for the Project was informed primarily from the results of the following surveys:

- short-term field investigations for the Project (October 2007);
- long-term in-situ logger data collection for the Project (November 2007 to March 2008); and
- long-term Boyd Point in-situ data logger information from December 2006 to July 2007 and December 2007 to March 2008, sourced from Chalco.

6.4.2.1 Short-term Field Investigation

In October 2007, 24 water quality monitoring sites were sampled over the Project development area. Locations included the Embley and Hey Rivers, the Port of Weipa spoil ground in Albatross Bay, the proposed port area, the proposed new spoil ground and near shore reef and soft sediment habitats adjacent to the proposed port. A map showing water quality sampling sites monitored during the October 2007 survey is presented in **Figure 6-22**.

At each site, physicochemical conditions were measured using a multi-parameter water quality meter which recorded salinity, oxidation-reduction potential, pH, temperature and turbidity. Dissolved oxygen was not recorded due to probe failure.

In addition, water samples were collected at approximately 0.5m below the surface from each site for laboratory analysis. Sampling was completed in accordance with DERM's *Water Quality Sampling Manual* (EPA 1999) and analysed for nutrients, dissolved metals and chlorophyll-a.

Results of the sort-term field investigations are discussed in **Section 6.4.3**.

6.4.2.2 Long-Term Data Collection

Three in-situ water quality data loggers were installed to characterise ambient water quality at the proposed port area, proposed new spoil ground and at the nearest sensitive receiving habitat at Pera Head. These sites represent the primary area of port dredging, spoil disposal and a sensitive receptor close to the dredging works, respectively. In-situ logger equipment was supplied, maintained and calibrated by James Cook University (JCU). A summary of data recording and logger deployment is provided in **Table 6-4.** Long-term water quality data logging was not undertaken in areas of minor dredging proposed for the barge/ferry terminals or at the existing Albatross Bay spoil ground which would receive the dredge spoil.

The loggers recorded turbidity and light (photo-synthetically active radiation, PAR) approximately 0.5m above the seabed at 10-minute intervals from November 2007 to March 2008. The JCU turbidity instrument uses an optical backscatter sensor to measure concentration of particles in the water. The output from this instrument is within +/–2% that of a standard nephelometer for silt and clay size particles and is expressed as Nephelometric Turbidity Units-equivalent (NTU-e).

Table 6-4 Summary of Project Long-Term Data Collection Program

Boyd Point	12/2006	Installation	Data provided by Chalco
	7/2007	Monthly downloads	Data provided by Chalco

Additional data from two in-situ loggers previously installed by JCU at Boyd Point to the north of the proposed port area was also considered. Reports of this data (GHD 2007c-2007h) were provided to RTA by Chalco and encompassed the period December 2006 to July 2007. The location of all data loggers is shown in **Figure 6-22**.

Results of the long-term data collection are discussed in **Section 6.4.4**.

6.4.3 Short-Term Physical and Chemical Water Quality Assessment

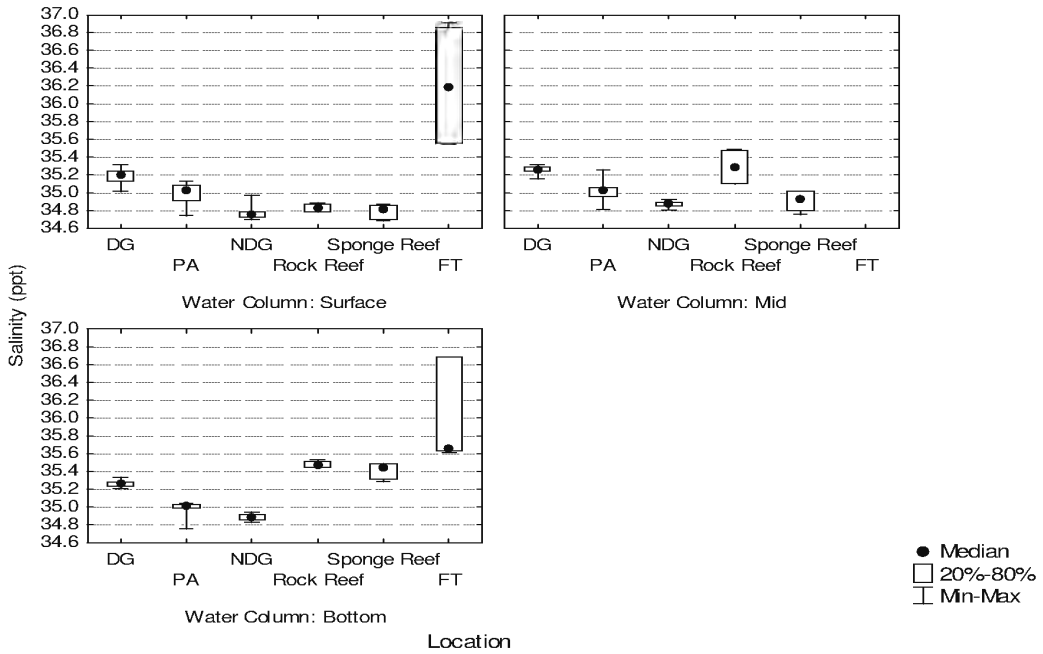
This section summarises the physical and chemical results from water sampling completed during the short-term field investigations in October 2007.

6.4.3.1 Salinity

The concentration of salinity in marine waters sampled ranged from 34.7 parts per thousand (ppt) adjacent to the proposed port development and spoil ground area to 36.9ppt at the proposed Hey River Terminal location. Apart from the barge/ferry terminal areas, salinity

concentrations in the Embley and Hey Rivers were generally consistent between all sites. Salinity concentrations within the barge/ferry terminal areas were marginally higher and more variable (35.6ppt to 36.9ppt) (refer **Figure 6-23**). In terms of vertical profiling, salinity was similar between surface, mid and bottom depths at each location, except for the rock reef and sponge habitats between Boyd Point and Pera Head, which exhibited a minor increase in salinity at increasing depths.

Salinity typically increases in estuary systems over the flooding tide due to "fresh" seawater intrusion. Interestingly, at the time of sampling, salinity at Hey River was elevated compared with all other sampling locations. It would normally be expected that due to daily freshwater input from the catchment, salinity and conductivity would be lower than those displayed at offshore marine locations. However, it has been previously identified that tropical estuary systems can develop elevated salinities towards the end of the dry season as a result of increased evaporation rates in their upper reaches.

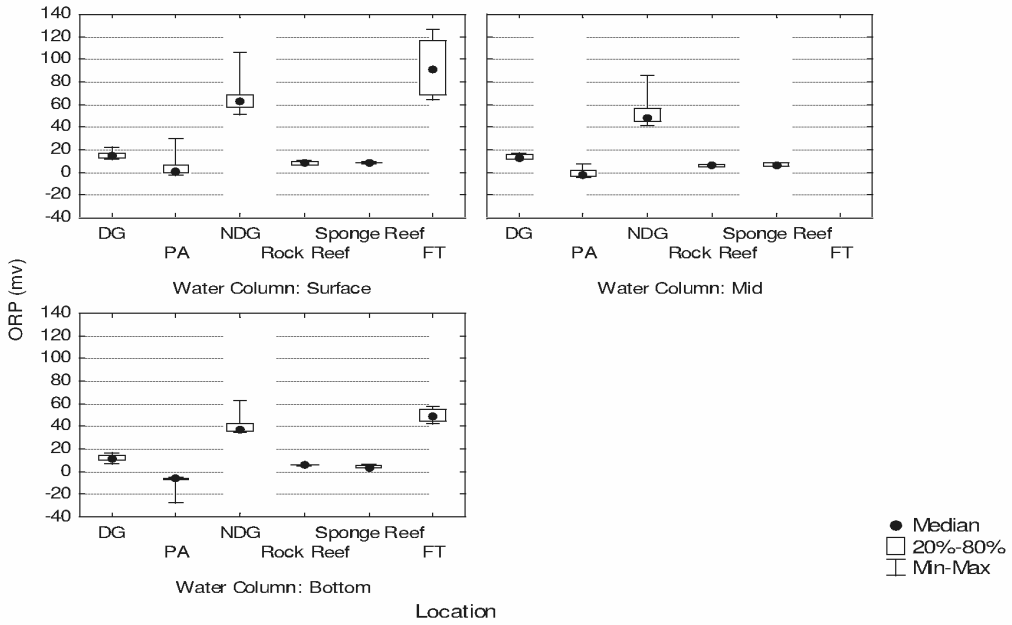


Legend: DG = Disposal Ground – Albatross Bay; PA = Port Area – Boyd Bay; NDG = New Disposal Ground – offshore from Boyd Point; FT = Ferry Terminals.
Note: Mid depths were not recorded at the ferry terminal due to the shallow depth.

Figure 6-23 Salinity Measured (October 2007) at Surface, Mid and Bottom Depths

6.4.3.2 Oxidation Reduction Potential (ORP)

Oxidation reduction potential (ORP) ranged from –27 millivolts (mv) in the port area to 126mv at the Hey River terminal area. The Albatross Bay spoil ground, port area, sponge reef and rock reef areas displayed similar median ORP values of between 0mv and 20mV while the new spoil ground and ferry terminal areas displayed higher ORP values compared with all other locations (median range was between 40mv and 90mv). Generally there was no variation in ORP between surface, mid and bottom depths within each location (refer **Figure 6-24**).

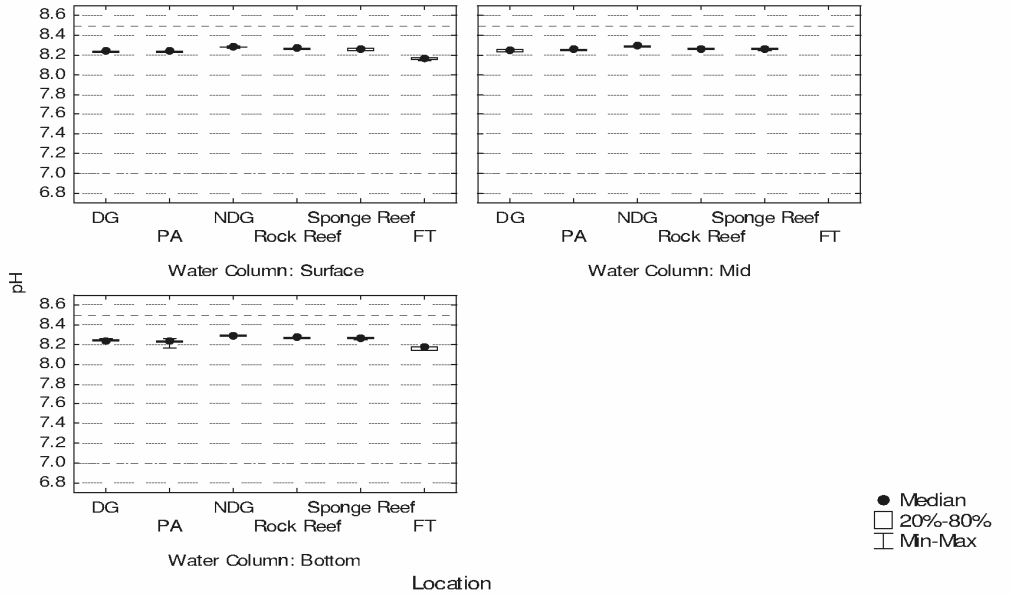


Legend: DG = Disposal Ground – Albatross Bay; PA = Port Area – Boyd Bay; NDG = New Disposal Ground – offshore from Boyd Point; FT = Ferry Terminals.
Note: Mid depths were not recorded at the ferry terminal due to the shallow depth.

Figure 6-24 ORP Measured (October 2007) at Surface, Mid and Bottom Depths

6.4.3.3 pH

pH ranged between 8.14 at the barge/ferry terminal locations in the Embley and Hey Rivers and 8.29 at the proposed new spoil ground. There was no variation in pH within and between locations across all sample depths. All locations were consistent with the ANZECC/ARMCANZ (2000) guideline range of between 7 and 8.5 (refer **Figure 6-25**).

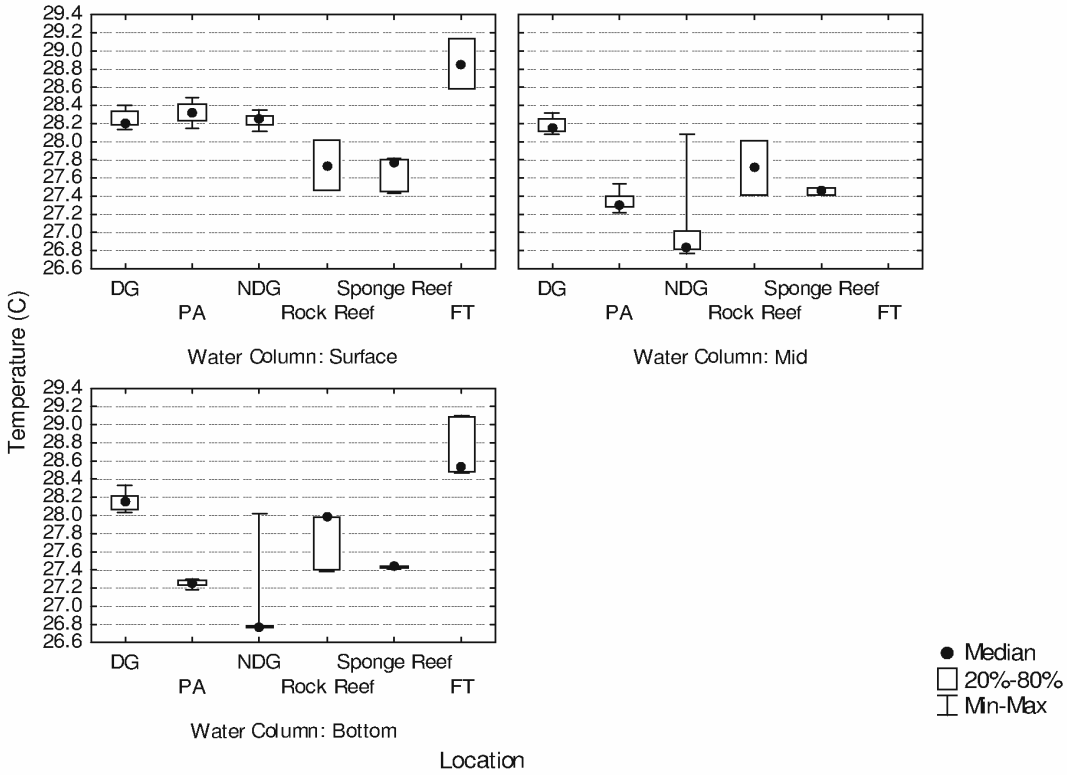


Legend: DG = Disposal Ground – Albatross Bay; PA = Port Area – Boyd Bay; NDG = New Disposal Ground – offshore from Boyd Point; FT = Ferry Terminals.
Red line = ANZECC/ARMCANZ (2000) guideline range.
Note: Mid depths were not recorded at the ferry terminal due to the shallow depth.

Figure 6-25 pH Measured (October 2007) at Surface, Mid and Bottom Depths

6.4.3.4 Temperature

Temperature ranged from 26.8°C at the new spoil ground to 29.1°C at the Hey River terminal area. While surface temperatures remained relatively constant between locations, mid and bottom depth temperatures were more variable (refer **Figure 6-26**).



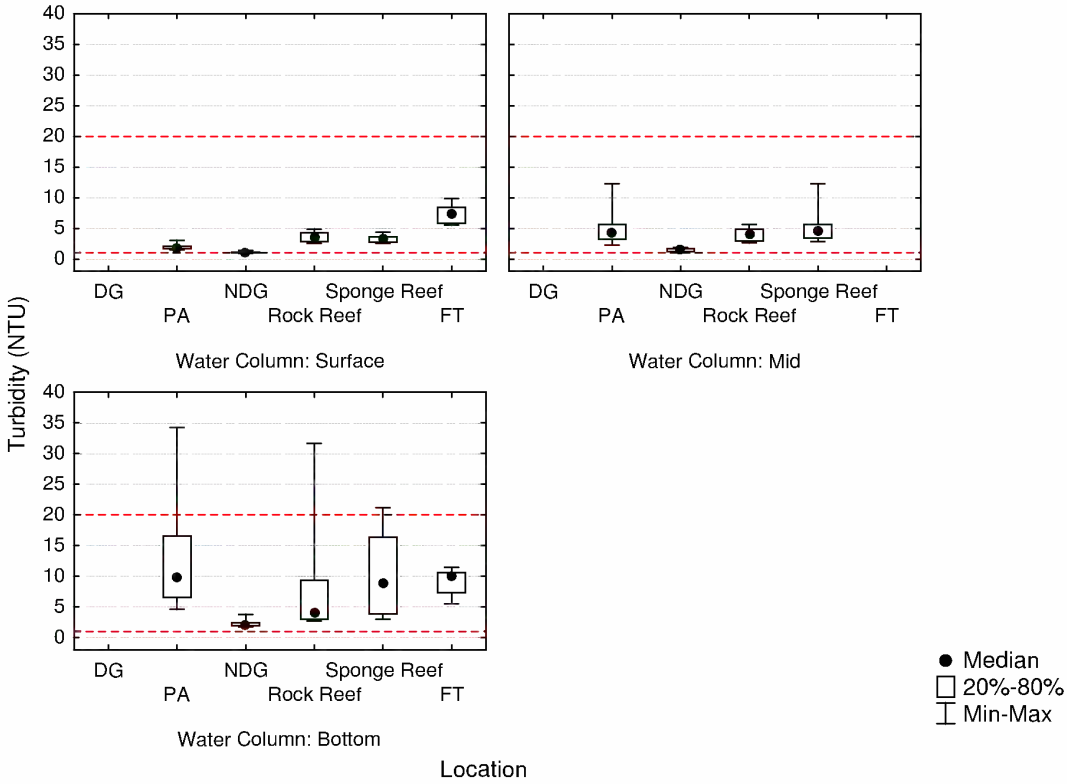
Legend: DG = Disposal Ground – Albatross Bay; PA = Port Area – Boyd Bay; NDG = New Disposal Ground – offshore from Boyd Point; FT = Ferry Terminals.
Note: Mid depths were not recorded at the ferry terminal due to the shallow depth.

Figure 6-26 Temperature Measured (October 2007) at Surface, Mid and Bottom Depths

6.4.3.5 Turbidity

Turbidity was measured with a Troll 9000 side scatter instrument. Values ranged from 0.86NTU at the proposed spoil ground to 34.25NTU at the proposed port area. Generally, median turbidity values were from 0–10NTU at all locations. Both surface and mid column depths tended to be lower and showed less variation in turbidity compared with bottom depths. The deeper waters of the proposed spoil ground did not follow this trend, recording similar turbidity ranges throughout the water column (refer **Figure 6-27**). Median turbidity values from each location complied with the adopted ANZECC/ARMCANZ (2000) guideline range of 1–20NTU (refer **Figure 6-27**). Turbidity concentrations were not recorded within the Albatross Bay spoil ground due to a malfunction of the sampling probe in the field.

Turbidity at estuarine sites recorded the highest median value compared with other locations. High turbidity regimes are typical in estuarine systems, with the effects of catchment runoff, shallow bathymetry and high current velocities mobilising fine sediments into the water column. The functioning of estuary dynamics acts to trap fine sediments, leading to a naturally turbid environment.



Legend: DG = Disposal Ground – Albatross Bay; PA = Port Area – Boyd Bay; NDG = New Disposal Ground – offshore from Boyd Point; FT = Ferry Terminals.
Red line = ANZECC/ARMCANZ (2000) water quality guideline range.
Note: Mid depths were not recorded at the ferry terminal due to the shallow depth.

Figure 6-27 Turbidity Measured (October 2007) at Surface, Mid and Bottom Depths

6.4.3.6 Dissolved Metals

Dissolved metal concentrations in water samples collected from the proposed port area and adjacent soft sediments habitat, Pera Head reef, proposed new spoil ground and the existing Albatross Bay spoil ground are summarised in **Table 6-5**. Summary findings of the metal analyses are:

- cadmium, chromium, copper, manganese, mercury, nickel and lead concentrations were at or below the laboratory limit of reporting (LOR) from all sites;
- aluminium concentrations were consistent across all sample sites, ranging between 34 micrograms per litre (µg/L) and 36µg/L;
- arsenic concentrations were consistent between sites, ranging between 1.7µg/L and 1.9µg/L;
- the concentration of iron in samples from all locations was 70µg/L; and
- with the exception of zinc, all sites displayed metal concentrations consistent with ANZECC/ ARMCANZ (2000) water quality guideline levels. Zinc concentrations ranged between 30µg/L and 120µg/L across all sites, which is above the guideline of 15µg/L.

Table 6-5 Dissolved Metal Concentrations in Water Samples, October 2007

Location	Site Name	Date Sampled	Aluminium	Arsenic	Cadmium	Chromium	Copper	Iron	Manganese	Mercury	Nickel	Lead	Zinc
Unit			µg/L	µg/L	µg/L	µg/L	µg/L	µg/L	µg/L	µg/L	µg/L	µg/L	µg/L

µg/L = micrograms per litre; LOR = limit of reporting by the laboratory
Note: Bold values indicate an exceedance of ANZECC/ARMCANZ (2000) water quality guideline for respective metals

6.4.3.7 Nutrients

Nutrient concentrations reported from the proposed port area and adjacent soft sediments habitat, Pera Head reef, proposed new spoil ground and the existing Albatross Bay spoil ground are provided in **Table 6-6**. Summary findings of the nutrient analyses are:

- Total nitrogen (TN) concentrations ranged between 0.7 milligrams per litre (mg/L) and 1.3mg/L, and mimic Total Kjeldahl Nitrogen (TKN) concentrations. The concentration of TN in samples from all locations was above the ANZECC/ARMCANZ (2000) water quality guideline of 0.1mg/L;
- Ammonia concentrations ranged between 0.01 and 0.04mg/L. Ammonia concentrations in samples from sites located within the existing spoil ground, new spoil ground and rock reef area exceeded the ANZECC/ARMCANZ (2000) guideline of 0.01mg/L;
- Nitrate, nitrite and reactive phosphorous concentrations were at, or below, the LOR in samples analysed from all locations. Compliance assessment was not possible as the LOR provided by the laboratory was above the guideline level for each of these parameters; and
- Total phosphorus (TP) concentrations ranged between 0.03mg/L and 0.06mg/L. All sites exceeded the ANZECC/ARMCANZ (2000) guideline of 0.015mg/L and 0.01mg/L for inshore and offshore environments respectively.

6.4.3.8 Biological

Chlorophyll-a concentrations measured at each location are provided in **Table 6-6.** Chlorophyll-a concentrations ranged between 0.09µg/L and 0.35µg/L. In all samples, the concentration of chlorophyll-a was less than the ANZECC/ARMCANZ (2000) water quality guidelines of 1.4µg/L and 0.9µg/L for inshore and offshore waters respectively.

Marine nutrient and chlorophyll-a concentrations generally demonstrated little or no variation between sites but were elevated against ANZECC/ARMCANZ (2000) guidelines. Nitrate and phosphorous concentrations were found to be similar to previous studies undertaken in Albatross Bay (Burford and Rothlisberg 1999) while chlorophyll-a concentrations were slightly lower.

Table 6-6 Nutrient and Chlorophyll-a Concentrations in Water Samples, October 2007

6.4.4 Long-Term Water Quality Assessment: Turbidity, TSS and PAR

This section summarises the long-term data collected for turbidity, total suspended solids (TSS) and photosynthetically active radiation (PAR) between November 2007 and March 2008 from in-situ data loggers as summarised in **Table 6-4**.

6.4.4.1 Turbidity and TSS

The turbidity recorded at each long-term monitoring location is summarised in **Table 6-7**and presented graphically as a line plot of NTU-e in **Figure 6-28**. Maximum turbidity data was recorded at the three in-situ logger locations during two periods in January and February 2008 (refer **Figure 6-28**). During these two periods turbidity reached levels of 503NTU-e, 339NTU-e and 149NTU-e at the proposed port area, Pera Head and proposed new spoil ground respectively. Median turbidity ranged from 2NTU-e at Pera Head to 13NTU-e at the proposed port area. Mean turbidity values recorded at the proposed port area were significantly higher than mean turbidity values at the proposed new spoil ground and Pera Head locations (ANOVA; $p<0.05$).

Table 6-7 Summary of Background Turbidity Data

Location	No. of samples	Units	Mean	Median	Minimum	Maximum	Standard Deviation
Port area	5341	NTU-e	25.2	15.0	<0.1	503	37.0
		TSS mg/L*	179	106	<1	3566	262
New disposal ground (offshore)	7994	NTU-e	19.0	4.6	<0.1	149	32.1
		TSS mg/L*	135	33	<1	1056	228
Pera Head (inshore reef)	5110	NTU-e	15.4	2.2	<0.1	339	30.2
		TSS mg/L*	109	16	<1	2405	214

*converted using factor of 7.09 (refer **Section 6.4.4.3**)

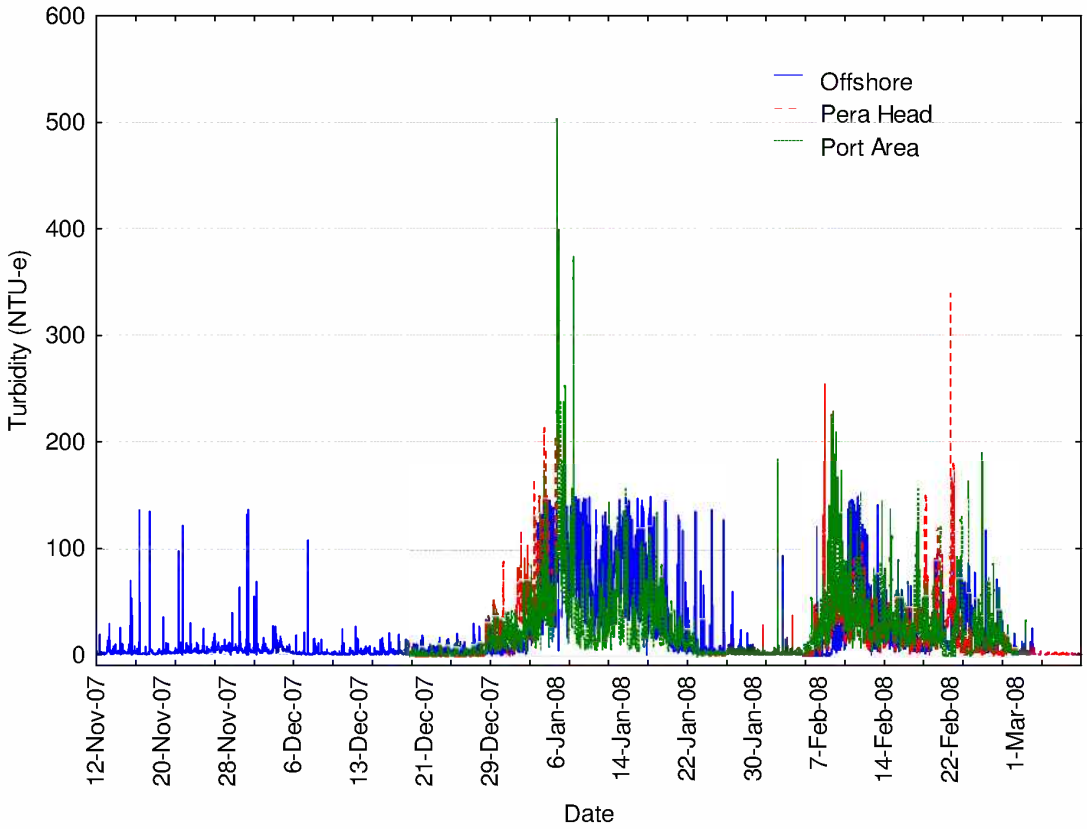

Figure 6-28 Turbidity as NTU-e Measured at Project Locations

6.4.4.2 Photosynthetically Active Radiation (PAR)

PAR measures the spectral range of solar light from 400–700 nanometers (nm), which is the range that organisms are able to use in the process of photosynthesis. The level of PAR penetrating the water column can be greatly affected by turbidity and water depth.

As to be expected, PAR was negatively correlated to turbidity levels at each logger location (refer **Figure 6-29** to **Figure 6-31**). The intensity of light reaching the seabed decreases markedly when suspended materials enter the water column following physical disturbance. Low PAR levels were observed at each logger location with increasing turbidity. Median PAR levels were less than 0.6 micro-Einsteins per square centimetre (µE/cm^2) at both inshore logger locations while the proposed new spoil ground recorded a median of 2.4µE/cm^2. Maximum light levels ranged from 89µE/cm^2 within the port area (refer **Table 6-8**) to 266µE/cm^2 at the proposed spoil ground (refer **Table 6-8**). Pera Head displayed significantly higher ambient PAR levels (mean 13µE/cm^2) compared with all other locations, while the proposed port area displayed considerably lower light levels compared with all other locations ($p<0.05$) (refer **Table 6-8**).

PAR levels were reduced to levels below 2.5µE/cm^2 at median turbidity values greater than 11NTU-e for all locations. Generally, PAR levels within both Pera Head and port site inshore locations were reduced to approximately 0µE/cm^2 PAR between 12 and 18NTU-e. PAR at the proposed new spoil ground was extinguished at median turbidity levels of 8NTU-e.

This relationship includes a function of depth, with significantly more light being stripped by the water column at the proposed disposal site (–23mLAT) as compared to both the proposed port location (–12mLAT) and the Pera Head site (–8mLAT).

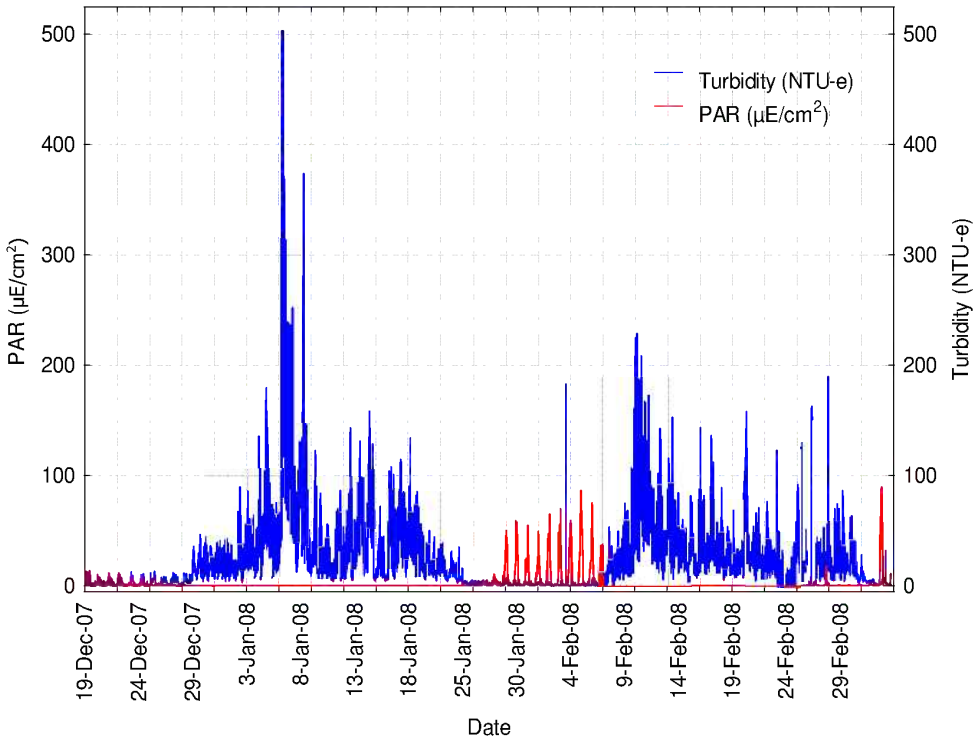

Figure 6-29 Turbidity and PAR Results for the Proposed Port Area

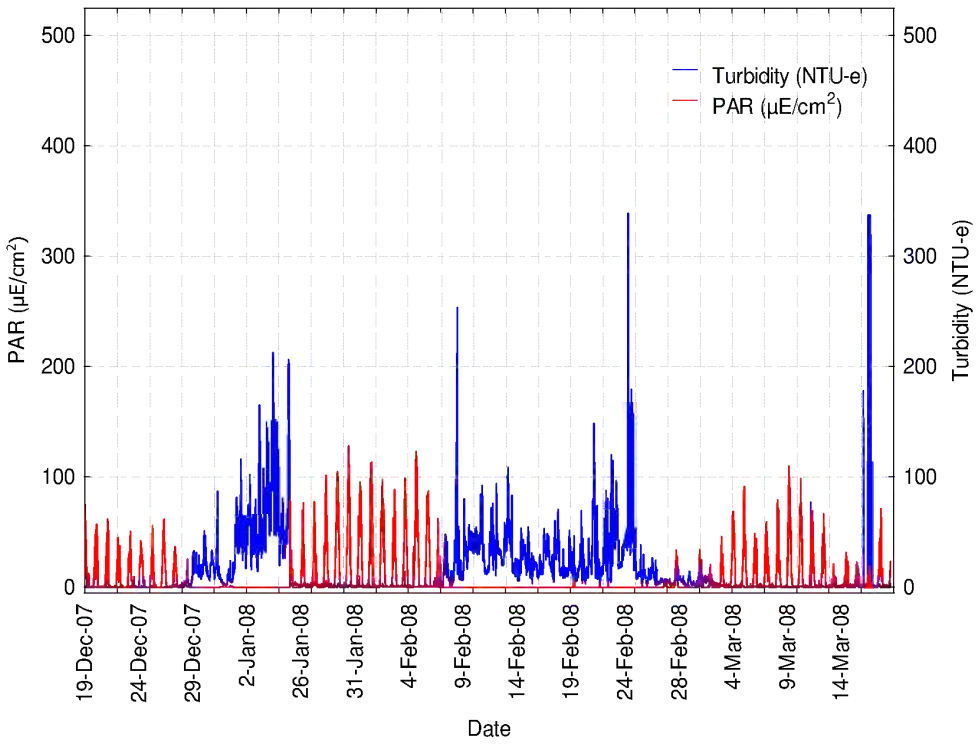

Figure 6-30 Turbidity and PAR Results for Pera Head

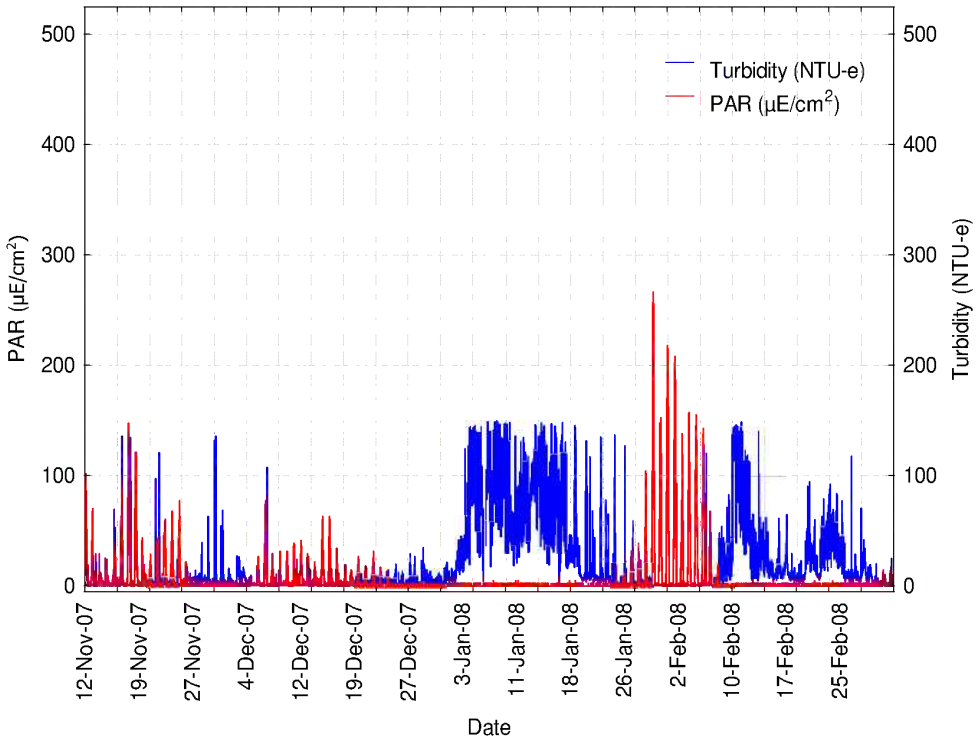

Figure 6-31 Turbidity and PAR Results for the Proposed New Spoil Ground Location

Table 6-8 Statistical Summary of PAR at Project Logger Locations

Location	Parameter	No. of samples	Mean	Median	Minimum	Maximum	Standard Deviation
Port area	PAR (uE/cm^2)	2701	4.2	0.55	0	89.8	11.5
Proposed spoil ground (offshore)	PAR (uE/cm^2)	4052	10.9	2.43	0	266.3	27.8
Pera Head	PAR (uE/cm^2)	2574	13.5	0.36	0	128.1	23.5

6.4.4.3 Turbidity – Total Suspended Solids Relationship

As part of the long-term water quality logger program, James Cook University established a relationship between turbidity (NTU-e) and TSS expressed in mg/L. Establishment of this relationship extended the turbidity/PAR relationship described above to include TSS, which is the primary predictive output of turbidity plume modelling undertaken for dredging projects.

To establish this relationship, the turbidity logging instrument was placed in a large container (50L or greater) with black sides and filled with seawater. The basic approach is to measure turbidity (NTU-e) after a known mass of marine sediment from the study site has been added to the container and stirred with a paddle connected to a slowly rotating electric drill. After a turbidity reading has been taken, a water sample is drawn off from the container and analysed for TSS using standard laboratory techniques. TSS analysis was undertaken by the JCU Australian Centre for Tropical and Freshwater Research which is accredited for these analytical techniques. Additional sediment is then added to increase the recorded TSS concentration and the sampling process repeated to achieve a strong calibration with turbidity (NTU-e).

The turbidity instrument was calibrated using surface sediments obtained at the proposed port location to derive a TSS-NTU-e relationship for existing background conditions. The following relationship was obtained:

TSS (mg/L) = 7.09 x turbidity (NTU-e).

Calibration was also undertaken using a combination of surface sediments and deeper clay sediments from the proposed port location to derive a TSS-NTU-e relationship for suspended sediment likely to be generated by dredging. Due to the nature of this material a different relationship was observed:

TSS (mg/L) = 5.4 x turbidity (NTU-e).

Application of the surface sediment calibration (i.e. 7.09) is appropriate in describing ambient TSS regimes. These have been used in the transformation of logger turbidity data to TSS, the correlation of TSS and light conditions (PAR), and predictions regarding light climate of the reef habitats. The application of the 5.4 calibration factor is appropriate when considering future logger based monitoring results during the dredging program. The variation between the two calibration factors originates from differing particle sizes and optical properties of the sediment, and is important to understand when utilising infield loggers for impact monitoring purposes.

6.4.4.4 Modelled PAR and TSS Correlation

The Pera Head in-situ light logger was established at the edge of hard coral habitat. This logger was deployed for a period of three months in a depth of approximately –8mLAT. PAR was logged simultaneously with NTU-e using a back scatter sensor and, by applying the calibration coefficient of 7.09 developed from previous field sediment sampling (refer **Section 6.4.2**), data in NTU-e was converted to TSS in mg/L. PAR and TSS data from Pera Head was analysed and a relationship developed to define ambient light regimes and allow predictive impact assessment for reef habitats within the Project study area. TSS ranges of 0 to 100mg/L have been plotted against the equivalent mean daytime PAR light regimes (µm/m^2/sec) ($r=0.85$, $p<0.0001$) and the following exponential trend fitted to the data (refer **Figure 6-32**):

$$PAR = 24.687e^{-0.0465x}$$

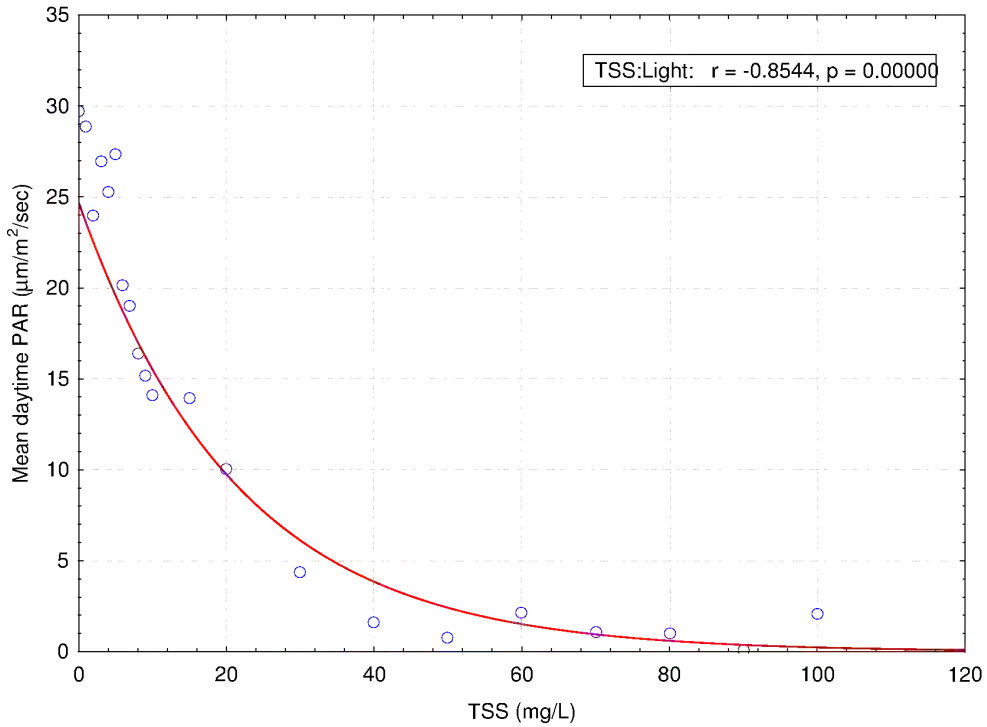

Figure 6-32 Scatterplot of Mean Daytime PAR (µm/m^2/sec) against TSS (mg/L)

By referencing a mean PAR of 500 µm/m^2/sec within the Weipa region (Rothlisberg *et al.* 2005), and adopting the trends presented within the above figure, predicted mean light regimes in 1m depth increments (–8 to –1mLAT) has been completed and light attenuation coefficients (Kd^m) developed for varying ambient TSS regimes (refer **Table 6-9**).

By analysing ambient light regimes, and reviewing lower light thresholds for coral reef survival, a preliminary ranking of the light regime has been developed. These predictions have been developed to help assess impacts from light regime alterations attributable to dredging and discussed within **Section 6.9.2.2**.

The median (50th percentile) of ambient daytime light (PAR) has been recorded at 2µm/m^2/sec from Pera Head. This fits well with published minimal light requirement of 2.0–0.5% surface PAR irradiance for scleractinarian reef building corals (Titlyanov, 1991; Porter *et al.* 1984; and Fricke and Meischner, 1985). Given a mean PAR surface irradiance of 500µm/m^2/sec at Pera Head (Rothlisberg *et al.* 2005) these published minimum light requirements (2.0–0.5%) equate to a PAR light range of approximately 10 to 2µm/m^2/sec. Given a median daytime ambient of 2µm/m^2/sec, the 8m depth contour at Pera Head is considered at the fringe of light regime suited to the long-term survival of inshore corals. Habitats surrounding Pera Head and Boyd Bay confirm a –8mLAT maximum for hard coral growth. Some depth increases in hard coral distribution have been recorded at several locations south of Pera Head. **Table 6-9** presets predicted light regimes down to the 12m depth contour to account for the known maximum hard coral distribution.

Table 6-9 Predicted Mean Light Regimes and Light Attenuation Coefficient (Kd^m) for Varying Ambient TSS Conditions and Depth Intervals (–12 to –1mLAT)

* TSS and PAR results recorded from logger at Pera Head situated at –8mLAT.
Colour regimes indicate (favourable for hard coral growth), (light limited) and (unsustainable for hard coral growth).
TSS = Total Suspended Solids

Given the limits described above, a PAR of 2µm/m^2/s has been set as the lower end of the "light limited" threshold for this study. The upper bound of "light limited" conditions has been set conservatively at 23µm/m^2/s, being the upper quartile boundary of the ambient light distribution, and above the upper light limited range, described by Titlyanov (1991), of 10µm/m^2/sec. Light regimes greater than a predicted daytime mean of 23µm/m^2/s are considered "favourable" for coral habitats and those below a daytime mean of 2µm/m^2/s "unsustainable".

6.4.4.5 Duration of Turbidity Events

Ambient turbidity events in the Project area can last for several weeks, as demonstrated by long-term water quality logger monitoring results.

Pera Head data loggers deployed during 2007–2008 recorded ambient turbidity events of 9 days and 24 days duration at median event TSS concentrations of 248mg/L and 127mg/L respectively (refer **Figure 6-33**). Data captured from Boyd Point (GHD 2008) reported ambient turbidity events of 23 days and 25 days duration, recording median event TSS concentrations of 163mg/L to 184mg/L respectively (refer **Figure 6-34**).

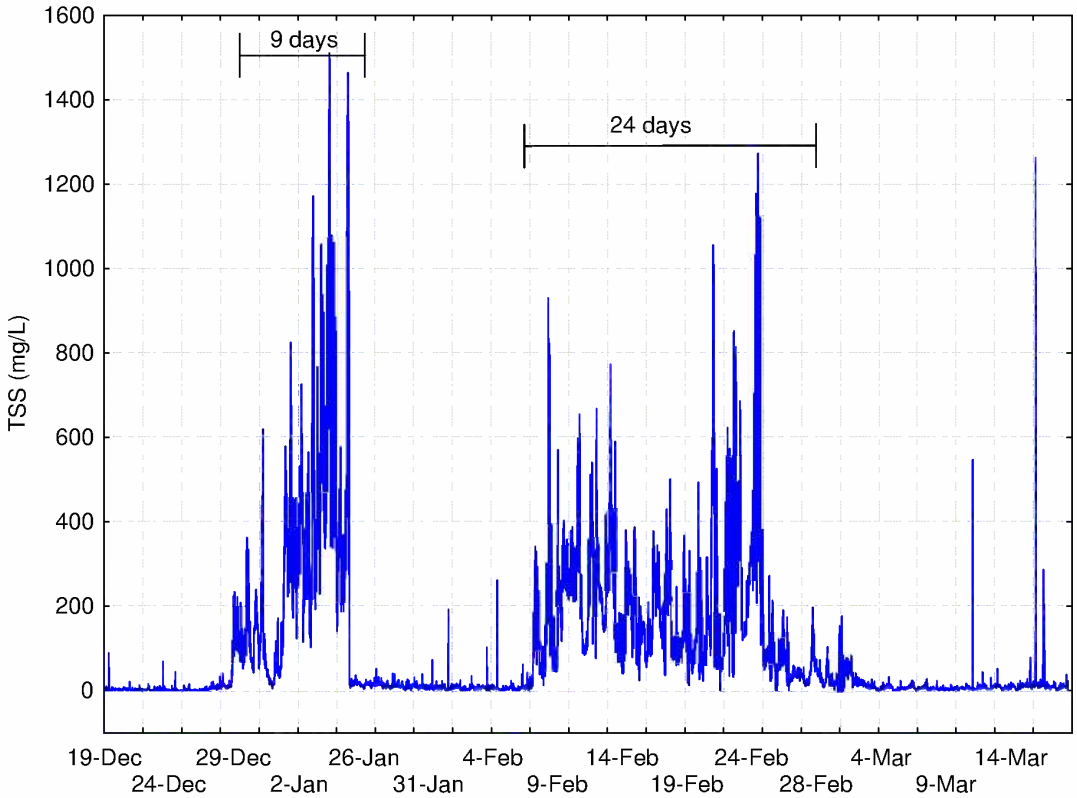

Figure 6-33 Recorded Ambient Turbidity Event Durations December 2007 to March 2008 – Pera Head

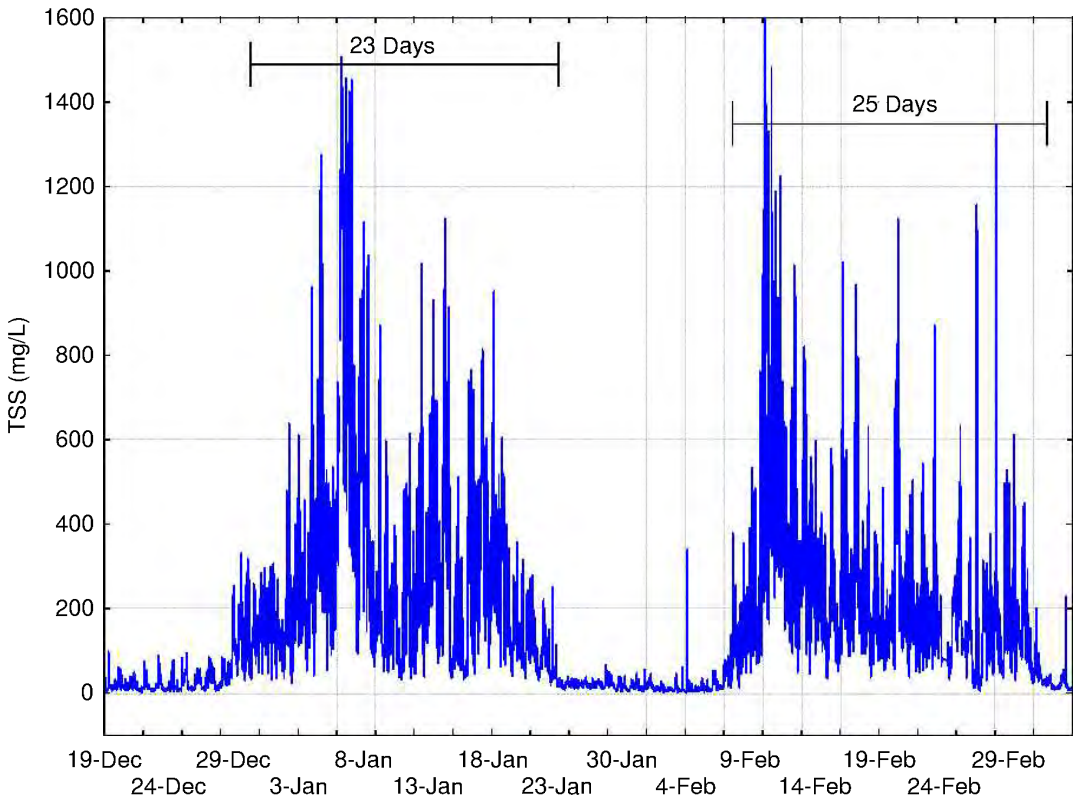

Figure 6-34 Recorded Turbidity Event Durations December 2007 to February 2008 – Boyd Point

Two distinct high ambient turbidity events occurred during the monitoring period from November 2007 to March 2008. These events represent the effects of tropical cyclones and monsoonal lows, which passed through the Gulf region during that period. Although the duration of physical wave and wind effects attributable to these events were experienced at each site over the same period, an extended duration of increased turbidity was recorded at the proposed port location compared to that over nearby Pera Head reef habitat. Field data indicates that even under typical conditions, the coast between Pera Head and Boyd Point, which includes the proposed port area, experiences a general elevation in ambient turbidity over nearby reef habitat. These differences are likely related to prevailing bathymetry, water depth, current dynamics, and increased proportion of fine sediment grain size. Although the Pera Head logger was located in much shallower waters than the port location logger (8m depth versus 12m depth) it exhibited almost 10 days less turbidity elevation.

6.4.4.6 Reef Habitat Turbidity

Ambient turbidity observed at different survey locations can be influenced by the depth, level of wind and wave exposure, bathymetric profile and prevailing sediment characteristics. Detailed video inspection confirmed a general increase in sediment grain size at locations surrounding Pera Head and Boyd Point compared with that of the bay between them. The shallow nature of these reef areas drives mobilisation of fine sediments through the area, with relatively minor wind and wave events being sufficient to mobilise fines and keep these materials in suspension. In combination with the presence of outcropping iron stone, shallow water, and increased light availability, fine sediment mobilisation is considered an important process facilitating the presence of hard coral around Boyd Point, Pera Head and reefs south to Thud Point. Summary statistics confirm these reef areas are subject to increased mean PAR levels (refer **Table 6-8**) and reduced mean turbidity concentrations (refer **Table 6-7**) compared to adjacent nearshore

habitats that don't experience significant sediment remobilisation, such as at the proposed port area between Pera Head and Boyd Point.

6.4.4.7 Key Turbidity Drivers

Turbidity can be generated by a range of natural processes including wind, wave and tidal action.

Wind direction and wind speed data were compared statistically against turbidity data from each logger location (proposed port area, proposed spoil ground and Pera Head reef). Significant differences were observed between wind direction and turbidity values displayed within each logger location ($p<0.05$) (refer **Figure 6-35**). Analysis using Tukeys unequal N HSD (StatSoft 2008) identified significantly higher turbidity values when wind was blowing onshore (westerly direction) compared with offshore (easterly) ($p<0.05$). The increased fetch over open water increases the energy imparted to the system from onshore winds. This process induces waves/swell or local sea chop, which mobilise sediments from the sea floor. Onshore westerly winds dominate the summer monsoon period at the proposed port facility, and can be expected to result in a naturally elevated background turbidity regime at this time.

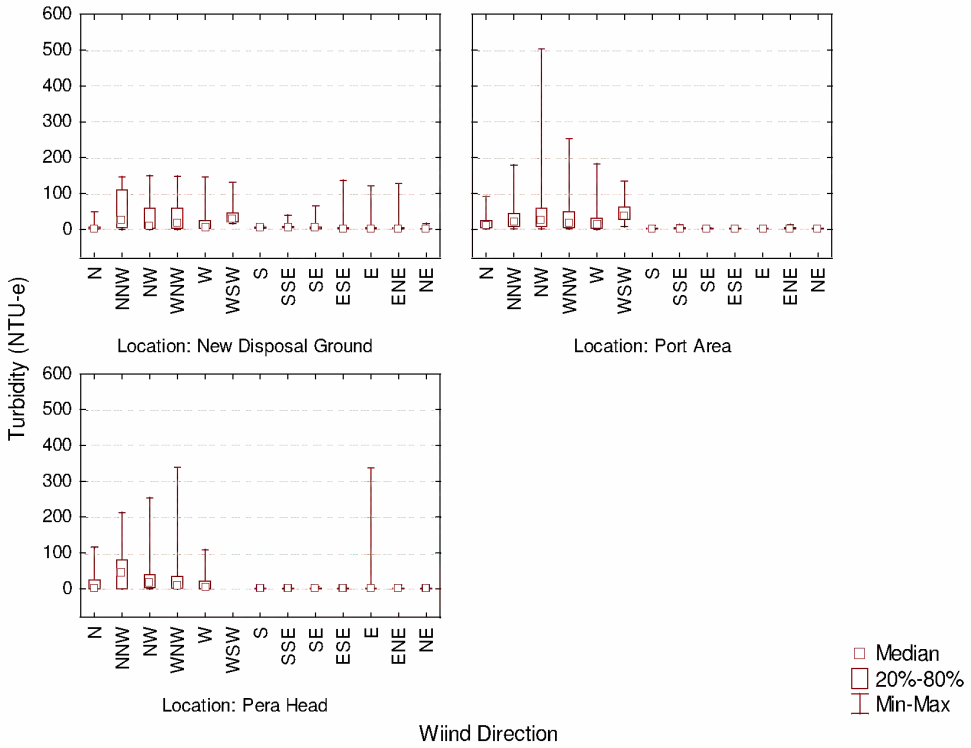

Figure 6-35 Turbidity (NTU-e) and Wind Direction at Project Turbidity Logger Locations

Data for the analysis of tidal influences over turbidity were extracted from Seafarer/Tides (Australian Hydrographic Service 2007) for Weipa Port. Tide data was divided into spring and neap tidal phases defined by tidal amplitude. Generally, neap tides displayed significantly higher turbidity at Pera Head and the proposed new spoil ground ($p<0.05$). However, no significant turbidity differences were identified within the port area between neap and spring tidal phases ($p>0.05$) (refer **Figure 6-36**). Neap tides result in reduced current flow and lower ambient energy within the water column. In the absence of significant wind and wave forces, increased turbidity at the seabed and subsequent sediment deposition can coincide with neap tidal periods.

Wave height and direction is also a critical factor in how ambient water quality is driven at the study site. This is demonstrated to some extent in **Figure 6-35**, which clearly shows the effect that wind direction, and more importantly, the waves generated from it, has on the observed turbidity. Under "event" based wind and wave conditions, the role of spring and neap tidal states in driving observed water quality is reduced markedly.

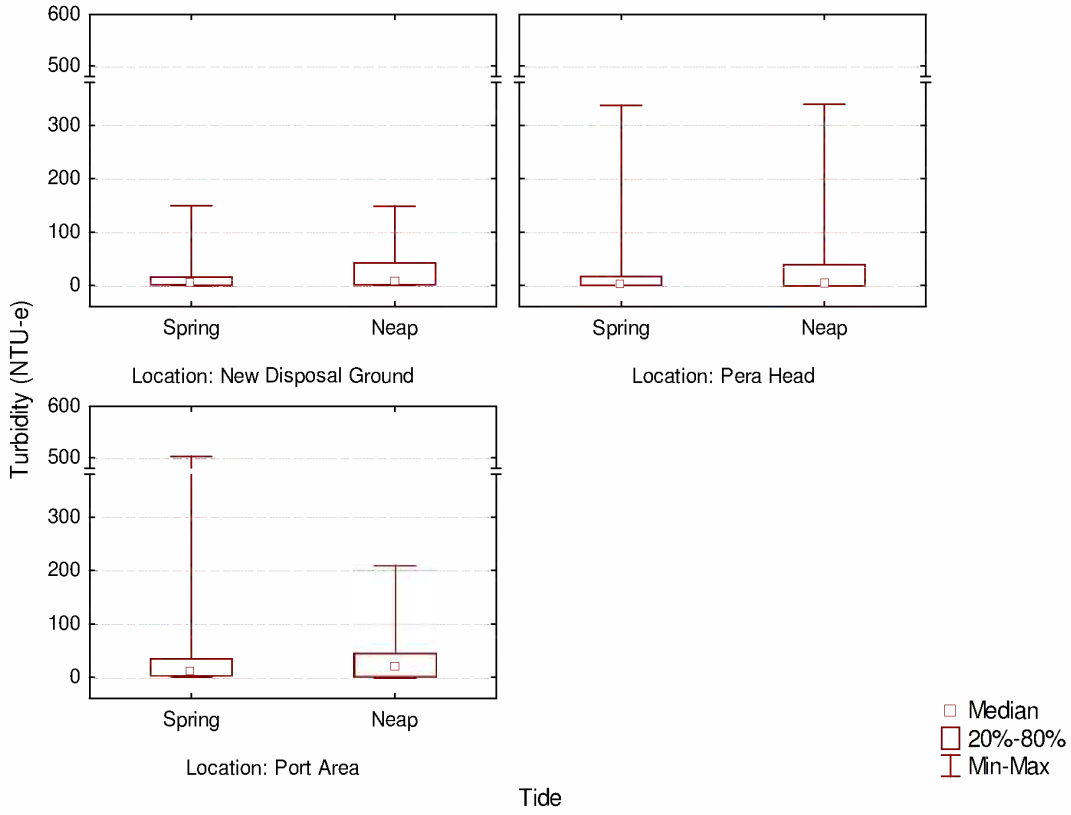

Figure 6-36 Turbidity, Spring and Neap Tidal Phases at Project Turbidity Logger Locations

6.4.4.8 Boyd Point Turbidity

Chalco surveys of Boyd Point turbidity during 2006–2007 confirm the trends identified during these studies for the Project (November 2007 – March 2008). As found in the Project study, it was concluded (GHD 2007c-h) that a coarser sediment fraction at shallow reef systems resulted in a generally reduced turbidity. Data collected from a deeper water logger at Boyd Point (–10mLAT) showed elevated turbidity concentrations, similar to those at the proposed port facility.

6.5 Sediment Characteristics

Dredging of sediments is required at the proposed port development site between Pera head and Boyd Point, and at the barge/ferry terminals at Hornibrook, Humbug and Hey River.

6.5.1 Port Area Dredging and Spoil Disposal Requirements

Approximately 6,500,000m^3 would be dredged as part of the proposed port development, including berth areas and departure channel. The dredging volume required is based on the assumption that the port has to be capable of accepting bulk carrier vessels up to 185,000 dead

weight tonnage (dwt) and 18.1m draft. For the purposes of evaluation studies, it has conservatively been assumed that vessel departures are unrestricted by tides and hence the depth of dredging required has been matched to this assumption.

Dredging is proposed to be undertaken using a cutter suction dredge (CSD), discharging the material part way up the ladder and leaving the material on the seabed for short duration before being extracted by a large trailing suction hopper dredge (TSHD). The cutter suction dredge would work in campaigns of approximately two weeks. This method, which requires rehandling, was selected to minimise the amount of time in overflow mode while using the TSHD compared with loading straight from the CSD to hopper barges. The selected method almost halves the potential overflow period, and fines generation. Overflow would be reduced from approximately 100 hours per week to 60 hours per week. Furthermore, the hopper of the TSHD would be significantly larger than a hopper barge and would provide a greater opportunity for fines to settle during loading. Alternative methods such as bucket dredgers loading into hopper barges would result in an impractically long dredging campaign as their rate of dredging is significantly slower than CSD or TSHD.

Once the TSHD dredge has filled its hopper the sediments will be transported by the TSHD to the proposed new spoil ground located approximately 17km west (central point) of Boyd Bay. Upon entering the designated area for dumping, the dredge would typically slow whilst material is being placed, however, a minimum steaming speed is required to maximise agitation within the hopper and clear dredged material, which would not otherwise be effected if the dredge were to remain stationary. Spoil will be discharged below keel level to minimise turbidity generation. Placement of spoil material at the spoil disposal ground would be completed so as to achieve a relatively uniform cover. The duration of each dump event would be approximately 30 minutes.

The route from loading to the disposal ground is a direct line west-north west from the loading area. There are no obstacles or hazards along this route. The return trip from the dredge area is approximately 4 – 4.5 hours.

Dredging and spoil disposal would be conducted 24 hours a day, seven days a week. Dredging would optimally occur over approximately 36-weeks starting at the beginning of the dry season and continuing until work is completed. This approximate 36-week dredging period does not allow for any delays such as for breakdowns, maintenance, or environmental monitoring, which would extend the duration of dredging but also interrupt suspended sediment plume generation. It also excludes stand-down time for inclement weather which is possible over the tropical wet season. Therefore whilst 36-week continuous dredge period has been conservatively assumed for modelling purposes in the EIS, a two-year Sea Dumping Permit is proposed to allow work to be completed in the following dry season if required. If all necessary approvals are attained, the dredging would occur between May 2012 and October 2013

Detailed dredging procedures would be developed with the dredging contractor following engagement. These procedures will be outlined in the Dredge Management Plan (DMP). A framework for the DMP is provided in **Section 6.10**. The DMP would be developed for approval by DSEWPaC.

Alternative spoil disposal options are not feasible for construction schedule and environmental reasons (refer **Section 1.6.11**). There is no requirement for reclamation in the Port area as part of the Project. Beach nourishment is not feasible due to the high clay content and deposition would likely result in impacts to turtle nesting and hatching success through smothering and change of beach profile. Placement of material on land is not feasible due to the significant volumes involved and the potential for saline water intrusion into a limited fresh groundwater resource. Sea disposal was considered the only viable option for spoil disposal.

6.5.2 Ferry and Barge Terminals Dredging and Spoil Disposal Requirements

The development of barge and ferry terminals at Hornibrook, Humbug and in the Hey River is proposed as part of the Project to provide a transport route for equipment and personnel. Minor capital dredging would be required in each of these areas to accommodate barge and/or ferry access to the proposed terminals. Respective dredge volumes and dredge footprint areas are:

- approximately 18,700m^3 to be removed from the Hornibrook ferry terminal over an area of 10,450m^2;
- approximately 17,300^3 to be removed from the Hey River barge/ferry terminal over an area of 8,250m^2; and
- approximately 10,700m^3 to be removed from the Humbug barge terminal over an area of 5,420m^2.
- annual maintenance dredging of approximately 7,000m^3 combined from each terminal post construction.

All dredge areas would be required to be dredged to a target depth of –2.0mLAT, corresponding to 0–2m of material being removed. Dredged material from these areas is proposed to be placed at the existing Albatross Bay spoil ground.

The dredging contractor has yet to be appointed and final details of dredging method will be determined with the dredging contractor. However, following a review of dredging equipment options for the Project, dredging for offshore spoil disposal is anticipated to be undertaken using a barge-mounted backhoe/dipper dredge, with a bucket up to approximately 13m^3.

The excavator/dipper type of dredge is not self-propelled but can move itself during the dredging process by manipulation of spuds and the excavator / dipper arm. A typical sequence of operation is as follows:

- The dredge, scow barges, and attendant plant are moved to the work site.
- The dredge is moved to the point where work is to start; part of the weight is placed on the forward spuds to provide stability.
- A split hull barge is brought alongside and moored into place by winches and cables on the excavator/dipper dredge.
- The dredge begins digging and placing the material into the moored barge.
- When all the material within reach of the bucket is removed, the dredge is moved forward by lifting the forward spuds and manoeuvring with the bucket and stern spud.
- The loaded barges are towed to the disposal area and emptied by bottom dumping. These procedures are repeated until the dredging operation is completed.

Material will be disposed of at the spoil ground via a split hull barge. The barge would typically dump the material in an arc within the spoil ground as it turned to return to the dredging site. Placement of spoil material at the disposal ground would be completed so as to achieve a relatively uniform cover. Disposal would be undertaken at a speed of approximately five to ten knots, typical for such a disposal operation. The duration of each disposal event within the spoil ground would be approximately 15-25 minutes.

The route from loading to the disposal ground is a direct line north-west from the end of the South Channel. There are no obstacles or hazards along this route. It is assumed that two barges would complete the return trip to the spoil ground in approximately three to four hours, travelling at 11 knots.

Dredging and spoil disposal would be conducted 24 hours a day, seven days a week. Dredging at the barge/ferry terminals should take only one to two weeks each and would preferably be undertaken in the dry season. This approximate 6-week dredging period does not allow for any delays such as for breakdowns, maintenance, or environmental monitoring, which would extend the duration of dredging but also interrupt suspended sediment plume generation. It also excludes stand-down time for inclement weather which is possible over the tropical wet season. A two-year Sea Dumping Permit is proposed to allow work to be completed in the following dry season if required. If all necessary approvals are attained, the dredging would occur between January 2012 and December 2013.

Detailed dredging procedures would be developed with the dredging contractor following engagement.

Alternative spoil disposal options for the Embley and Hey River barge terminals were not considered to be viable (refer **Section 1.6.11**) even though minor reclamation is required at each location (refer **Section 3.9**). The use of silty-clay marine sediments presents significant dewatering, material strength and settling issues when being considered for engineering uses, including routine support of heavy machinery. Placement of the small volumes of material at the existing Albatross Bay spoil ground was considered to be the only viable option and was considered to be a relatively benign option.

6.5.3 Sediment Assessment Framework

Australia is party to the *1996 Protocol to the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter 1972*, now known as the London Protocol. The aims of the London Protocol are to protect and preserve the marine environment from all sources of pollution and to prevent, reduce and eliminate pollution by controlling the dumping of wastes and other materials at sea. The London Protocol limits the types of materials that may be considered for ocean disposal. Annex 2 of the London Protocol outlines a procedure for considering disposal at sea and includes guidance on waste prevention, pollution prevention, monitoring and assessment. Parties to the London Protocol must adopt administrative or legislative measures to ensure that issuance of permits and permit conditions comply with provisions of Annex 2.

The loading and disposal of dredged material in Australian waters is regulated by DSEWPaC under the *Environment Protection (Sea Dumping) Act 1981* (Sea Dumping Act). To gain a permit for ocean disposal, sediments are required to be assessed using the framework of the *National Assessment Guidelines for Dredging* (NAGD) (Commonwealth of Australia 2009), which supersedes the *National Ocean Disposal Guidelines for Dredged Materials* (NODGDM) (Commonwealth of Australia 2002), to demonstrate their chemical and physical nature is suitable for placement at sea and would not adversely affect the marine environment.

The sections below describe the sampling and analyses completed at the proposed port area, and the Hornibrook, Humbug and Hey River Terminal locations, in accordance with NAGD/NODGDM sediment assessment frameworks. Characteristics of sediments at the proposed new spoil ground are also provided. The assessment of dredged material for the Project is consistent with the assessment guidance described in *National Assessment Guidelines for Dredging* (NAGD), Annex 2 of the London Protocol, and the *Waste Specific Guidelines for Assessment of Dredged Material* (IMO 2000). Alternative options for disposal of dredged material are presented in **Section 1.6.10**.

6.5.4 Port Area Sediment Characterisation

The proposed port is located in a remote and largely undeveloped area. The coastal land from Aurukun in the south to Weipa in the north is undeveloped and largely undisturbed, except for mineral exploration activities. As such, there have been no prior land use activities of a nature that may have contaminated existing coastal sediments.

The pristine nature of the port development site between Boyd Point and Pera Head, its remote location and current lack of potential contaminant sources, either from shipping activity or from land use, suggests there should not be any anthropogenic contaminants present in the sediments to be dredged and that concentrations present would represent natural background levels.

Sampling and analysis of the sediment material at the proposed port has been undertaken on several occasions to determine background concentrations of trace metals, particle size distribution, and nutrients prior to development. Acid sulphate soil potential was also assessed early in sediment characterisation studies for the inshore berth area only in the event that material was required to be placed on land. Organotin concentrations were analysed to confirm their absence and provide a baseline for comparison during future maintenance dredging.

6.5.4.1 Summary of Sediment Sampling and Analysis Program

Sampling was completed over the following three stages due to Project changes: 20 to 22 October 2007, 30 June 2009 and 18 to 21 June 2010. Sediment sampling and analysis plans (SAP) were submitted to the DSEWPaC and approved for each phase of sampling.

2007 Sediment Sampling and Analysis

A draft sediment SAP was submitted to DSEWPaC in September 2007 and comments were responded to in a sediment characterisation report submitted in February 2008. The approach to sampling and analysis recognised the remote location of the proposed dredge area with no likely input of contaminant substances from the surrounding catchment. A pilot-program level of assessment comprising 20% of the total number of sample locations required under Table 1 of the NODGDM (Commonwealth of Australia 2002) was adopted.

The October 2007 sampling included collection of sediments at five sites (SoE1 – SoE5; refer **Figure 6-37**) using a pneumatic head vibrocorer operated by GeoCoastal Pty Ltd off the stern of the James Cook University research vessel *James Kirby*. A total of nine samples were collected from a maximum of two horizons (A horizon 0–0.5m and B horizon 0.5–1.0m) depending largely on the depth of surface sediments overlying stiff clays. Power analysis of results indicated the number of samples taken was sufficient to provide a statistically rigorous comparison with the NODGDM screening levels for contaminants. Sampling to the intended dredge depth through stiff clays was not possible as the vibrocorer met resistance typically from 0.2–0.5m sediment depth and refusal marginally beyond that. Typically, at least half the lower horizon sample (B horizon 0.5-1.0m) submitted consisted of stiff clay material. It is extremely unlikely that any anthropogenic contaminants could have been introduced to the underlying clay material due to the high binding capacity of the clay sediments and lack of porosity. Accordingly, the NAGD does not normally require chemical testing of consolidated natural geological materials.

The collected sediment samples were consigned to NATA registered laboratories (Advanced Analytical Australia (AAA) and Australian Laboratory Services (ALS)) and analysed for the constituents detailed below:

- Total trace elements (Ag, Al, As, Cd, Cu, Co, Cr, Fe, Mn, Pb, Hg, Ni, Sb, Se, V, Zn);
- Bioavailability of trace elements using dilute acid extraction (1M HCl; DAE) (Ag, Al, As, Cd, Cu, Co, Cr, Fe, Mn, Pb, Hg, Ni, Sb, Se, V, Zn);
- Elutriate concentration of trace elements (Ag, Al, As, Cd, Cu, Co, Cr, Fe, Mn, Pb, Hg, Ni, Sb, Se, V, Zn);
- Organotin compounds (MBT, DBT, TBT);
- Nutrients (TN, NO_2, NO_3, TKN, TP);
- Total Organic Carbon (TOC);
- Particle size distribution (PSD); and
- Acid sulphate soils (ASS).

Analysis of metals in elutriate water and metals bioavailability was undertaken as published studies of sediments within northern Australia by Munksgaard and Parry (2002) indicated total metals concentrations could naturally exceed relevant guideline screening levels.

Following correspondence, DSEWPaC (formerly DEWHA) confirmed on 15 October 2008 that sediment characterisation had been characterised according to the NODGDM.

2009 Sediment Sampling and Analysis

In 2009, the volume of proposed dredging was increased to 505,800m^3. A supplementary SAP was submitted to DSEWPaC (formerly DEWHA) on 5 June 2009 and approved for implementation on 27 July 2009. Sampling for the expanded dredge area was completed at 10

sites (2SoE6-10, 2SoE12, 2SoE14, 2SoE18-20), making a total of 15 sites over the whole dredge area over the 2007 and 2009 surveys. Elutriate and porewater analyses were undertaken on samples from seven locations making a total of 12 sampling locations over the 2007 and 2009 surveys. Sampling locations are shown on **Figure 6-37**.

Based on the prior experience of there being a relatively thin layer of unconsolidated material overlying stiff clays, surface samples only were collected using a stainless steel grab instead of a coring device.

Samples were tested for the same suite of analyses as in the 2007 survey. The results were combined with 2010 data and provided to DSEWPaC in December 2010.

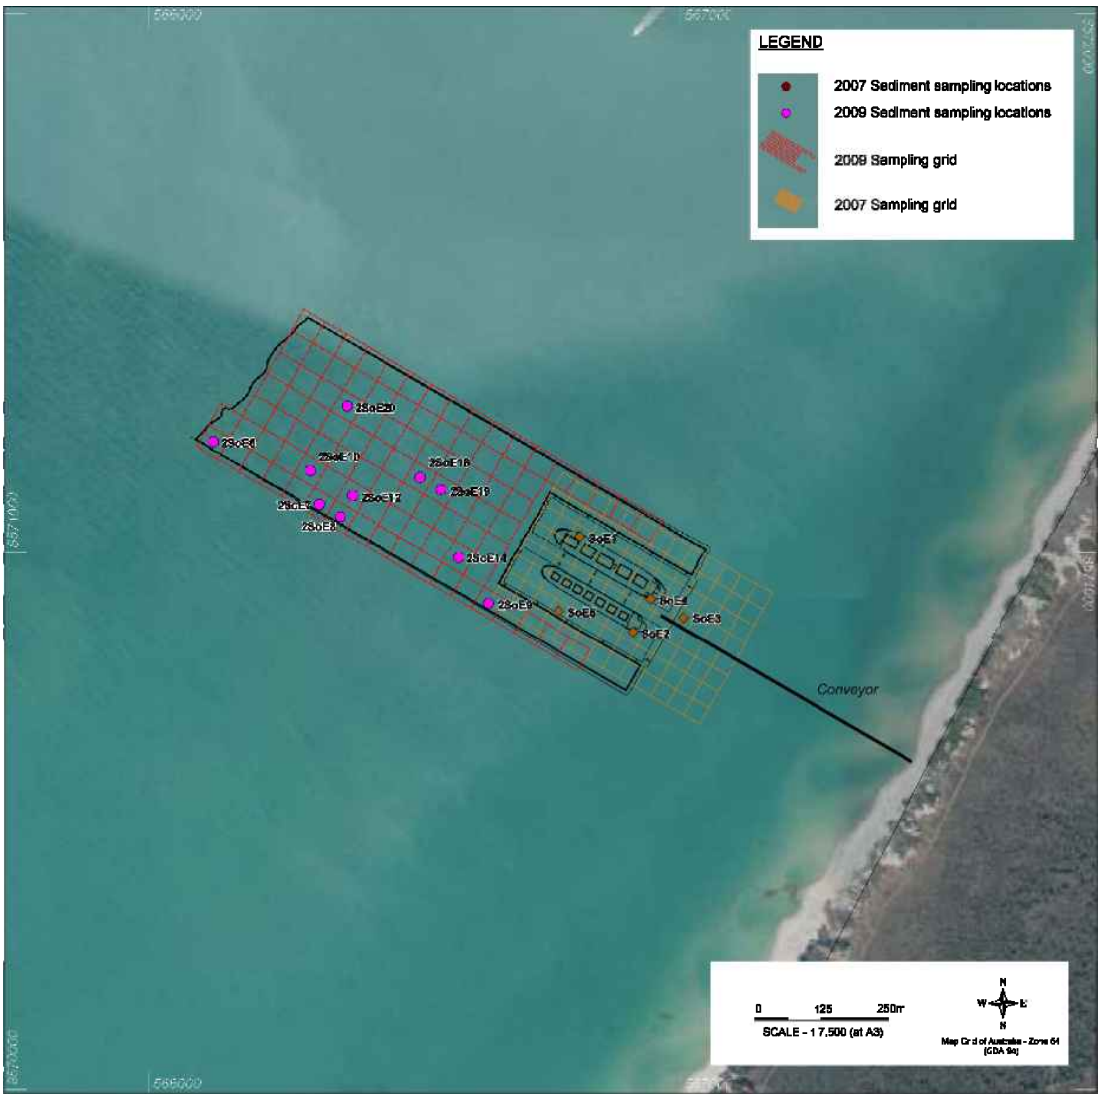

Figure 6-37 2007 and 2009 Sediment Sampling Sites at the Port Berth and Departure Area

2010 Sediment Sampling and Analysis

A new SAP was developed in 2010 to accommodate a major expansion in dredge footprint, which now included a 5.5km departure channel, and increase in proposed dredge depth to –20.2mLAT and volume increase to approximately 6,500,000m^3.

Sampling was undertaken at 20 locations, more than the minimum 17 locations required for the conservatively estimated volume of 730,000m^3 of "potentially contaminated" loose surface sediments overlying stiff clays. The volume of "potentially contaminated" material determines the number of sampling locations under the NAGD. The NAGD recommends that for capital dredging projects, this volume would be represented by the upper 1m of sediment over the dredging footprint area. The volume of "potentially contaminated" sediments was calculated from the proposed dredge footprint of 1,460,062m^2 and a typically maximum depth of 0.5m to stiff underlying clays. The number of sampling locations required under the NAGD (34) was halved on the basis that there was good quality current data available for the area from the two previous sampling campaigns in 2007 and 2009. The position of sampling locations is provided in **Figure 6-38**. Samples were collected using a vibrocorer, deployed from the research vessel *James Kirby*.

Penetration into the substrate was again limited by the stiff underlying clays, with a maximum of 0.6m but typically less than 0.2m, particularly along the departure channel. Because of the shallow penetration, samples were submitted as single horizons.

Samples were analysed only for metals and particle size distribution since organotin concentrations were previously not detected. The sediment characterisation report was provided to DSEWPaC in December 2010 and this EIS provides a summary of the results.

Assessment Methodology

Given the inshore nature of the 2007 and 2009 surveys, results were pooled for the purposes of assessment against the NAGD Table 2 screening levels at the 95% confidence level of the mean (95%UCL; i.e. the upper limit of the sample mean, with 95% confidence). 2010 results were assessed separately to the 2007 and 2009 sampling due to the significantly different dredge footprint areas assessed.

For the purposes of calculation of 95%UCLs, values below detection limit (laboratory Level of Reporting, LOR) were set to half of the detection limit in accordance with NAGD recommendations. Results for organic parameters were normalised to 1% total organic carbon (TOC) where the recorded value was within the range of 0.2–10%. Organic contaminants below detection limits were not normalised to 1% TOC in 95%UCL calculations. The methods used to calculate the 95%UCLs were based on the methods required in Appendix A of the NAGD. According to the NAGD sediment assessment framework, if total contaminant concentrations are below respective screening levels at the 95%UCL then dredged material is considered chemically suitable for unconfined ocean disposal.

Under the NAGD sediment assessment framework, elutriate and bioavailability assessment is generally only required if sediments do not pass screening level assessment. Even though contaminants were typically below NAGD screening levels in the present study, elutriate and bioavailability assessments for trace elements were undertaken. The analytical procedures were undertaken in accordance with NAGD requirements and are described briefly below.

- Elutriate analysis is achieved by shaking one part sediment with four parts sea water for 30 minutes, allowing to settle for one hour and analysing filtered/centrifuged supernatant for ultratrace contaminant concentrations. This investigates release of contaminants from the sediments to the water column during dredged material disposal. Results of elutriate analysis are compared with ANZECC/ARMCANZ (2000) marine water quality guidelines at the 95% species protection level as detailed in Appendix A of the NAGD. According to the NAGD, if concentrations of contaminants are below respective guideline levels after allowing for initial mixing that takes place during material placement and over the following four hour period, then dredge material is considered chemically suitable for unconfined sea disposal.

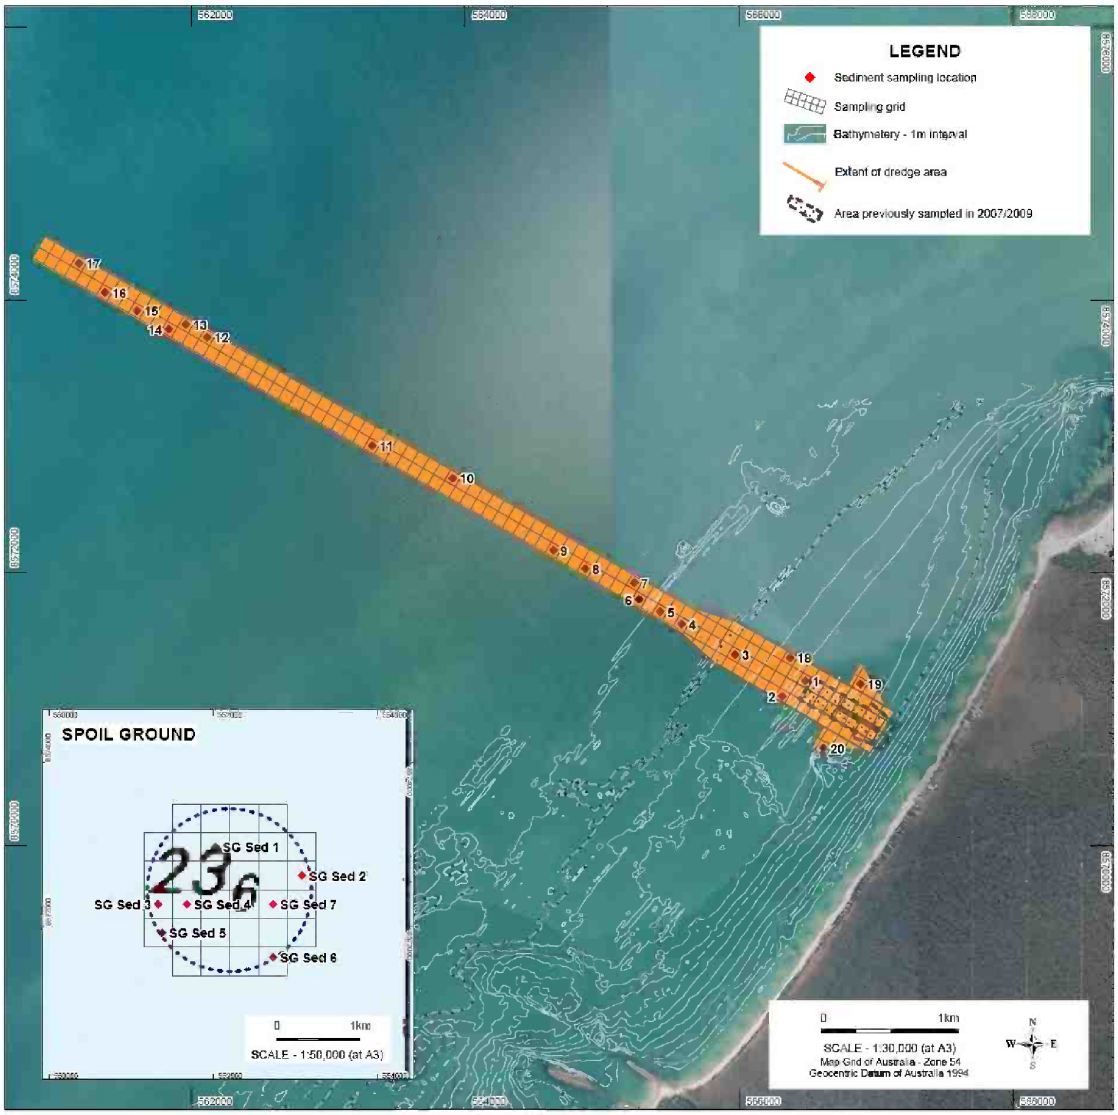

Figure 6-38 2010 Sediment Sampling Locations at the Port Berth, Departure Apron, Departure Channel Areas and Proposed New Spoil Ground (inset)

- Dilute acid extraction (DAE) provided an estimate of bioavailability of metals in sediments. Analysis is achieved by mildly extracting metals from sediments using 1M HCl acid. This approximates metal concentrations bioavailability to sediment ingesting organisms. Each of the 16 DAE metal and metalloid concentration results were compared to screening levels in NAGD in the same manner as for total sediment concentrations. According to NAGD, if DAE concentrations are below respective screening levels at the 95%UCL then dredged material is considered suitable for unconfined ocean disposal from a toxicant bioavailability perspective.

An assessment of data quality was undertaken and the data were considered suitable to assess the material's suitability for sea dumping.

Full sediment characterisation reports have been provided to DSEWPaC for respective dredge areas. This Environmental Impact Statement (EIS) contains summary information.

6.5.4.2 Physical Characteristics – Port Area

Sediment sampling identified the sediment profile at the proposed port area – including berth areas, departure apron and departure channel – as generally comprising a relatively thin, moist, silty-clay surface layer (0.1m–0.5m) overlying a mottled, stiff, relatively dry sandy-clay layer (refer **Figure 6-39**).

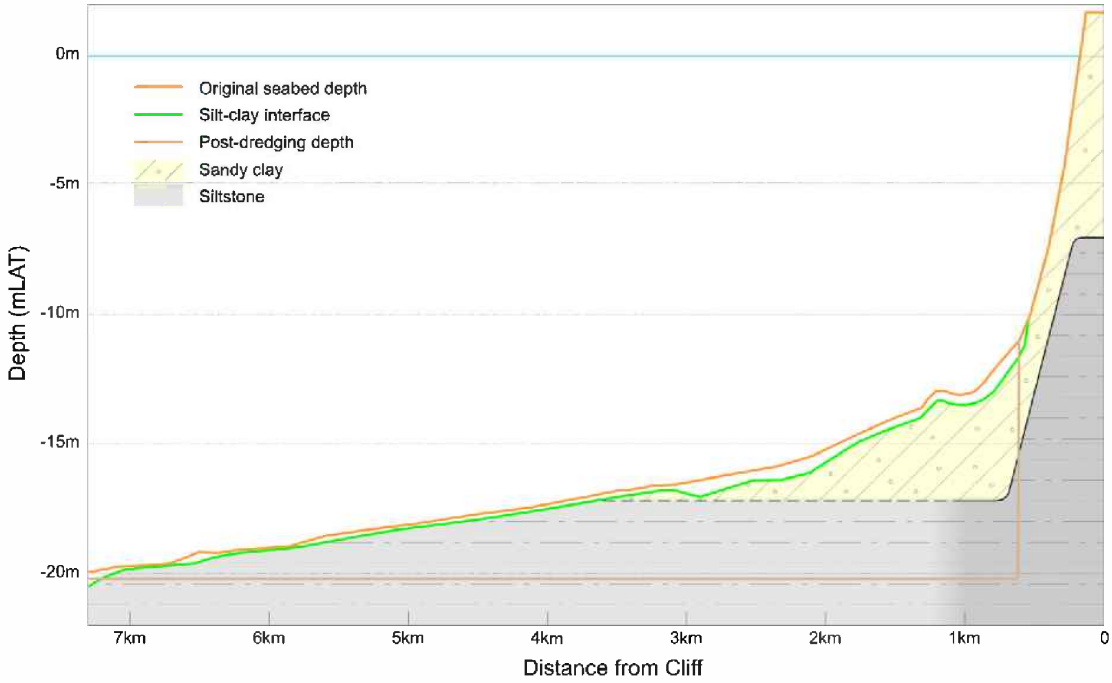

Figure 6-39 Longitudinal Sediment Profile along Dredging Footprint

Subsequent inspection of geotechnical cores (refer **Plate 6-7**) taken within the jetty/berth area identifies that siltstone is present below the stiff sandy clay layer. While the extent of the geotechnical investigations are limited to the nearshore area, geotechnical consultants to the Project (Coffey Geotechnics) consider that it is reasonable to assume that the siltstone unit continues seaward at a similar level as identified by the nearshore boreholes. The level at which siltstone occurs corresponds to approximately –17m LAT. The overlying stiff sandy-clay layer is believed to be weathered siltstone material.

All sediment samples were physically described and photographed in the field. Samples were also collected and analysed for particle size distribution. A graphical summary of the PSD results for port development area sediments in 2007, 2009 and 2010 surveys is presented in **Figure 6-40**. 2007 sampling results have greater sand and gravel content than 2009 samples; however this is likely to be due to different sample collection methods. 2007 samples were collected using a vibrocorer, while 2009 samples were collected using a sediment grab. The vibrocorer was able to partially penetrate the underlying stiff clays, while sediment grabs collected only surface sediments up to about 0.1m depth.

2010 samples were collected using a vibrocorer and demonstrate a significant change in particle size distribution approximately 4km offshore in about –17mLAT water depth, between sampling locations 9 and 10. Due to the significant change of PSD, summary statistics are provided separately for inshore sample locations (locations 1–9) and offshore sample locations (locations 10–17) shown in **Table 6-10** and **Table 6-11** respectively and in **Figure 6-40**.

Inshore surface sediments (unconsolidated silts and underlying stiff sandy clays) are dominated by silt and clay fractions, comprising 71 to 96% (mean 84%) of the sediments (refer **Table 6-10**); the remainder of the sediments contain gravel and sand in similar proportions. Offshore

sediments are dominated by sand particles, comprising about 66% of the sediments (refer **Table 6-11**); the remainder of the sediments contain a slightly greater proportion of silts and clays (19%) than gravel (15%).

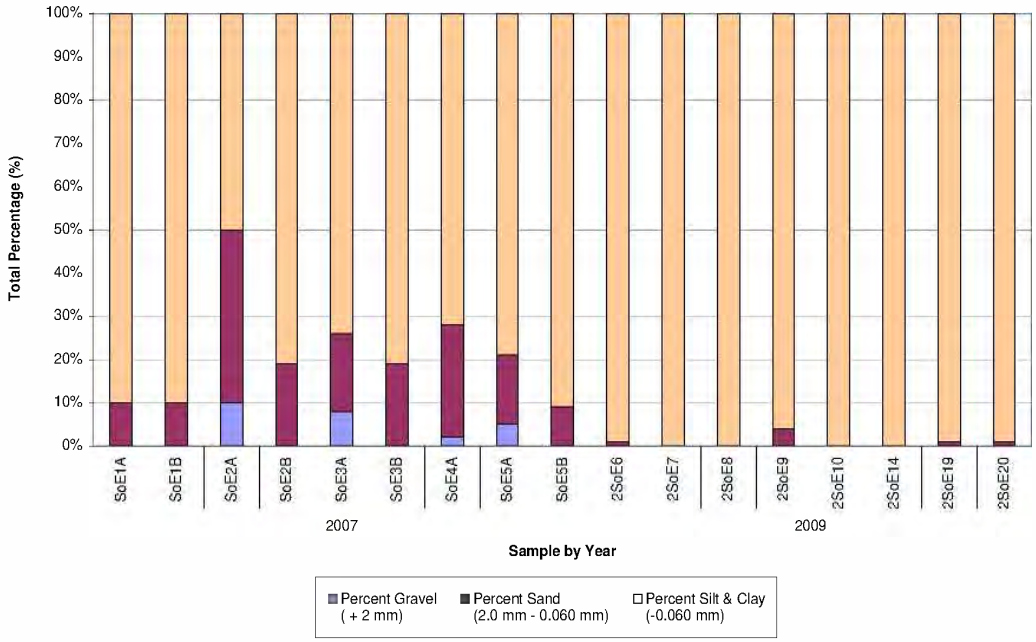
Plate 6-7 Geotechnical Core from within the Port Jetty/Berth Area

Table 6-10 Summary of 2010 Inshore Particle Size Distributions

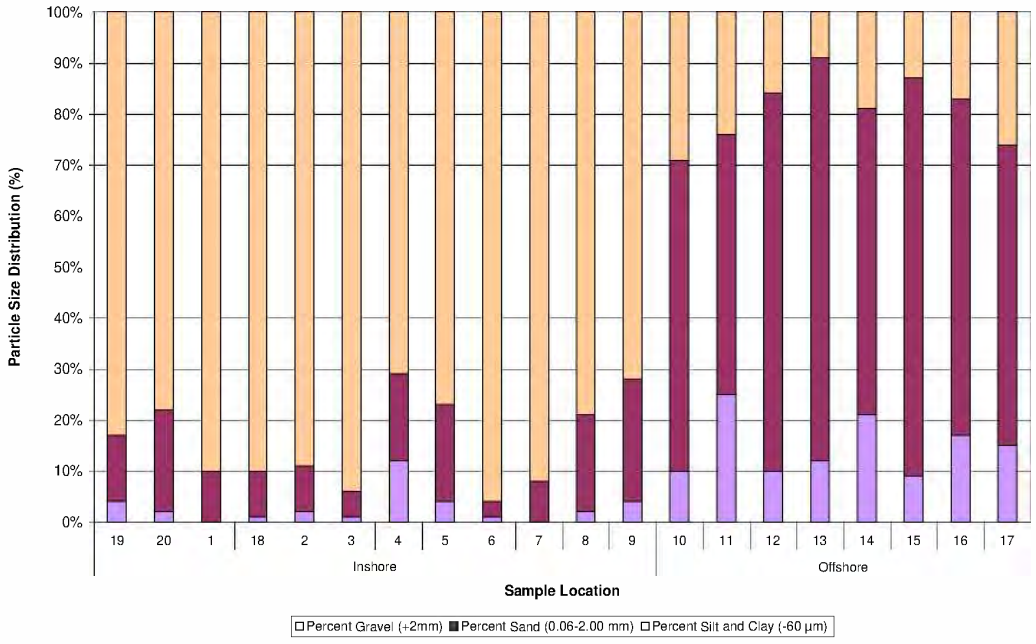
Statistic	Gravel (>2mm)	Sand (2mm–0.060mm)	Silt & Clay (<.060mm)
Number of samples	12	12	12
Mean (%)	13	13	84
Standard deviation (%)	3	7	9
Minimum (%)	0	3	71
Maximum (%)	12	24	96

Table 6-11 Summary of 2010 Offshore Particle Size Distributions

Statistic	Gravel (>2mm)	Sand (2mm–0.060mm)	Silt & Clay (<0.060mm)
Number of samples	8	8	8
Mean (%)	15	66	19
Standard deviation (%)	6	10	7
Minimum (%)	9	51	9
Maximum (%)	25	79	29



Note: 2007 sample suffixes relate to depth horizons: A = 0–0.5m; and B = 0.5–1m. 2009 samples were surface grabs so contain only one horizon.



Note: 2010 samples were surface grabs so contain only one horizon.

Figure 6-40 Particle Size Distribution at the Proposed Port Dredging Area during 2007 and 2009 (top) and 2010 Surveys (bottom)

Particle size analysis performed on geotechnical core material identified that the stiff sandy clays contained clay, silt and fine sand in proportions of 11%, 50% and 20% respectively. Siltstone material was found to be comprised of clay, silt and fine sand in 13%, 10% and 47% respectively. The remainder of the fractions were made almost entirely of coarse sand. Beach sediments were analysed to provide particle size distributions and sand grain fall velocities for use in sediment mobilisation modelling. **Plate 6-8** shows the composition of the upper beach

sediments and the individual sand grains, which are a mixture of well sorted, rounded, calcareous and silica material containing 11% gravel, 88% sand, and less than 1% clay. Grains of ironstone and pisolitic (bauxite) material are present.

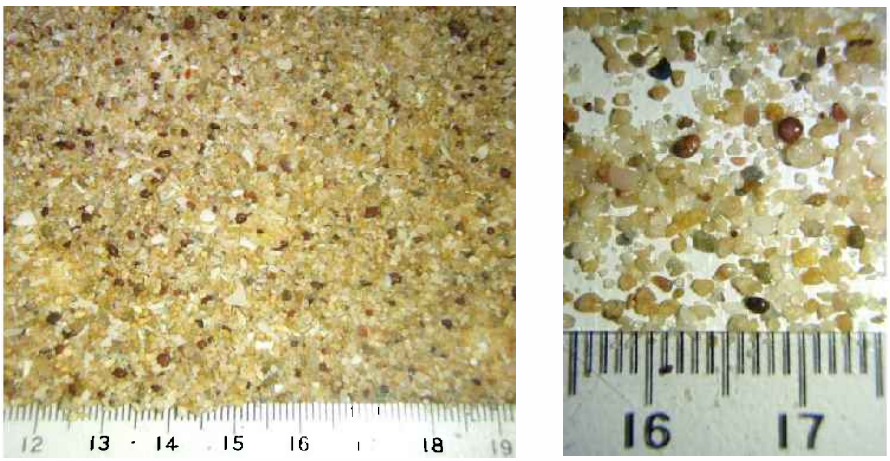


Plate 6-8 Upper Beach Sediment and Individual Grains

6.5.4.3 Chemical Characteristics – Port Area

Chemical characteristics of the sediments within the dredge footprint of the proposed port area are summarised below.

Trace metals – Totals

Total trace metals results are summarised in **Table 6-12** and **Table 6-13** and identify the following:

- Total metals concentrations commonly were similar across the three sampling events although the 2007 results demonstrated higher variability than those of 2009 and 2010, particularly for: antimony, cadmium, copper, manganese, mercury, nickel and zinc. The differences likely reflect the 2007 survey footprint, being the most inshore of all the surveys and hence with a likely greater content of beach sand, which contains ironstone and pisolitic material (bauxite) eroded from the adjacent cliff faces;
- Except for nickel and antimony, all total metals concentrations for individual samples were below respective NAGD screening levels in all three surveys. In 2007 only, nickel and antimony exceeded respective screening concentrations at sites SoE1 (upper and lower horizon) and SoE 4 (upper horizon);
- The mean and 95%UCLs of the mean for nickel and antimony were below respective NAGD screening levels for combined inshore (2007 and 2009) surveys and for the 2010 survey over the extended dredge footprint;
- Mercury concentrations were below the LOR of 0.01 mg/kg except for three samples collected in 2007, which were well below the NAGD screening level; and
- Silver was not detected at any location in any survey.

Graphing of metals concentrations from inshore to offshore locations (refer **Figure 6-41**) demonstrates a distinct reduction in total concentrations at sampling locations 9 and 10 approximately 4km from shore. The trend in metals concentrations is consistent with a reduction in silt and clay (fines) content.

Legend

Note	When calculating averages and 95% UCLs, values below detection for individual results were set to half the detection levels, consistent with the NAGD
PQL	Practical Quantitation Limit
LOR	Laboratory Limit of Reporting
50	Value exceeds NAGD Screening Level

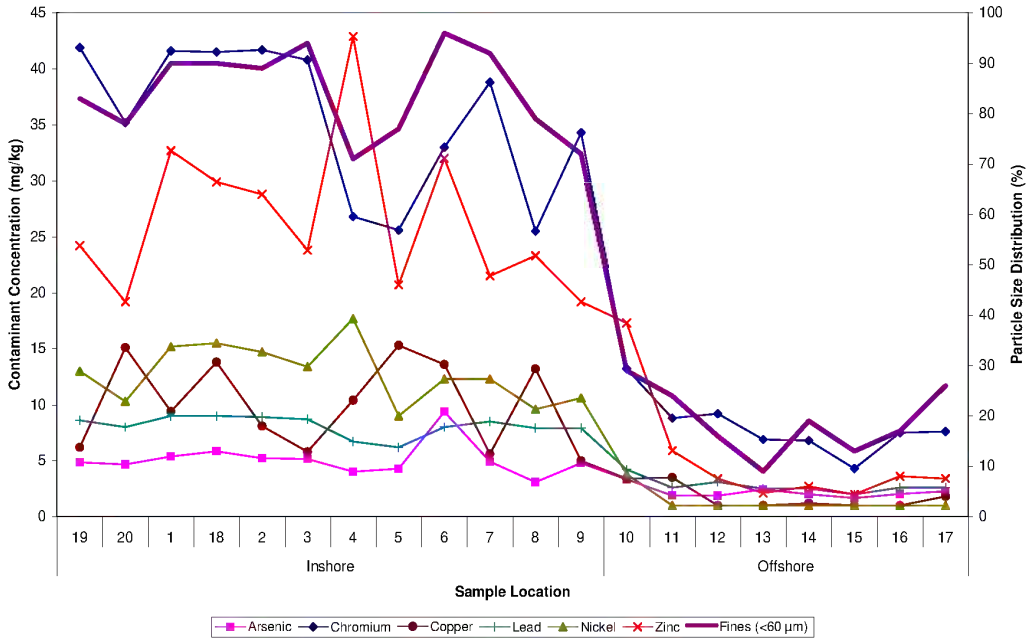

Figure 6-41 NAGD Metals Contaminant Concentrations and Percentage Fines Content from Inshore to Offshore in 2010 Survey

Organotins

- In 2007 and 2009, organotin concentrations (MBT, DBT, and TBT) at each sampling location were less than the LOR of 0.5µgSn/kg and the NAGD screening level for TBT (9µgSn/kg).
- Organotins were not tested for in 2010.

Nutrients

Nutrients were analysed in 2007 and 2009.

- Nitrate was below detection levels across all sites;
- Nitrite was below detection levels across all sites in all surveys, except two sites in 2007;
- Total nitrogen across all sites was comprised entirely of organic nitrogen (TKN). Total nitrogen concentrations ranged from <20 to 2050mg/kg;
- Total phosphorus concentrations ranged from 310 to 710mg/kg;
- Total ammonia was analysed in the 2009 sampling campaign and ranged from 3.5 to 7mg/kg across sites; and
- There are no guideline values for nutrients in sediments.

Trace metals – Dilute Acid Extraction

Summary results of DAE analysis are provided in **Table 6-14** and **Table 6-15** and identify the following:

- Results of the DAE analyses indicate bioavailable metal concentrations are below respective NAGD screening levels across all samples in all surveys. The 95%UCL of the mean for metals was also below NAGD screening levels.

Table 6-14 Summary Results for DAE Analysis on Metals – Port Berth and Departure Area in 2007 and 2009

Legend

1*	Results were adjusted to the LOR given that they were recorded above total concentrations, which is not plausible
Note	When calculating averages and 95% UCLs, values below detection for individual results were set to half the detection levels, consistent with the NAGD
PQL	Practical Quantitation Limit
LOR	Laboratory Limit of Reporting
50	Value exceeds NAGD Screening Level

Trace Metals – Elutriate Analysis

Summary results of elutriate analysis over 2007, 2009 and 2010 surveys are provided in **Table 6-16** and **Table 6-17** and identify the following:

- Elutriate metal concentrations were generally below respective ANZECC/ARMCANZ (2000) marine water quality guidelines at the 95% species protection level. The exceptions to this are cobalt and copper during the 2007 survey and zinc in 2010 survey. It should be noted that total copper, cobalt and zinc concentrations within respective surveys were below NAGD screening levels;
- Cobalt exceeded the ANZECC/ARMCANZ (2000) guideline for 95% species protection level at two sites (SoE1 and SoE3) in 2007 and occurred in the sub-surface horizon. Exceedances do not take into account dilution during placement;
- Copper exceeded the ANZECC/ARMCANZ (2000) guideline for 95% species protection level at four sites for samples SoE1, SoE3a, SoE4a, SoE5a and SoE5b in 2007. Exceedances do not take into account dilution during placement at the spoil ground;
- Zinc exceeded the ANZECC/ARMCANZ (2000) guideline for 95&% species protection level at one sampling location (site 4) in 2010. This single result appears to be an outlier, given it is about 20 times greater than other concentrations in 2010; and
- Cobalt, copper and zinc marginally exceed the ANZECC/ARMCANZ (2000) guideline for 95% species protection level at the 95th percentile value, prior to allowing any dilution following disposal. Exclusion of the 2010 zinc outlier results in a concentration of 7.1µg/L, less than half the guideline.

While cobalt, copper and zinc exceed the guidelines, the NAGD recommends the application of an initial mixing within the spoil disposal area when making an assessment of suitability for sea disposal. The NAGD states: "*The elutriate test uses a dilution of 1:4, wet sediment: added seawater, and will greatly overestimate water quality impacts given that, within the four hour period, dilutions of the order of a hundred times or more would normally be expected*". In the present study, minimal dilution of up to four times would be required for the material to achieve concentrations less than the ANZECC/ARMCANZ (2000) water quality guideline level. A conservative estimate of immediate dilution alone over the spoil ground is at least 13 times, prior to any allowance for dilution over the next four hours.

Acid Sulphate Soils

Potential Acid Sulphate Soils (PASS) were investigated in 2007 and 2009 and tested using the Suspension Peroxide Oxidation Combined Acidity and Sulphate (SPOCAS) suite of analyses. Analysis of departure area or departure channel sediments has not been undertaken. A summary of the results of acid sulphate soil analysis from the port area is provided below:

- Sediments pH ranged from 6.6 to 8.4, indicating no sulphur oxidation has yet taken place;
- Titratable Actual Acidity (TAA), which measures the sediment's actual acidity prior to any oxidation taking place, was below the detection level for all samples. This indicates no acid generation has yet taken place in the sediments;
- Potential sulphidic acidity (S_{POS}) indicated the oxidisable sulphur content was higher than the corresponding Queensland Acid Sulphate Soils Investigation Team (QASSIT) action criteria in samples from several sites. This indicates some of the material at these sites has the potential to generate sulphidic acidity. The remaining sites were below QASSIT action criteria, if detected;
- Retained acidity, net acid soluble sulphur (S_{NAS}), was below detection limits in several samples. Low retained acidity is also indicated since all samples had a pH higher than 4.5, indicating no sulphur oxidation has yet taken place;
- Net acidity, which is used to predict the acid risk of a soil, was lower than detection limit across all sites tested;

Legend

Value exceeds ANZECC/ARMCANZ (2000) water quality toxicant guideline for 95% species protection

- All sites have the ability to neutralise acidity with acid neutralising capacities above detection; and
- Low net acidity and the ability to neutralise some acid means the addition of lime to manage acid generation from the dredged material would not be required if the material was to be placed on land.

Overall, assessment of acid sulphate soils indicated the berth area sediments had potential to generate acidity. However, sediments appeared to have the capacity to neutralise some acid generation and would be unlikely to require the addition of lime to manage acid generation, should the material be placed on land. The placement of material on land however is not considered a viable disposal option.

6.5.4.4 Suitability of Dredged Material for Sea Dumping

In accordance with the potential contaminant assessment framework in the NAGD, there are no chemical impediments to unconfined sea disposal of dredge spoil from the port development site on the basis that:

- despite some samples of antimony and nickel marginally exceeding respective screening levels in 2007, all contaminant substances were below respective NAGD screening levels at the 95%UCL of the mean;
- organotins were not detected in the sediments;
- DAE metal concentrations were not above screening levels; and
- allowing for minimal dilution following disposal at the spoil ground for copper, cobalt and zinc, the dredge material would readily achieve the respective ANZECC/ARMCANZ (2000) 95% species protection level toxicant guideline values.

6.5.5 Proposed Offshore Spoil Ground Sediment Characterisation

The proposed new spoil ground is located approximately 17 km offshore from the proposed new wharf facilities located between Pera Head and Boyd Point, 40km south of Weipa. Specifically, the location of the spoil ground is described as 0.5nm radius around the central point:

S12° 54' 46.44" E141° 28' 51.60" (GDA94; equivalent to WGS84).

The location of the new spoil ground in relation to the proposed SoE port site and existing Albatross Bay spoil ground is shown in **Figure 2-9**. The relevant AusMap is Au301. The reasons that this location was chosen for the proposed spoil ground as well as the alternatives considered are discussed in **Section 1.6.11**.

Sampling and analysis of sediments at the proposed offshore spoil ground was undertaken in 2010. This provides baseline information on concentrations of contaminant substances and particle size at the spoil ground prior to disposal of dredged material. The results of this inform the application for a sea dumping permit for dredging and sea disposal of dredged material.

In accordance with NAGD requirements, seven sites were sampled (refer **Figure 6-38**) and were analysed for trace metals and particle size analysis. Organotins were not analysed as these were not identified in sediments to be dredged from the proposed port area.

Physical Characteristics

A graphical summary of the PSD results is presented in **Figure 6-42** while summary statistics are provided in **Table 6-18**.

The surface sediments are relatively uniform in their composition, being dominated by sand, which had a mean of 57% across all samples. The remainder of the material contains a slightly greater percentage of silt and clay (23%) than gravel (20%). Such sediments would be typical for benthic habitats in the area, judging by the high degree of uniformity observed.

A comparison of proposed spoil ground and port area sediments (refer **Section 6.5.4**) shows the spoil ground sediments are significantly higher in gravel and sand fractions. It is likely that placement of port sediments at the proposed spoil ground would locally increase the fraction of finer sediments; however, it is this fraction that would most easily be mobilised under moderate to high wave and current conditions (refer **Section 6.9.2**), leaving grain sizes similar to the existing habitat.

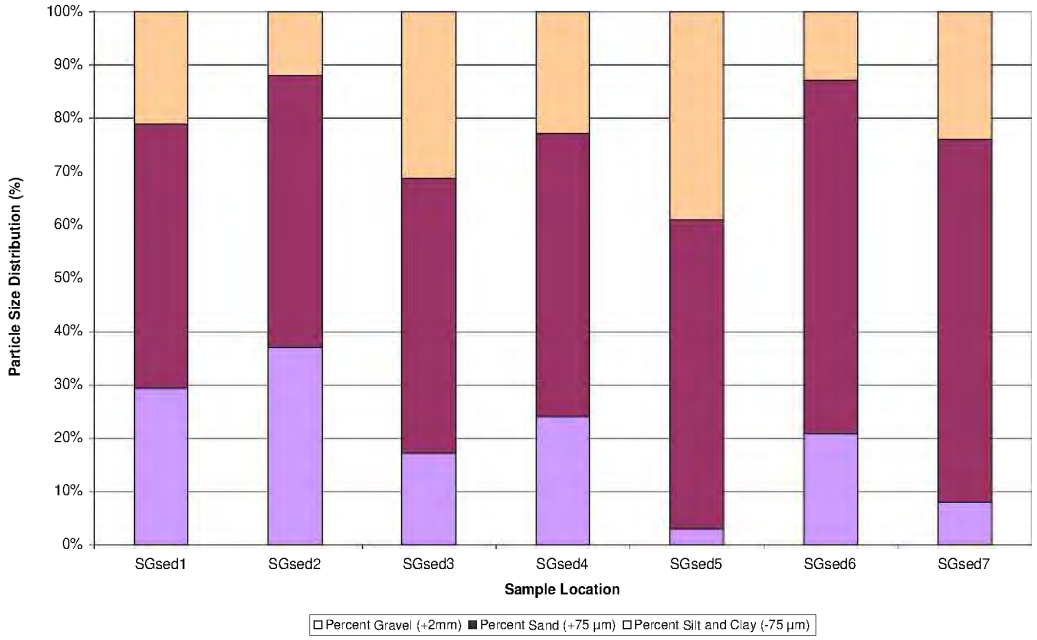

Figure 6-42 Particle Size Distribution for Proposed Spoil Ground Samples

Table 6-18 Summary of Sediment Particle Size at the Proposed Spoil Ground

Statistic	Gravel (>2mm)	Sand (2mm–0.075 mm)	Silt & Clay (<0.075mm)
Number of samples	7	7	7
Mean (%)	20	57	23
Standard deviation (%)	12	8	10
Minimum (%)	3	49	12
Maximum (%)	37	68	39

Chemical Characteristics – Proposed Offshore Spoil Ground

Chemical characteristics of the proposed spoil ground sediments are presented in **Table 6-19**.

All metals contaminant concentrations were very consistent between samples and well below the respective NAGD screening levels. Antimony, cadmium, mercury and silver were not detected at any site. Mean concentrations were all less than one-tenth the NAGD screening levels. The 95%UCL of the mean was a maximum of 12.5% of the NAGD screening levels.

Comparison of trace metals concentrations between proposed spoil new ground sediments, sediments from the port area and regional inshore (Bing Bong, Karumba offshore and Norman Channel) background levels reported by Munksgaard and Parry (2002) is presented in **Table 6-20**. This comparison identifies that:

- the mean of the majority of metals in the proposed dredge area and regional inshore data exceeded the 80th percentile value from the spoil ground. Exceptions were antimony, manganese and silver; and
- the mean of port area sediments was generally consistent with or slightly lower than those reported for regional inshore areas.

0.15 Value exceeds NAGD screening level

0.15 Mean value exceeds 80th percentile of background (spoil ground)

The results of the comparison of port area and proposed spoil ground background concentrations are not unexpected given the presence of pisolitic and ironstone materials in sediments proposed to be dredged from the port area. This material is likely to have originated from the adjacent bauxite cliff face and surrounding geology of the dredge area and, by nature, these geological materials are elevated in a range of metals concentrations. These metals, however, are highly bound and not bioavailable or likely to dissolve into the water column as evidenced from the DAE and elutriate testing (refer **Section 6.5.4.3**).

6.5.6 Barge and Ferry Terminals Sediment Characterisation

The Port of Weipa and its approach channel were developed through capital dredging from 1961 through to 1975 (PCQ 1995). The most recent capital dredging program occurred in 2006 to widen the existing channel and maintenance dredging generally occurs on an annual basis, typically during the dry season (PCQ 2009). Currently within the Port of Weipa there are four wharves located at Lorim Point East, Lorim Point West, Humbug Wharf and Evans Landing. These wharves require maintenance dredging on a regular basis.

Hornibrook Point is an area of land adjacent to Lorim Point and was reclaimed in the 1960s using dredge spoil from the Embley River, including dredge spoil from the original capital dredging of the Lorim Point Wharf. Hornibrook Point has remained as vacant parkland. Humbug Wharf is located approximately 1.25km downstream from Hornibrook Point and is a general cargo wharf currently managed by RTA.

The proposed Hey River terminal site south of Hey Point in the Hey River is an undeveloped area approximately 8km south of Hornibrook Point. No dredging has previously occurred within this area.

The material to be dredged from the barge/ferry terminals has physical characteristics similar to Weipa shipping channel (South Channel) sediments which were characterised by GHD (2005). This material was determined to be suitable for unconfined sea disposal and in addition annual maintenance material from the Port is routinely identified as suitable for unconfined sea disposal. Material at the barge/ferry terminals is considered to be similar to the capital dredging and maintenance dredging material previously disposed of at the spoil ground under NQBP sea dumping permits.

6.5.6.1 Summary of Sediment Sampling and Analysis Program

Sampling of each of the three dredging areas was undertaken in accordance with DSEWPaC approved sediment sampling and analysis plans (Worley Parsons 2009; RTA 2009a). Sampling within the three areas was conducted over two field sampling campaigns, due to slight changes in dredging design:

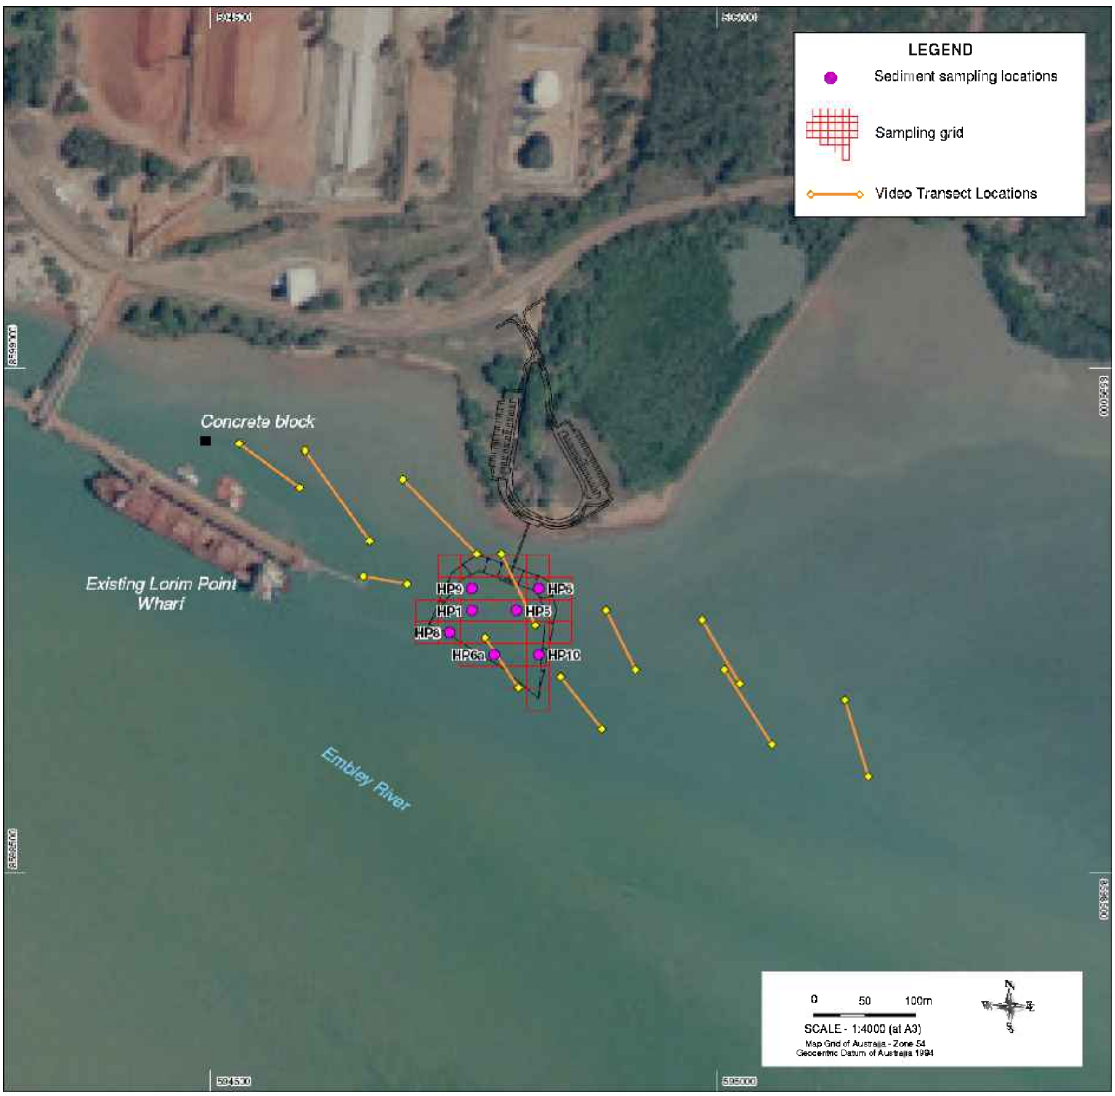
- Hornibrook Terminal – November 2008 and July 2009;
- Hey River Terminal – November 2008; and
- Humbug Terminal – July 2009.

Sampling was undertaken at a total of 20 sites from the three dredge areas: Hornibrook – 7 sites (refer **Figure 6-43**); Humbug – 6 sites (refer **Figure 6-44**); and Hey River – 7 sites (refer **Figure 6-45**). Sampling locations in each area were randomly selected in accordance with NAGD requirements. Sediment was collected using a boat-deployed piston corer to a depth of 1m, or until stiff clays were met. Cores were split into a maximum of three horizons (0–0.5m; 0.5–1m; >1m) where the length of core allowed. Collected samples were transported under refrigerated conditions to the primary analytical laboratory (Advanced Analytical Australia, AAA) and the secondary analytical laboratory (Australian Laboratory Service, ALS) within relevant holding times. Samples were analysed for the following substances:

- trace metals (As, Cd, Cu, Cr, Fe, Pb, Hg, Mn, Ni, and Zn);
- polyaromatic hydrocarbons (PAHs);
- organotin compounds (TBT, DBT, MBT);
- total organic carbon;

- Acid Sulphate Soils (SPOCAS method);
- particle size distribution; and
- moisture content.

Concentrations of contaminant substances at the 95%UCL of the mean were compared against screening levels listed in Table 2 of the NAGD using the same statistical methods as described for assessment of the proposed port area (refer **Section 6.5.4.1**).



Note: Preliminary seagrass inspection locations not shown.

Figure 6-43 Sediment Sampling Locations and Detailed Seagrass Video Transects at Hornibrook Ferry Terminal

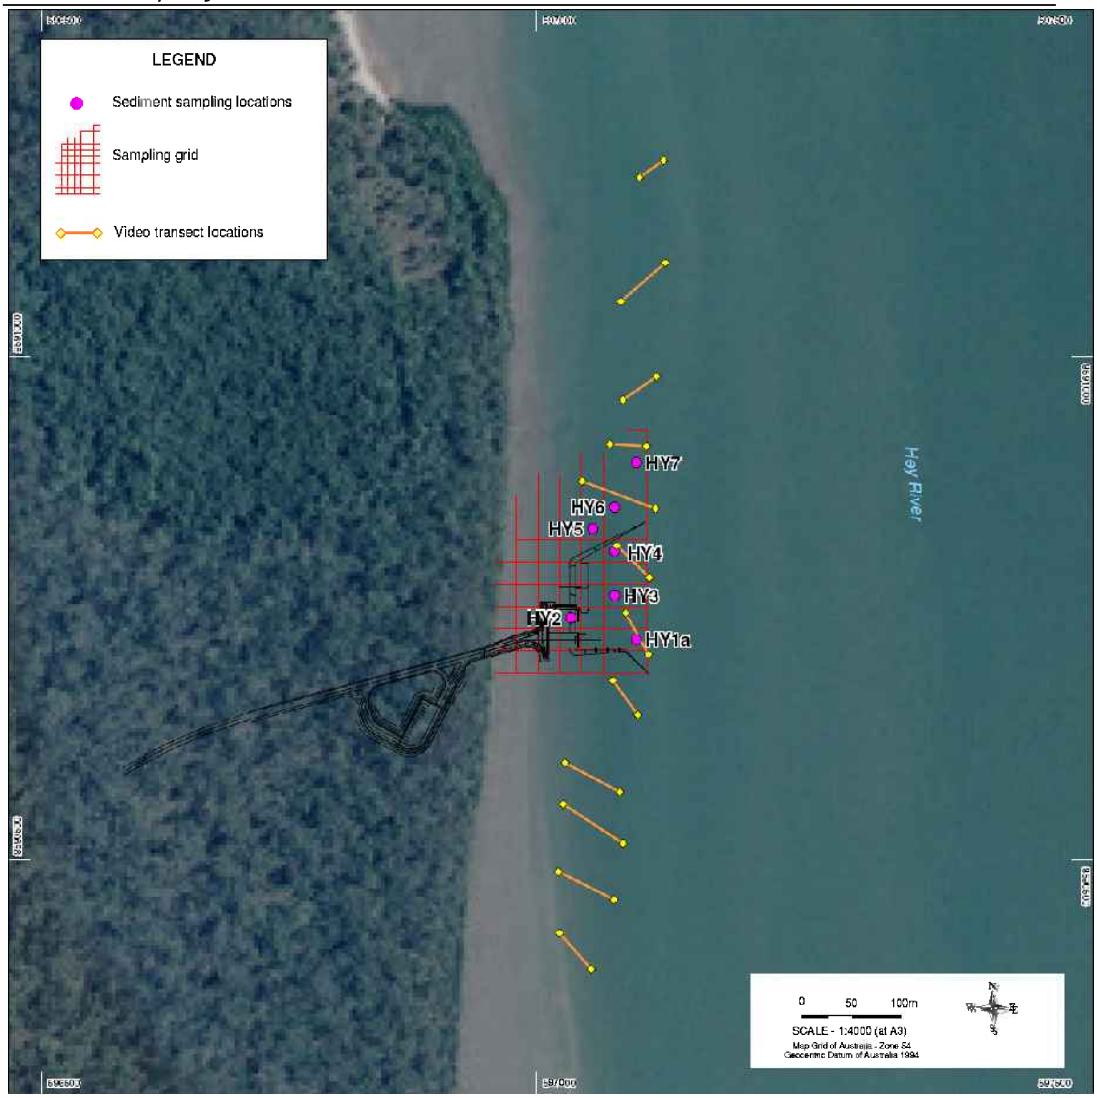
Figure 6-44 Sediment Sampling Locations and Detailed Seagrass Video Transects at Humbug Barge Terminal



Note: Preliminary seagrass inspection locations not shown.

Figure 6-45 Sediment Sampling Locations and Detailed Seagrass Video Transects at Hey River Barge/Ferry Terminal

6.5.6.2 Physical Characteristics – Hornibrook Terminal

A graphical summary of the PSD results for the Hornibrook Terminal dredging area sediments is presented in **Figure 6-46** while summary statistics are provided in **Table 6-21**.

Generally, the sediment profile within the Hornibrook Terminal dredging area comprises a full depth of moderately soft silt/clay to the depth of required dredging (–2mLAT). Sediments are dominated by silt and clay fractions, which account for a mean of 73% of sediments. There is minimal gravel present. In general there was more sand in the upper horizon (0–0.5m) of each site.

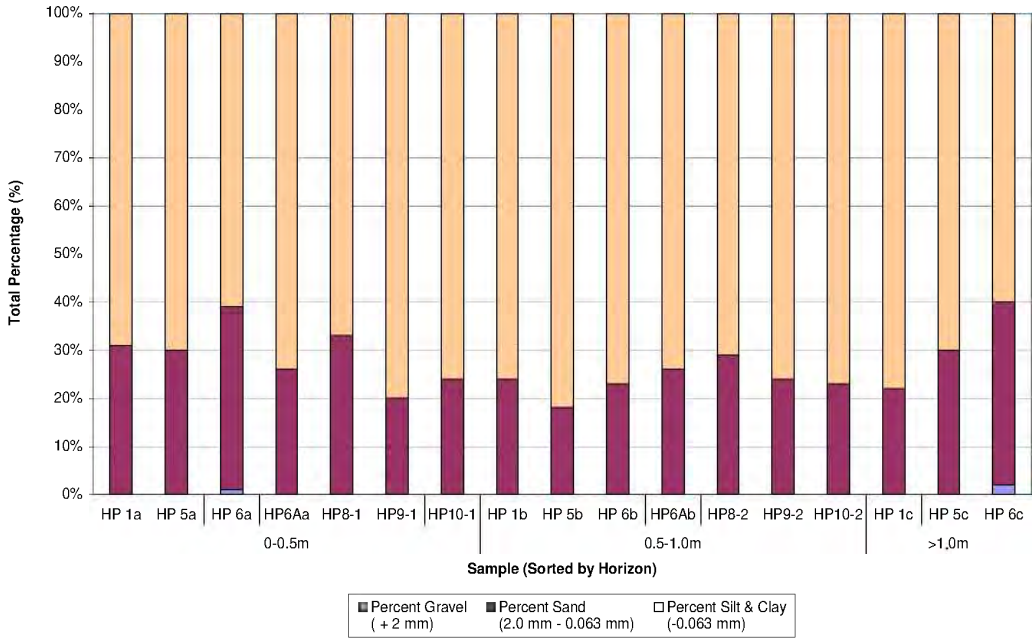


Figure 6-46 Particle Size Distribution within the Hornibrook Terminal Dredging Area

Table 6-21 Summary of Sediment Particle Size within the Hornibrook Terminal Dredging Area

Statistic	Gravel (+2mm)	Sand (2mm – 0.060mm)	Silt & Clay (<0.060mm)
Number of samples	17	17	17
Mean (%)	0.2	27	73
Standard deviation (%)	0.5	6	6
Minimum (%)	0	18	60
Maximum (%)	2	38	82

6.5.6.3 Chemical Characteristics – Hornibrook Terminal

The chemical characteristics of sediment samples collected from the proposed Hornibrook Terminal are presented in **Table 6-22** and summarised below:

Trace Metals - Total

- Mercury and cadmium were detected (i.e. above the laboratory LOR) in samples from one or more horizons from all sites except HP8 (mercury) and HP6A (cadmium). All detections were below respective NAGD screening levels. The mean and 95%UCL of the mean were also below NAGD screening levels.
- All other metals (Al, As, Cr, Cu, Fe, Mn, Ni, Pb and Zn) were detected across all sites and horizons. Concentrations were generally consistent across all samples. All detections were below respective NAGD screening levels. All means and 95%UCL of the mean were also below NAGD screening levels.

Polyaromatic Hydrocarbons (PAH)

- The concentration of naphthalene, 1-methylnaphthalene, 2-methylnaphthalene, acenaphthylene, acenaphthene, dibenz(a,h)anthracene and coronene in samples was less than the LOR across all sites.

- Sites HP5a & c, HP6a-c, and HP8-1 did not record any detection of PAHs. Site HP10-1 recorded only one PAH, fluorene at a concentration equal to the LOR of 5µg/kg.
- The majority of PAH species were detected at sites HP6Aa, HP8-2 and HP9-2.
- There are no NAGD screening levels for individual PAHs for comparison. Total PAHs are below the screening level for the mean and 95%UCL of the mean.

Organotins

- Monobutyltin was below detection levels across all sites.
- Dibutyltin was detected from sites HP6A and HP8–HP10. There are no NAGD screening levels for dibutyltin for comparison.
- Tributyltin was detected from one site only (HP8-1), below the NAGD screening level of 9µgSn/kg. All other sites were below detection levels. The mean and 95%UCL of the mean was also below the NAGD screening level.

Acid Sulphate Soils

A summary of the results of acid sulphate soil analysis is provided below, and the laboratory results are summarised in **Table 6-23**.

- Sediments pH ranged from 7.5 to 8, indicating no sulphur oxidation has yet taken place.
- Titratable Actual Acidity (TAA), which measures the soils actual acidity prior to any oxidation taking place, was below the detection level for all samples, indicating no acid generation has yet taken place in the sediments.
- Potential sulphidic acidity (S_{POS}) indicated the oxidisable sulphur content was higher than the corresponding QASSIT action criteria across all locations tested. This indicates the material has the potential to generate sulphidic acidity.
- Retained acidity, net acid soluble sulphur (S_{NAS}), was below detection limits in all but four sites (HP1b & c, HP5c, HP8-2, HP9-1). Low retained acidity is also indicated since all samples had a pH higher than 4.5, indicating o sulphur oxidation has yet taken place.
- Net acidity, which is used to predict the acid risk of a soil, was lower than detection limit across all sites.
- All sites have the ability to neutralise acidity with acid neutralising capacities above detection.
- Low net acidity and the ability to neutralise some acid means the addition of lime to manage acid generation from the dredged material would not be required if the material was to be placed on land.

6.5.6.4 Physical Characteristics – Humbug Terminal

Not all sampling locations were able to achieve the required depth of dredging, with refusal occasionally occurring close to the desired dredge depth on kaolin clay. A graphical summary of the PSD results for the Humbug Terminal dredging area sediments is presented in **Figure 6-47** with summary statistics provided in **Table 6-24**. Sediments located within the Humbug Terminal dredging area are dominated by silt and clay fractions (73%).

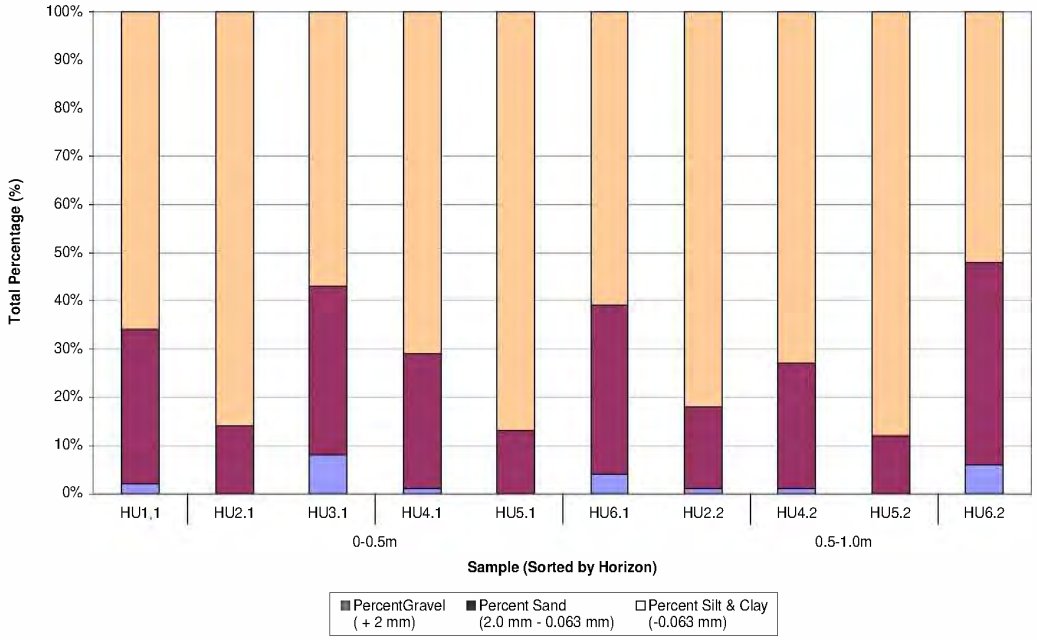

Figure 6-47 Particle Size Distribution within the Humbug Terminal Dredging Area

Table 6-24 Summary of Sediment Particle Size within the Humbug Terminal Dredging Area

Statistic	Gravel (>2mm)	Sand (0.060mm–2mm)	Silt & Clay (<0.060mm)
Number of samples	10	10	10
Mean (%)	2	25	73
Standard deviation (%)	3	11	13
Minimum (%)	0	12	52
Maximum (%)	8	42	88

6.5.6.5 Chemical Characteristics – Humbug Terminal

The chemical characteristics of the sediments from Humbug Terminal are presented in **Table 6-25** and summarised below:

Trace Metals – Total

- Mercury was below the detection level of 0.01mg/kg in three samples. Mercury was reported at the detection level in six samples. The concentration of mercury was above the detection level in one sample, HU5.2 at a concentration of 0.15mg/kg, which equals the NAGD screening level. The mean and 95%UCL of the mean for mercury were both below the NAGD screening level.

- Cadmium was detected across all sites except HU1. All detections, mean and 95%UCL of the mean were below the NAGD screening level.
- All other metals (Al, As, Cr, Cu, Fe, Mn, Ni, Pb and Zn) were detected across all sites. All detection levels, means and 95%UCLs of the mean were below respective NAGD screening criteria.

Polyaromatic Hydrocarbons (PAH)

- The concentration of naphthalene, 1-methylnaphthalene, 2-methylnaphthalene, acenaphthylene, acenaphthene, fluorene, anthracene, dibenz(a,h)anthracene and coronene was less than the LOR across all sites.
- All PAHs were below detection limits in the lower horizon samples from sites HU4 and HU6. Each of these sites only had one detection (fluoranthene and phenanthrene respectively) in the upper horizon.
- Phenanthrene, fluoranthene, pyrene, benz(a)anthracene, chrysene, benzo(b)&(k)fluoranthene, benzo(a)pyrene, indeno(1,2,3-cd)pyrene, benzo(g,h,i)perylene, benzo(e)pyrene were above detection limits across the majority of remaining sites.
- There are no NAGD screening levels for individual PAH species. Total PAHs were below the screening level at the mean and 95%UCL of the mean.

Organotins

- Monobutyltin and tributyltin were not detected at any site.
- Dibutyltin was detected in the upper horizon of HU2 and both the upper and lower horizons of HU5. There are no NAGD screening levels for dibutlytin.

Acid Sulphate Soils

The potential for the dredge material to be characterised as an acid sulphate soil was assessed using the SPOCAS suite of analyses. A summary of the results of acid sulphate soil analysis is provided below, and the laboratory results are provided in **Table 6-26**:

- Sediments pH ranged from 7.6 to 8.1, indicating no sulphur oxidation has yet taken place.
- TAA, which measures the soil's actual acidity prior to any oxidation taking place, was below the detection level for all samples, indicating no acid generation has yet taken place in the sediments.
- Potential sulphidic acidity (S_{POS}) indicated the oxidisable sulphur content was higher than the corresponding QASSIT action criteria across all locations tested. This indicates the material has the potential to generate sulphidic acidity;
- Retained acidity, net acid soluble sulphur (S_{NAS}), was below detection limits in all but one site (HU2.2). Low retained acidity is also indicated since all samples had a pH higher than 4.5, indicating no sulphur oxidation has yet taken place;
- Net acidity, which is used to predict the acid risk of a soil, was lower than detection limit across all sites;
- All sites have the ability to neutralise acidity with acid neutralising capacities above detection; and
- Low net acidity and the ability to neutralise some acid means the addition of lime to manage acid generation from the dredged material would not be required if the material was to be placed on land.

6.5.6.6 Physical Characteristics – Hey River Terminal

During sampling, refusal frequently occurred between 0.1 and 0.8m sediment depth on kaolin clay. Targeted dredging depths were not reached at all locations. Due to the shallow depth of penetration, sediments were submitted as single horizons for each site. A graphical summary of the PSD results for the Hey River Terminal dredging area sediments is presented in **Figure 6-48** while summary statistics are provided in **Table 6-27**. Gravel was the dominant particle size (41%), followed by sand (35%), and silt and clay (24%).

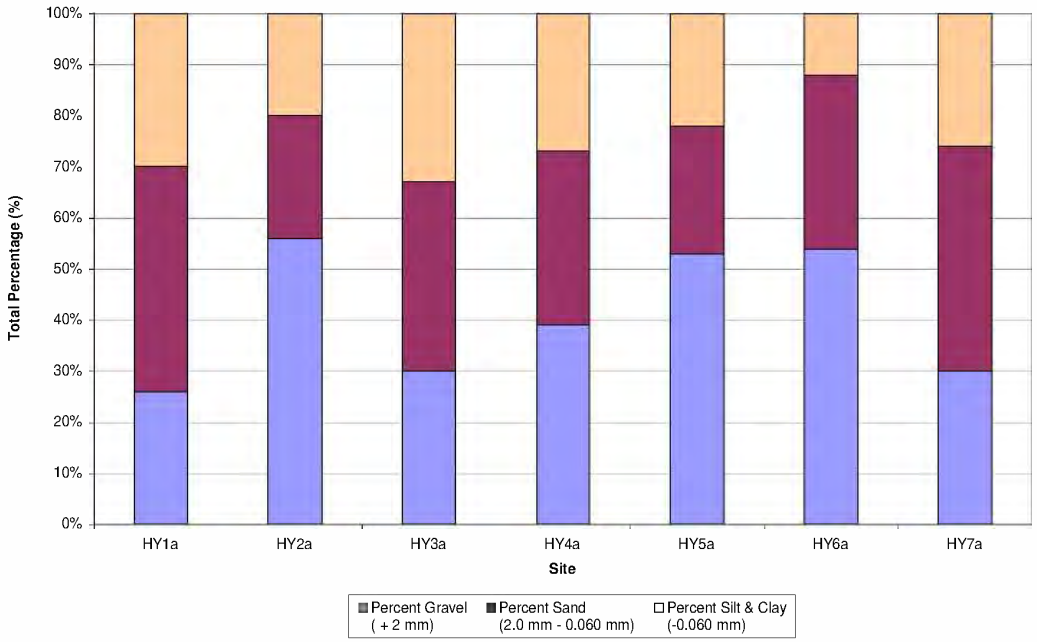

Figure 6-48 Particle Size Distribution within the Hey River Terminal Dredging Area

Minimum (%)	26	24	12
Maximum (%)	56	44	33

6.5.6.7 Chemical Characteristics – Hey River Terminal

The chemical characteristics of the sediments at the Hey River Terminal are presented in **Table 6-29** and summarised below:

Trace Metals - Total

- Mercury was below detection limits across all sites.

- Cadmium was below detection limits at three (HY1, HY2 and HY5) of the seven sites. Detection at the remaining sites was below the NAGD screening limits.
- Arsenic was detected across all sites. Three (HY4, HY6 and HY7) of the seven sites had detections above the NAGD screening level. The mean (20.7mg/kg) and 95%UCL of the mean (25.8mg/kg) for arsenic were above the NAGD screening level of 20mg/kg. Although there is an absence of potential anthropogenic arsenic sources in the region, further core samples were taken on 23 September 2009 at the three sites (HY4, HY6 and HY7) with highest arsenic concentrations. These were tested for total arsenic, concentrations in elutriate water, and bioavailable arsenic using dilute acid extraction (refer **Section 6.5.4.1** for methods).
- Elutriate arsenic concentrations were all reported above the low reliability ANZECC/ARMCANZ (2000) water quality guideline values for arsenic (III) and arsenic (V) (refer **Table 6-28**) (no guideline for arsenic in marine waters is provided in the toxicant table of ANZECC/ARMCANZ (2000); however "low reliability" values are provided in supporting rationale and background information). A dilution factor of four would be required to achieve the lower of the guideline values (2.3µg/L) and would be readily achieved upon release from the barge hopper.
- Dilute acid extraction results identify that arsenic in the Hey River Terminal sediments has low bioavailability, with DAE concentrations being only about 11% of total concentrations. The mean and 95%UCL of the mean are well below the NAGD screening level (refer **Table 6-28**).
- All other metals (Cr, Cu, Fe, Mn, Ni, Pb, and Zn) were detected across all sites in concentrations below respective NAGD screening levels. All 95%UCLs of the mean for these elements were also below respective NAGD screening levels.

Table 6-28 Summary of Arsenic Total, Elutriate and Dilute Acid Extraction Results

Analysis	Units	LOR	NAGD PQL	NAGD Screening Level	ANZECC/ ARMCANZ Water Quality Guideline	HY7	HY6	HY4	Arithmetic Mean	Standard Deviation	95%UCL	95th Percentile (and dilution factor required to meet WQ Guideline)
Total arsenic	mg/kg	<0.4	0.5	20		11	26	27	21.3	8.96	36.4	-
Elutriate arsenic	µg/L	<5	-	-	2.3 & 4.5*	7.9	5.3	7.5	6.9	1.42	-	7.87 (4)
DAE Arsenic	mg/kg	<0.4	0.5	20		1.6	2.5	2.5	2.2	0.52	3.1	-

Legend

PQL	Practical Quantitation Limit
DAE	Dilute acid exctraction using 1M HCl
-	No guidelines levels set in NAGD for given parameter, or no analysis undertaken for a given sample
	Value exceeds NAGD Screening Level
	Value exceeds ANZECC/ARMCANZ(2000) guideline
*	ANZECC/ARMCANZ (2000) low reliability trigger values for As (III) and As (V) in marine waters.
mg/kg	Milligrams per kilograms
µg/L	Micrograms per litre

Polyaromatic Hydrocarbons *(PAH)*

- The concentration of all polyaromatic hydrocarbons in sediment samples was less than the LOR across all sites.

Organotins

- The concentration of all organotins in sediment samples was less than the LOR across all sites.

Acid Sulphate Soils

The potential for the dredge material to be characterised as an acid sulphate soil was assessed using the SPOCAS suite of analyses. A summary of the results of acid sulphate soil analysis is provided below, and the laboratory results are provided in **Table 6-31**.

- Sediments pH ranged from 7.5 to 7.9, indicating no sulphur oxidation has yet taken place.
- TAA, which measures the soils actual acidity prior to any oxidation taking place, was below the detection level for all samples, indicating no acid generation has yet taken place in the sediments.
- Potential sulphidic acidity (S_{POS}) indicated the oxidisable sulphur content was higher than the corresponding QASSIT action criteria across all locations tested. This indicates the material has the potential to generate sulphidic acidity.
- Retained acidity, net acid soluble sulphur (S_{NAS}), was below detection limits in all but two sites (HY2 and HY3). Low retained acidity is also indicated since all samples had a pH higher than 4.5 indicating that no sulphur oxidation has yet taken place.
- Net acidity, which is used to predict the acid risk of a soil, was lower than detection limit across all sites.
- All sites have the ability to neutralise acidity with acid neutralising capacities above detection.
- Low net acidity and the ability to neutralise some acid means the addition of lime to manage acid generation from the dredged material would not be required if the material was to be placed on land.

6.5.6.8 Suitability of Dredged Material for Sea Dumping – Hornibrook, Humbug and Hey River Sediments

Chemical analyses of sediments to be dredged from the Hornibrook Terminal area demonstrate that potential contaminants, if present, are all below respective NAGD screening level criteria for individual samples, the mean and 95%UCL of the mean. Based on this assessment it is considered that dredge material from the Hornibrook Terminal area is suitable for unconfined ocean disposal at the Albatross Bay spoil ground.

At the Humbug Terminal area, no contaminants in sediments exceeded NAGD screening levels for any samples; however one sample contained mercury at the screening level. Despite this, the mean and 95%UCL of the mean for all contaminants was below respective NAGD screening levels. Based on this assessment it is considered that dredge material from the Humbug Terminal area is suitable for unconfined ocean disposal at the Albatross Bay spoil ground.

Analyses of sediment samples collected from the Hey River Terminal area demonstrate that concentrations for all but one contaminant were below respective NAGD screening levels. Arsenic is the exception, with three of the seven sites exceeding the NAGD screening level of 20mg/kg. The mean and the 95%UCL of the mean were also above the NAGD screening levels. Further testing of sediments identified the arsenic had low bioavailability, with DAE concentrations well below the NAGD screening level and elutriate concentrations requiring only minimal dilution to achieve ANZECC/ARMCANZ (2000) low reliability water quality guidelines. Accordingly, the sediments to be dredged from the Hey River Terminal area are considered suitable for unconfined ocean disposal at the Albatross Bay spoil ground.

For each of the three dredge areas, sediments have the ability to generate acidity; however it was evident this had not yet taken place. All sediments also had sufficient acid neutralising capacity to neutralise any acid generated. Consequently, the addition of lime to manage acid generation would not be required for any sediments if they were to be placed on land.

6.5.7 Albatross Bay Spoil Ground Sediment Characterisation

The material is proposed to be disposed of in the existing Port of Weipa spoil ground in Albatross Bay. The disposal ground is located approximately 5km northwest of the seaward end of the South Channel.

The spoil ground is defined by a 2,000m radius, centred on the following coordinates:

S12° 39′ 34.7″ E141° 39′ 24.1″ (WGS84)

The location of the Albatross Bay spoil ground in relation to the Project area and the proposed new spoil ground is shown in **Figure 2-9**. The relevant AusMap is Au301.

The approved Albatross Bay spoil ground was commissioned in 1998 and since that time has received capital and maintenance dredging material from operations within the Port of Weipa. **Table 6-31** shows the volumes disposed in the spoil ground between 2002 and 2008. The spoil ground received over 3,000,000m^3 of capital dredging material from the entrance channel in 2006–2007. Before any material is placed at the Albatross Bay spoil ground, the spoil must be proven to be suitable for placement at sea using the NAGD assessment framework.

Table 6-31 History of Disposal at the Albatross Bay Spoil Ground (2002-2008)

Year of Dredging	Type of Dredging	Volume of In-situ Materials (m^3)
2002	Maintenance	976,585
2003	Maintenance	463,513
2004	Maintenance	621,650
2005	Maintenance	803,098
2006	Capital and Maintenance	2,976,868
2007	Maintenance	796,848
2008	Maintenance	779,599

Source: SKM (2009b)

The existing Albatross Bay spoil ground is south of the boundary of the proposed Fish Habitat Area (refer **Section 1.9.16**).

6.5.7.1 Chemical Characteristics

Chemical characteristics of the Albatross Bay spoil ground sediments is not available from published sources; however it is an active spoil ground and would receive only sediments that have been identified as suitable and approved for sea dumping.

The most recent chemical characterisation of materials to be placed at the Albatross Bay spoil ground was undertaken by SKM (2009b) on behalf of NQBP. This survey physically and chemically characterised material from 68 locations from seven dredge areas from within the Port of Weipa. Three reference locations were also analysed. The dredge areas, estimated annual dredge volumes and number of sampling locations area provided in **Table 6-32**.

Table 6-32 Port of Weipa 2008 Maintenance Dredging Sediment Characterisation

Dredge Area	Estimated Annual Dredge Volume (m^3)	Number of Sampling Locations
South Channel	1,000,000	21
Evans Landing Wharf	8,000	6
Humbug Wharf	8,000	6
Lorim Point Wharf	31,000	10
Approach Channel	23,000	9
Departure Channel	31,000	10
Tug berth	10,000	6
Reference Site	Not applicable	3

Samples were collected and analysed for:

- metals (As, Cd, Cr, Cu, Hg, Ni, Pb, Zn);
- polynuclear aromatic hydrocarbons (PAHs);
    - Individual species;
    - Sum of low molecular weight;
    - Sum of high molecular weight; and
    - Total PAHs.
- organotins (MBT, DBT and TBT); and
- total organic carbon for the purposes of normalising organic contaminants.

Sample results were compared to the screening levels identified in the NODGDM (Commonwealth of Australia 2002), which is the guideline document superseded by the NAGD in 2009. Under the NAGD, screening levels for TBT and total PAHs increased.

The South Channel, Approach Channel, Departure Channel and Tug Berth sample results were below all NODGDM screening levels. Samples that were above the NODGDM criteria in the remaining dredge areas were as follows.

- Lorim Point: two samples of TBT, with one of these well above the maximum level. This was likely due to the presence of a flake of antifouling paint in the sample. Only one of these samples would have exceeded the NAGD screening levels.
- Evans Landing: Two samples had PAH concentrations that exceeded screening and maximum concentrations across a range of species.
- Humbug Wharf: Nickel exceeded the screening level in one sample.

The 95%UCL of the mean calculated for Lorim Point, Evans Landing and Humbug Wharf identified the following exceedances of the NODGDM screening levels.

- Lorim Point: TBT was above the maximum level. This is due to the influence of the single result that likely had a flake of antifouling paint in the sample.
- Evans Landing: PAH species, sum of low molecular weight PAHs , sum of high molecular weight PAHs and total PAHs were all above the NODGDM screening levels. However these levels would be complaint with the current NAGD criteria.
- Humbug Wharf: Nickel was below the NODGDM.

In accordance with the NODGDM and NAGD sediment assessment framework, further testing was conducted in these areas.

Elutriate and direct toxicity testing was undertaken on Lorim Point sediments to assess the potential impacts of TBT on water quality during placement a sea and toxicity to benthic organisms following placement. Elutriate analysis results were below the ANZECC/ARMCANZ (2000) guideline value for TBT of 0.06ng Sn/L. Ecotoxicity assessment on whole sediments and porewaters from Lorim Point and Evans Landing identified that samples from both areas showed no observable toxicity.

On the basis of the results obtained, the maintenance dredging material to be sourced from the South Channel, Evans Landing, Humbug Wharf, Lorim Point, the Tug Berth and the Approach and Departure Channels were recommended as being suitable for unconfined placement at the Albatross Bay spoil ground.

Further chemical characterisation of sediments from the Albatross Bay spoil ground was not completed as part of this study on the basis that:

- The volumes to be placed by the Project are small in comparison to the annual loads being deposited by routine maintenance dredging at the Port of Weipa; and
- The physical and chemical characteristics of the spoil may change due to further routine maintenance dredging at the Port of Weipa prior to dredging at the ferry/barge terminal locations in the Hey and Embley Rivers.

6.5.7.2 Physical Characteristics

As part of infauna sediment assessments for the present study (refer **Section 6.6.8**), nine sediment samples (DG1-DG9) were collected within the Albatross Bay spoil ground using a van Veen sediment grab and analysed for particle size distribution (PSD). A graphical summary of the PSD results is presented in **Figure 6-49** while summary statistics are provided in **Table 6.33**.

Surface sediments are dominated by silt and clay (62%) and sand fractions (37%). Gravel comprises only about 1% of the sediments.

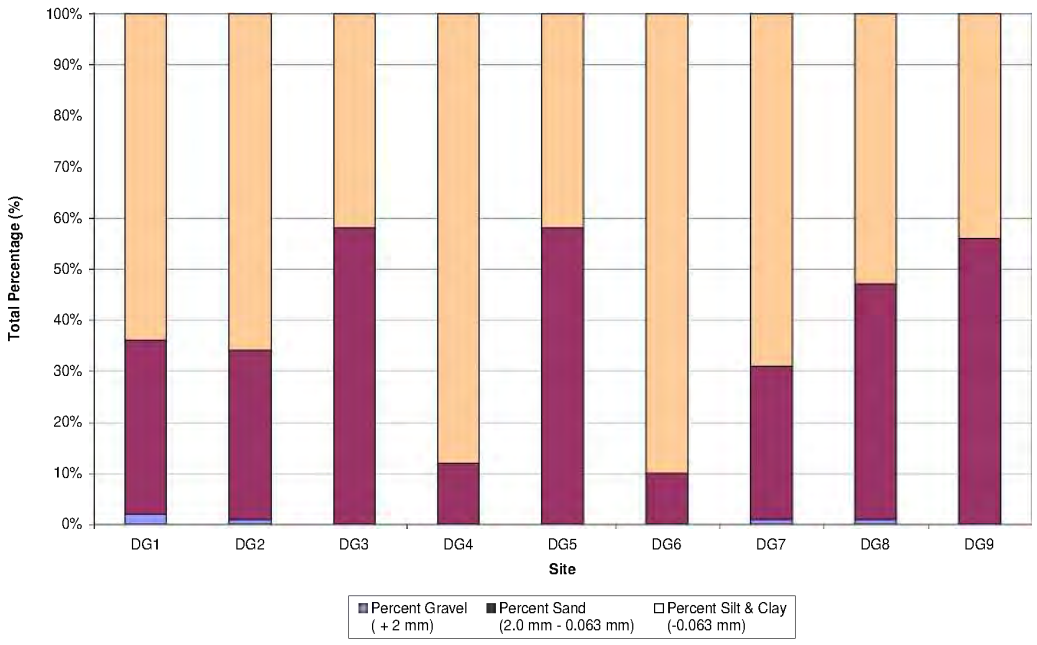

Figure 6-49 Particle Size Distribution Results for the Albatross Bay Spoil Ground

Table 6-33 Summary of Sediment Particle Size at the Albatross Bay Spoil Ground

Statistic	Gravel (>2mm)	Sand (0.063mm–2mm)	Silt & Clay (<0.063mm)
Number of samples	9	9	9
Mean (%)	1	37	62
Standard deviation	0.7	18	18
Minimum (%)	0	10	42
Maximum (%)	2	58	90

6.6 Marine Fauna

6.6.1 Listed Threatened and Migratory Species

This section identifies the threatened species and migratory marine species that are Matters of National Environmental Significance (MNES) under the *Environment Protection and Biodiversity Conservation Act 1999* (Commonwealth) (EPBC Act) that occur or potentially occur in the Project area. A search using the EPBC Act "Protected matters search tool" was conducted over three areas to define the Project area bound by coordinates listed in **Table 6-34** with a 5km buffer.

Table 6-34 EPBC Act "Protected Matters Search Tool" Coordinates

	Latitude			Longitude		
Location point	degrees	minutes	seconds	degrees	minutes	seconds
A1	–12	41	4.5	141	34	34
A2	–12	41	4.5	141	54	55

EPBC Act = *Environment Protection and Biodiversity Conservation Act 1999* (Commonwealth)

The status of threatened and migratory species is shown in **Table 6-35** along with the likelihood of occurrence in the Project area. Marine species protected under the *Nature Conservation Act 1992* (Queensland) (NC Act) are included. The conservation status of relevant marine species under The *IUCN Red List of Threatened Species* (IUCN 2008) is also presented.

Marine species of conservation significance are described in **Section 6.6.2 to Section 6.6.6** below and potential impacts are described in **Section 6.9.4**.

Table 6-35 Threatened and Migratory Marine Species Status

Species name	IUCN Red List	EPBC Act	NC Act	Preferred habitat in the Weipa/ Cape York region	Likelihood of Occurrence within the Project Area and Areas of Proposed Disturbance within the Project Area
Estuarine Crocodile (*Crocodylus porosus*)	Lower risk	Migratory species	Vulnerable	Estuarine and inshore waters	**Project Area** ***Known to Occur*** Tracks of this species were recorded during field work within the study area and verified by Traditional Owners. Nesting was observed near Norman Creek. **Proposed Port Site** ***Known to Occur:*** This species has been recorded in marine environments within the Project area. **Proposed Spoil Ground** ***Possible:*** This species has been recorded within marine environments within the Project area, although not as far out to sea as the proposed spoil ground. However this species is known to occasionally traverse some distance into the marine environment, so it is possible that this species may occur in this area on occasion. **Albatross Bay Spoil Ground** ***Possible:*** This species has been recorded within marine environments within the Project area, although not as far out to sea as the Albatross Bay spoil ground. However this species is known to occasionally traverse some distance into the marine environment, so it is possible that this species may occur in this area on occasion. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Known to Occur:*** This species has been recorded in estuarine environments within the Project area. The ferry/barge terminal sites are within estuarine and sometimes mangrove environments. Estuarine and mangrove habitats of which the ferry/ barge terminal areas are the main habitat for this species. The species is likely to use the habitat within the ferry/barge terminal areas for foraging and shelter. **Dam C on a Freshwater Tributary of Norman Creek and Upstream of Dam C** ***Known to Occur:*** This species has been recorded in freshwater environments within the Project area. Foraging and nesting habitats for this species have been recorded within the footprint of Dam C.

Species name	IUCN Red List	EPBC Act	NC Act	Preferred habitat in the Weipa/ Cape York region	Likelihood of Occurrence within the Project Area and Areas of Proposed Disturbance within the Project Area
Indo-Pacific Humpback Dolphin (*Sousa chinensis*)	Data deficient	Migratory species	Near threatened	Inshore coastal waters to a depth of approximately 20 metres.	**Project Area** ***Known to Occur:*** Incidental sightings of this species were recorded during field studies. **Proposed Port Site** ***Known to Occur:*** Incidental sightings of this species were recorded within the proposed port footprint during field studies. **Proposed Spoil Ground** ***Possible:*** This species usually inhabits shallow coastal waters less than 20m deep and are often associated with tidal riverine and estuarine systems, enclosed bays and coastal lagoons (Corkeron *et al.* 1997; Hale *et al.* 1998; Jefferson 2000; Parra 2006). While the proposed spoil ground does not represent preferred habitat, it is possible they are transient in the area. **Albatross Bay Spoil Ground** ***Possible:*** For the same reasons as the proposed spoil ground, while preferred habitat isn't present, it is possible they are transient in the area. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Likely:*** As this species is often associated with tidal riverine and estuarine systems, it is likely that this species may occur in the vicinity of the ferry/barge terminals.
Bottlenose Dolphins (*Tursiops aduncus* and *Tursiops truncatus*)	Data deficient	—	—	Inshore and nearshore coastal waters to a depth of approximately 50 metres.	**Project Area** ***Known to Occur:*** Incidental sightings of this species were recorded during field studies. **Proposed Port Site** ***Known to Occur:*** Incidental sightings of this species were recorded within the proposed port footprint during field studies. **Proposed Spoil Ground** ***Likely:*** Although this species distribution does not normally include the vicinity of the Project area, the offshore species of this dolphin is likely to occur within the proposed spoil ground as the site as the depth of waters at the proposed spoil ground is within the preferred rang of this species. **Albatross Bay Spoil Ground** ***Likely:*** For the same reasons as the proposed spoil ground, it is likely that the offshore species of this dolphin is would occur at the Albatross Bay spoil ground. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Likely:*** Inshore species likely to occur in estuarine areas as part of inshore habitat.

Species name	IUCN Red List	EPBC Act	NC Act	Preferred habitat in the Weipa/ Cape York region	Likelihood of Occurrence within the Project Area and Areas of Proposed Disturbance within the Project Area
Australian Snubfin Dolphin (*Orcaella heinsohni*) (Note: Previously the Australian Snubfin Dolphin was identified as the widely distributed Irrawaddy Dolphin (*Orcaella brevirostris*) (Beasley et al. 2005))	Data deficient	Migratory species	Near threatened	Inshore coastal waters to a depth of approximately 20 metres.	**Project Area** ***Known to Occur:*** Incidental sightings of this species were recorded during field studies. **Proposed Port Site** ***Known to Occur:*** Incidental sightings of this species were recorded in the vicinity of the proposed port footprint during field studies. **Proposed Spoil Ground** ***Possible:*** This species usually inhabits shallow coastal waters less than 20m deep and are often associated with tidal riverine and estuarine systems, enclosed bays and coastal lagoons (Corkeron *et al.* 1997; Hale *et al.* 1998; Jefferson 2000; Parra 2006). The proposed spoil ground is in deeper water than this and therefore it is unlikely to represent preferred habitat for this species. However, it is possible they may be transient in the area. **Albatross Bay Spoil Ground** ***Possible:*** For the same reasons as the proposed spoil ground while preferred habitat isn't present, it is possible they are transient in the area. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Likely:*** As this species is often associated with tidal riverine and estuarine systems, it is likely that this species may occur in the vicinity of the ferry/barge terminals.
Bryde's Whale (*Balaenoptera edeni*)	—	Migratory species	—	Pelagic environment including principally continental shelf waters but also extending into coastal and inshore waters	**Project Area** ***Possible:*** While the Project area does not contain preferred habitat, the recording of the species from tropical inshore waters suggests it is possible the species may occur sporadically in the Project area. **Proposed Port Site** ***Possible:*** While the proposed port site does not contain preferred habitat, the recording of the species from tropical inshore waters suggests it is possible the species may occur sporadically in the vicinity of the proposed port footprint. **Proposed Spoil Ground** ***Possible:*** This species may possibly occur within the proposed spoil ground footprint for the same reasons that it possibly occurs in the vicinity of the proposed port site. **Albatross Bay Spoil Ground** ***Possible:*** This species may occur within the Albatross Bay spoil ground footprint for the same reasons that it possibly occurs in the vicinity of the proposed port site. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Unlikely:*** Although this species occurs in shallow water, it generally is found in coastal areas rather than estuaries. It is therefore unlikely to occur within the Embley and Hey River estuaries, including in the vicinity of the barge/ferry terminal footprints.

Species name	IUCN Red List	EPBC Act	NC Act	Preferred habitat in the Weipa/ Cape York region	Likelihood of Occurrence within the Project Area and Areas of Proposed Disturbance within the Project Area
Humpback Whale (*Megaptera novaeangliae*)	—	Vulnerable Migratory species	Vulnerable	Pelagic environment, including but not limited to coastal waters. No feeding areas are located in the Gulf of Carpentaria and the Gulf of Carpentaria is not along the migratory path.	***Unlikely:*** No feeding areas are located in the Project area and it is not along the migratory path of the species.
Killer Whale (*Orcinus orca*)	—	Migratory species	—	Pelagic environment primarily limited to the continental shelf.	***Unlikely:*** The species prefers offshore waters and as such is unlikely to occur in the Project area.
Blue Whale (*Balaenoptera musculus*)	—	Endangered Migratory species	—	Pelagic environment near the edge of the continental shelf. They are unlikely to occur in the Gulf of Carpentaria, preferring the cooler waters of southern Australia.	***Unlikely:*** The species principally occurs near the edge of the continental shelf in cooler waters and not in inshore areas of the Project area.
Dugong (*Dugong dugon*)	Vulnerable	Migratory species	Vulnerable	The species prefers shallow seagrass beds dominated by pioneering species of species such as *Halophila* spp.	**Project Area** ***Known to Occur:*** Dugong is known to occur in the area associated with seagrass beds. Traditional Owners report that the species migrates through Boyd Bay. The species is highly migratory and will traverse coastal waters between seagrass beds. **Proposed Port Site** ***Known to Occur:*** Traditional Owners report that the species migrates through Boyd Bay which also indicates migration past the proposed port site. **Proposed Spoil Ground** ***Possible:*** This species may migrate through this area between feeding grounds, however it is more likely that the species would migrate through shallower waters than where the footprint of the proposed spoil ground occurs. **Albatross Bay Spoil Ground** ***Possible:*** This species may possibly occur within the Albatross Bay spoil ground footprint for the same reasons that it possibly occurs in the vicinity of the proposed spoil ground footprint. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Known to Occur:*** The Dugong is known to occur in the area associated with seagrass beds. The seagrass beds in the Embley and Hey Rivers potentially constitute feeding habitat for Dugong; however, no Dugong were incidentally observed associating with these seagrass beds during marine field surveys for this Project.

Species name	IUCN Red List	EPBC Act	NC Act	Preferred habitat in the Weipa/ Cape York region	Likelihood of Occurrence within the Project Area and Areas of Proposed Disturbance within the Project Area
Green Sawfish (*Pristis zijsron*)	Critically endangered	Vulnerable	—	Occurs in estuaries, river mouths, embayments and along sandy and muddy beaches.	**Project Area** ***Likely:*** The species has been recorded from Albatross Bay and the Project area contains suitable habitat for the species. **Proposed Port Site** ***Likely:*** The species has been recorded from Albatross Bay and the proposed port footprint contains suitable habitat for the species. **Proposed Spoil Ground** ***Unlikely:*** This species prefers shallower waters. The proposed spoil ground is in waters that are deeper than what this species would usually prefer. **Albatross Bay Spoil Ground** ***Unlikely:*** For the same reasons as the proposed spoil ground, it is unlikely that this species would occur at the Albatross Bay spoil ground. **Dam C on a Freshwater Tributary of Norman Creek and Upstream of Dam C** ***Unlikely:*** This species is not found within freshwater environments. Dam C would be located on a freshwater reach of Norman Creek. Therefore this species is unlikely to occur within the footprint of the proposed Dam C or upstream of this dam. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Likely:*** Records from Albatross Bay adjoining the mouth of the Embley River make occurrence of this species within the estuarine sections of the Hey and Embley Rivers likely. The extent of Project related disturbance of these areas would be minimal in relation to the total estuarine environment available within these rivers. Disturbance would consist of the clearance of 400m^2 of mangroves (0.008% of the associated vegetation community within the Project area) and 2.1ha of riverbed. The dredging in these areas would only be to a depth of -2m LAT.

Species name	IUCN Red List	EPBC Act	NC Act	Preferred habitat in the Weipa/ Cape York region	Likelihood of Occurrence within the Project Area and Areas of Proposed Disturbance within the Project Area
Narrow Sawfish (*Anoxypristis cuspidata*)	Critically endangered	—	—	Occurs in estuaries, river mouths, embayments and along sandy and muddy beaches.	**Project Area** ***Likely:*** The species has been recorded from Albatross Bay and the Project area contains suitable habitat for the species. **Proposed Port Site** ***Likely:*** The species has been recorded from Albatross Bay and the proposed port footprint contains suitable habitat for the species. **Proposed Spoil Ground** ***Unlikely:*** This species prefers shallower waters. The proposed spoil ground is in waters that are deeper than what this species would usually prefer. **Albatross Bay Spoil Ground** ***Unlikely:*** For the same reasons as the proposed spoil ground, it is unlikely that this species would occur at the Albatross Bay spoil ground. **Dam C on a Freshwater Tributary of Norman Creek and Upstream of Dam C** ***Unlikely:*** This species does not occur in freshwater; therefore it is unlikely to traverse as far as the footprint of Dam C, which is on a freshwater tributary of Norman Creek. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Possible:*** This species is known to inhabit the floor of estuaries. The ferry/barge terminal footprints are within estuarine environments, therefore it is possible that this species may occur in these areas.

Species name	IUCN Red List	EPBC Act	NC Act	Preferred habitat in the Weipa/ Cape York region	Likelihood of Occurrence within the Project Area and Areas of Proposed Disturbance within the Project Area
Dwarf Sawfish (*Pristis clavata*)	Critically endangered	Vulnerable	—	Occurs in estuaries, river mouths, embayments and along sandy and muddy beaches.	**Project Area** ***Likely:*** The species is likely to occur within Albatross Bay and the Project area contains suitable habitat for the species. **Proposed Port Site** ***Likely:*** The species has been recorded from Albatross Bay and the proposed port footprint contains suitable habitat for the species. **Proposed Spoil Ground** ***Unlikely:*** This species prefers shallower waters. The proposed spoil ground is in waters that are deeper than what this species would usually prefer. **Albatross Bay Spoil Ground** ***Unlikely:*** For the same reasons as the proposed spoil ground, it is unlikely that this species would occur at the Albatross Bay spoil ground. **Dam C on a Freshwater Tributary of Norman Creek and Upstream of Dam C** ***Unlikely:*** This species is not found and does not breed within freshwater environments. Dam C would be located in a freshwater reach of Norman Creek. Therefore this species is unlikely to occur within the proposed footprint of Dam C or upstream of the dam. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Likely:*** Suitable habitat for this species is present in near coastal areas and the estuary of the Embley River. Disturbance in the Embley River associated with the Project would be limited to a small amount of dredging activities related to the construction and maintenance of the Hornibrook Ferry Terminal. This species may also utilise as a resting place either side of high tide, the 400m^2 of mangrove forest that would be cleared for the construction of the Hey River ferry/barge terminal. The area of mangroves that would be cleared only represents 0.008% of this mangrove community within the Project area. Therefore there would be sufficient remaining mangrove habitat in the surrounding area which the species would be able to utilise for resting.
Whale Shark (*Rhincodon typus*)	Vulnerable	Vulnerable	—	Pelagic environment near the edge of the continental shelf. The Gulf of Carpentaria does not represent preferred habitat.	***Unlikely:*** This species is unlikely to occur in the study area. The species prefers oceanic environments. The Project area does not provide the preferred habitat.

Species name	IUCN Red List	EPBC Act	NC Act	Preferred habitat in the Weipa/ Cape York region	Likelihood of Occurrence within the Project Area and Areas of Proposed Disturbance within the Project Area
Green Turtle (*Chelonia mydas*)	Endangered	Vulnerable Migratory species	Vulnerable	Coastal waters, in particular seagrass beds. The Wellesley Island area in the south-western corner of the Gulf of Carpentaria is a significant nesting site.	**Project Area** ***Likely:*** The species is likely to forage in the Project area. Surveys have found no nests in the Project area. No large rookeries are present in the region. **Proposed Port Site** ***Likely:*** This species is known to forage in shallow coastal areas, which would include the proposed port site footprint. Surveys have found no nests within the footprint of the proposed port site. **Proposed Spoil Ground** ***Possible*** This species prefers to forage in shallow coastal areas or within seagrass beds. The proposed spoil ground would be too deep to provide preferred foraging habitat for this species and it contains no seagrass beds. While the proposed proposes spoil ground does not represent preferred habitat, it is possible they are transient in the area. **Albatross Bay Spoil Ground** ***Possible:*** For the same reasons as the proposed spoil ground, it is unlikely that this species would frequently occur at the Albatross Bay spoil ground; however, it is possible that they transit the area. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Likely:*** As this species is known to forage within shallow coastal areas and seagrass beds. Foraging habitat for this species is present in the estuaries.
Hawksbill Turtle (*Eretmochelys imbricata*)	Critically endangered	Vulnerable Migratory species	Vulnerable	Hawksbill Turtle nesting sites occur on islands adjacent to Arnhem Land and north-eastern Cape York. The main feeding habitat for the species tends to be tidal and sub-tidal reefs.	**Project Area** ***Known to Occur:*** Although difficulties in identifying nest activity of this species exist, low density nesting is recorded from a number of locations from False Pera Head to Boyd Bay. Reef habitat in the area is also likely to provide significant foraging habitat for the species. **Proposed Port Site** ***Likely:*** Near shore fringing reef communities occur within the vicinity of the proposed port area occur at Boyd Point, Pera Head and between Pera Head and Thud Point. This species may therefore traverse across the proposed port site to access preferred feeding habitat. This species is also known to nest on the beaches in the vicinity of the Project area. Therefore it may be assumed that the footprint of the proposed port site may also contain suitable nesting habitat for this species. **Proposed Spoil Ground** ***Possible:*** As Nine Mile Reef which includes suitable foraging habitat for this species is located approximately 6km south-south-west of the proposed spoil ground, this species may traverse the proposed spoil ground to access Nine Mine Reef for foraging. **Albatross Bay Spoil Ground** ***Possible:*** The Albatross Bay Spoil ground does not contain or is not close to any reef communities. It is therefore unlikely this species would frequently occur in this area; however they may transit the site. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Unlikely:*** The ferry barge terminals would be located within an estuarine environment, which is not a preferred habitat of this species.

Species name	IUCN Red List	EPBC Act	NC Act	Preferred habitat in the Weipa/ Cape York region	Likelihood of Occurrence within the Project Area and Areas of Proposed Disturbance within the Project Area
Flatback Turtle (*Natator depressus*)	—	Vulnerable Migratory species	Vulnerable	Coastal waters including but not limited to shallow water habitats. Nesting is confined to Australia. The species forages in shallow inshore areas.	**Project Area** ***Known to Occur:*** The Flatback Turtle is likely to forage in the Project Area and nesting has been regularly recorded and is best described as medium density nesting. The area is not a major location for breeding aggregations of the species. **Proposed Port Site** ***Known to Occur:*** Nesting has been regularly recorded within and surrounding the proposed port site footprint and is best described as medium density nesting. The area is not a major location for breeding aggregations of the species. This species forages in shallow coastal habitats. The proposed footprint of the port would therefore be considered foraging habitat for this species. **Proposed Spoil Ground** ***Possible:*** As Nine Mile Reef which includes suitable foraging habitat for this species is located approximately 6km south-south-west of the proposed spoil ground, this species may traverse the proposed spoil ground to access Nine Mine Reef for foraging. **Albatross Bay Spoil Ground** ***Possible:*** The Albatross Bay Spoil ground does not contain or is not close to any reef communities and is not shallow in nature. It is therefore unlikely this species would occur in this area beyond transiting the site. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Likely:*** This species forages in shallow coastal habitats. The proposed footprints of the ferry/barge terminals are within an estuarine environment which may be considered foraging habitat for this species.
Olive Ridley Turtle (*Lepidochelys olivacea*) (also known as the Pacific Ridley Turtle under the NC Act)	Vulnerable	Endangered Migratory species	Endangered	Coastal waters including but not limited to reefs. The species forages in benthic habitats over a range of depths from a few metres to hundreds of metres. Low density nesting has been historically recorded from a number of locations including the eastern Gulf of Carpentaria.	**Project Area** ***Known to Occur:*** Although there are uncertainties regarding whether nesting of Olive Ridley Turtles is still occurring in the western Cape York region, low density nesting has previously been recorded from a number of locations from False Pera Head to Boyd Bay. **Proposed Port Site** ***Known to Occur:*** Sporadic nesting has been recorded surrounding the proposed port site footprint. This species forages in shallow unvegetated coastal habitats. The proposed footprint of the port would therefore be considered foraging habitat for this species. **Proposed Spoil Ground** ***Possible:*** The proposed spoil ground is too deep to provide foraging habitat for this species; however it is possible that it sporadically transits this area. **Albatross Bay Spoil Ground** ***Possible:*** For the same reasons as the proposed spoil ground, this species is unlikely to frequently occur within the Albatross Bay spoil ground due o lack of preferred habitat; however it may transit the site. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Likely:*** This species forages in shallow unvegetated coastal habitats. The parts of the proposed footprints of the ferry/barge terminals that are not vegetated may therefore provide foraging habitat for this species.

Species name	IUCN Red List	EPBC Act	NC Act	Preferred habitat in the Weipa/ Cape York region	Likelihood of Occurrence within the Project Area and Areas of Proposed Disturbance within the Project Area
Leatherback Turtle (*Dermochelys coriacea*)	Critically endangered	Endangered Migratory species	Endangered	Pelagic environment. The Albatross Bay area is identified as a potential foraging area for the species.	**Project Area** ***Likely:*** The species is likely to occur in the Project Area, using it for foraging. However, Leatherback turtles are rarely found in Queensland so any presence would be sporadic. No Leatherback Turtle nesting has been recorded in eastern Australia since 1996. **Proposed Port Site** ***Likely:*** The species is likely to occur sporadically in the vicinity of the proposed port site, using it for foraging. **Proposed Spoil Ground** ***Likely:*** The species is likely to occur sporadically in the vicinity of the proposed spoil ground, using it for foraging. **Albatross Bay Spoil Ground** ***Likely:*** The species is likely to occur sporadically in the vicinity of the Albatross Bay spoil ground, using it for foraging. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Unlikely:*** This species prefers oceanic environments to estuarine environments, so it is unlikely to utilise the estuaries that contain the proposed footprints of the ferry/barge terminals as habitat.
Loggerhead Turtle (*Caretta caretta*)	Endangered	Endangered Migratory species	Endangered	Coastal waters including subtidal and intertidal coral and rocky reefs and seagrass meadows as well as soft-bottomed habitats.	**Project Area** ***Likely:*** The species is likely to be transient in the Project area and use it for foraging or resting. No rookeries are present in the Project Area. **Proposed Port Site** ***Likely:*** The species is likely to be transient in the vicinity of the proposed port and use it for foraging or resting. **Proposed Spoil Ground** ***Likely:*** This species is likely to occur within the proposed spoil ground for the same reasons that it is likely to occur in the vicinity of the proposed port. **Albatross Bay Spoil Ground** ***Likely:*** This species is likely to occur within the Albatross Bay spoil ground for the same reasons that it is likely to occur in the vicinity of the proposed port. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Likely:*** This species is likely to occur in the vicinity of the ferry/barge terminals for the same reasons that it is likely to occur within the proposed port footprint.

— = Species not listed

6.6.2 Whales and Dolphins (Cetaceans)

A number of dolphin species are known to occur in the Gulf of Carpentaria. These include the Indo-Pacific Humpback Dolphin (*Sousa chinensis*), inshore (*Tursiops aduncus*) and offshore (*Tursiops truncatus*) forms of the Bottlenose Dolphin, and the Australian Snubfin Dolphin (*Orcaella heinsohni*). One whale species, Bryde's Whale (*Balaenoptera edeni*) inhabits inshore tropical waters, so it may occur sporadically in the Project area.

There are no specific studies of the distribution and abundance of cetaceans in the Project area. Incidental observations while undertaking the habitat mapping at the proposed port site described in **Section 6.3.2** confirmed the presence of the Indo-Pacific Humpback Dolphin, at least one species of the Bottlenose Dolphin (most probably the inshore form) and the Australian Snubfin Dolphin.

Potential impacts on cetacean populations in the vicinity of the Project area, including potential impacts on these populations associated with the construction of the port, barge and ferry terminals (including dredging and spoil dumping operations) is discussed in **Section 6.9.2.4**.

Dolphins

The Indo-Pacific Humpback Dolphin and Australian Snubfin Dolphin are listed migratory species under the EPBC Act. They usually inhabit shallow coastal waters less than 20m deep and are often associated with tidal riverine and estuarine systems, enclosed bays and coastal lagoons (Corkeron *et al.* 1997; Hale *et al.* 1998; Jefferson 2000; Parra 2006). On the east coast of Australia, the inshore bottlenose dolphin inhabits estuaries and shallow offshore waters (<30m) (Hale *et al.* 1998, 2000).

The SPRAT database suggests that the regional population levels (e.g. Queensland) of the Indo-Pacific Humpback Dolphin are likely to be in the order of thousands rather than tens of thousands (Parra *et al.* 2002). Aerial survey in the western Gulf of Carpentaria (which includes the Project area) estimated a population of about 1000 Australian Snubfin Dolphins (Freeland & Bayliss 1989). However, the estimate has been questioned due to the known difficulty of identifying dolphin species in turbid waters from the air (Parra *et al.* 2002). Based on the low numbers of Australian Snubfin Dolphins sighted during aerial and boat based surveys of the east coast of Queensland (Parra *et al.* 2002; Parra 2006) the population at a regional level (Queensland) is likely to be in the thousands rather than tens of thousands (Parra 2006). It is therefore difficult to quantify exactly an actual population size of this species within the vicinity of the Project area, however based on the above information; the Indo-Pacific Dolphin population within the vicinity of the Project area is likely to be negligible.

Bottlenose dolphins are listed cetacean species under the EPBC Act but are not threatened or a migratory species (It is noted that the Arafura/Timor Sea sub-population of *Tursiops aduncus* is migratory, but their distribution does not include the Project area or Gulf of Carpentaria). The SPRAT database notes that the Bottlenose Dolphin total population size is not known, but it is likely to be common in offshore waters of south-eastern and southern Australia (V. Peddemors & R. Harcourt 2006, pers. comm.). The total population size of inshore Bottlenose Dolphin (*Tursiops aduncus*) is also not known. However, it is likely that this species is common in inshore and nearshore waters of eastern, western and northern Australia (Ross 2006). Local population estimates suggest that 102 individuals occur in Jervis Bay, 140 in Port Stephens (Möller *et al.* 2002), about 350 in Moreton Bay (Corkeron 1990), 900 in coastal waters off North Stradbroke Island (Chilvers & Corkeron 2003), and about 1800–2400 in Shark Bay, Western Australia (Preen *et al.* 1997). Although incidental sightings were recorded of this species during field studies, its distribution does not normally include the vicinity of the Project area, therefore any population within the vicinity of the Project area is likely to be transient and of a small size.

The DSEWPaC (2010) Species Profile and Threats Database (SPRAT Database) identifies the main threats to the Indo-Pacific Humpback Dolphin and Australian Snubfin Dolphin as habitat destruction and degradation, bycatch in gillnets and shark nets, overfishing of prey species, pollution and poisoning, and interaction with vessels. The main threats likely to affect Australian Bottlenose Dolphin populations include bycatch in gillnets, entanglements in debris, and overfishing. Elsewhere in Australia, the three dolphin species co-exist with coastal development including extensive port facilities such as the Port of Brisbane and Cleveland Bay (Townsville) (Hale *et al.* 1998; Parra 2006).

Bryde's Whale

There are two forms of Bryde's Whales: coastal and offshore. The coastal form of Bryde's whale appears to be limited to the 200m depth contour, moving along the coast in response to availability of suitable prey (Best *et al.* 1984). The SPRAT database states that it is likely that Australian inshore stocks of Bryde's Whales will be small, possibly of similar size to those off South Africa (estimated at 582 ±184 animals: Best *et al.* 1984), and therefore it is unlikely that significant numbers would occur in the vicinity of the Project area. There is no evidence of large-scale migrations of the inshore form of Bryde's Whales. The offshore form is found in deeper water (500 to 1000m). Bryde's Whale is considered to be a fairly opportunistic feeder, readily consuming whatever shoaling prey is available (Kato 2002; Martin 1990). The DSEWPaC (2010) SPRAT Database identifies the main threats to Bryde's Whales as ingestion of discarded plastic, pollution, disturbance (possibly from seismic and/or defence operations), collisions with large vessels, and entanglement in fishing gear. In addition, competition with commercial fisheries may also affect these animals. The following listed threatened and migratory species were recorded on the EPBC Act protected matters search as possibly occurring within the Project area; however, they are unlikely to be present due to a lack of suitable habitat: Humpback Whale, Killer Whale and Blue Whale.

Review of the Queensland Marine Wildlife Stranding and Mortality Database annual reports from 2002-2007 (most recent) indicates that no cetacean deaths were recorded in the Western Cape York region associated with boat strikes.

6.6.3 Dugong

In the Gulf of Carpentaria, most dugongs are found in the shallow waters around the Wellesley Islands in Queensland (485km from the project area) and from the Sir Edward Pellew Islands to Blue Mud Bay in the Northern Territory (Saalfeld and Marsh 2004). Aerial surveys of the Queensland coast of the Gulf in 1997 and the Northern Territory coast of the Gulf in 1985 and 1994 indicate that the total number of Dugongs in the Gulf of Carpentaria is in the range 20,000 to 30,000 (Seagrass Watch, 2005). In 1997, Saalfeld and Marsh (2004) estimated that the population of Dugong on the Queensland Gulf of Carpentaria Coast to be 4,266 +/-657, which represents approximately 14-21% of the estimated Gulf of Carpentaria population. Based on an estimated Australian population of 80,000 (Saalfeld and Marsh 2004), the Queensland Gulf of Carpentaria dugong population represents approximately 5% of the Australian population.

In a 1997 survey (Saalfeld and Marsh 2004), the following number of Dugongs were sighted within the vicinity of the Project area.

- two Dugongs within Albatross Bay;
- three Dugongs at sea adjacent to Albatross Bay;
- one Dugong near Aurukun; and
- one Dugong to the north of Jantz Point.

This represents a total of seven Dugongs sighted within the vicinity of the Project area, which represents approximately 0.2% of the Queensland Gulf of Carpentaria Coast population, between 0.023% and 0.035% of the Gulf of Carpentaria population and 0.009% of the Australian population.

Dugongs prefer to feed on seagrasses that are early or "pioneer" species, particularly species of the genera *Halophila* and *Halodule* (DEWHA 2010a). Field studies verify that seagrass beds do not occur at the proposed port site or the proposed new dredge disposal area. While no foraging areas for Dugong occur in the area of the port development, it is likely Dugong traverse it as they travel between seagrass resources. However, Dugongs were not observed at the proposed port location during the marine ecology surveys undertaken for the purposes of this EIS. The seagrass beds in the Embley and Hey Rivers potentially constitute feeding habitat for Dugong; however, no Dugong were observed associating with these seagrass beds during field studies. The long, strap-like seagrass *Enhalus acoroides*, which dominates the seagrass beds of the Embley and Hey Rivers, is not a preferred species in the Dugong diet.

Dugong mortality in the Gulf of Carpentaria may currently be caused by traditional hunting, incidental capture in commercial mesh nets, targeted capture by illegal foreign fishing vessels in Australian waters, and boat strikes from fast moving vessels. Populations would be vulnerable to a reduction in the area and quality of seagrass beds.

Potential impacts on any Dugong population in the vicinity of the Project area, including potential impacts on any dugong population associated with the construction of the port, barge and ferry terminals (including dredging and spoil dumping operations) is discussed in **Section 6.9.2.3**.

6.6.4 Sharks and Rays

The shark and ray fauna of Albatross Bay is diverse and abundant (Blaber *et al.* 1990): 23 shark species are recorded, 18 of these being whaler sharks (Family Carcharhinidae). The numerically dominant shark species in Albatross Bay is the spot-tail shark (*Carcharhinus sorrah*) and the blacktip shark (*Carcharhinus tilstoni*), comprising 83% of the shark and ray assemblage (Salini *et al.* 1992). Three species of sawfish are also recorded:

- Green Sawfish, *Prisitis zijsron*;
- Narrow Sawfish, *Anoxypristis cuspidata*; and
- Dwarf Sawfish, *Pristis clavata.*

While only the Green Sawfish and Dwarf Sawfish are listed threatened species (Vulnerable) under the EPBC Act, all are listed as critically endangered by the IUCN. The populations of sawfishes in the Gulf of Carpentaria are of global significance. The major threat to sawfish populations is incidental capture in fishing nets (refer also to **Section 8.10**).

The preferred habitat of sawfishes is shallow inshore sedimentary habitats (less than 10m), although they have been recorded in the Gulf of Carpentaria from waters deeper than 20m. Sawfishes in the Gulf of Carpentaria breed through the wet season until the beginning of the dry period in May (Peverell 2005). A further 16 species of stingrays and shovelnose rays are also recorded from Albatross Bay, all with a wide geographic distribution.

The Whale Shark was recorded on the EPBC Act protected matters search as possibly occurring within the Project area; however, this species is unlikely to be present due to a lack of suitable habitat.

6.6.5 Marine Turtles

Three species of marine turtles – the Flatback Turtle (*Natator depressus*), the Olive Ridley Turtle (*Lepidochelys olivacea*), and the Hawksbill Turtle (*Eretmochelys imbricata*) – are known to nest on the beaches in the vicinity of the Project area and feed in the surrounding waters. The Flatback Turtles nest all year round, peaking in May through to September. Uncertainty exists over the peak timing of nesting of the other species in the Project area.

A further three marine turtle species – the Loggerhead Turtle (*Caretta caretta*), the Leatherback Turtle (*Dermochelys coariacea*) and the Green Turtle (*Chelonia mydas*) – also feed in the waters surrounding the proposed port but do not nest on the beaches. The Leatherback Turtle is generally recognised as principally utilising offshore pelagic areas for foraging. Coastal waters such as the proposed port site are not key habitat. The known nesting locations of these marine turtle species in northern and eastern Australia are shown in **Figure 6-50** to **Figure 6-52**. All are listed as threatened species under the EPBC Act. The foraging characteristics of all six turtle species are summarised in **Table 6-35**.

Figure 6-52 Nesting Locations for Olive Ridley Turtles (top) and Leatherback Turtles (bottom)

Table 6-36 Sea Turtle Foraging Characteristics

Turtle Species	Foraging Habitats	Preferred Food Items	Reference
Green Turtle (*Chelonia mydas*)	Shallow coastal area, in particular seagrass beds	Seagrass and seaweeds, although juveniles are also carnivorous	Brand-Gardner et al. (1999)
Hawksbill Turtle (*Eretmochelys imbricata*)	Rocky reef and coral reef habitats	Algae, seagrass and sponges	Limpus (2009a)
Flatback Turtle (*Natator depressus*)	Shallow coastal environments including rocky reef and sedimentary habitats	A wide variety of soft-bodied animals including soft corals, sea pens, sea cucumbers, jellyfish and other large plankton	Limpus (2007)
Loggerhead Turtle (*Caretta caretta*)	A wide range of intertidal and subtidal habitats including coral and rocky reefs, seagrass meadows, and unvegetated sand or mud areas	Although their diet is diverse, typical items include bivalve and gastropod molluscs and crabs	Limpus (2008a)
Olive Ridley Turtle (*Lepidochelys olivacea*)	Principally shallow unvegetated coastal environments	Principally feeds on gastropod molluscs and crabs	Limpus (2008b)
Leatherback Turtle (*Dermochelys coriacea*)	Oceanic environments from the sea surface to the seabed	Principally feeds on colonial ascidians such as *Pyrosoma* spp., jellyfish such as *Catostylus* spp. and other soft-bodied invertebrates	Limpus (2009b)

The methodology for the turtle nesting activity survey was developed based on advice from Dr. Colin Limpus (Chief Scientist, Freshwater and Marine Sciences, Queensland Department of Environment and Resource Management). Daylight field surveys were undertaken on foot from 22 to 24 April 2008 to identify marine turtle tracks and nests between Norman Creek to approximately 5km north of Boyd Point, encompassing 27km of beach, including the proposed port site. Consent to conduct the survey was provided by Traditional Owners. The survey was led by Dr Daryl McPhee (Worley Parsons) assisted by Mr Les Player (RTA) and two Traditional Owners – Mr Henry Kelinda and Mr Norman Kerindun.

April was chosen as a survey month to complement previous studies and to focus on a period when Olive Ridley Turtles may be more likely to nest in the area. Previous studies of nesting activity in the area were undertaken in May to July (GHD 2007b) and August to September (Bell 2003). Surveys were undertaken between 7.00am and 12.00pm to maximise the visibility of nests from the previous night's nesting activity (Schroeder and Murphy 1999).

Previously, field investigations by Bell (2004) recorded 41 Flatback Turtle nests and two Olive Ridley/Hawksbill Turtle nests over a 4 day survey in August 2003 along 38km of beach from Boyd Point south to False Pera Head. During 2007 field investigations, GHD (2007b) recorded 15 nesting events during three separate daily survey periods between May and July 2007 along a 10km stretch of foreshore between Boyd Point and Pera Head, with most nesting activity occurring at Boyd Point. Again, the majority of nesting activity represented that of Flatback Turtles, with Olive Ridley or Hawksbill Turtles next identified. Methodologies for the 2003 and 2007 surveys are provided in the survey reports. In the 2003 survey nesting beaches were accessed by water or land and observations of nesting tracks were documented and an assessment of the impact of pig predation on individual nests was recorded. In the 2007 survey standard beach surveying methodology was used.

For the current study and the 2007 survey, nesting activity is described in **Table 6-37** and an example of a Flatback Turtle nesting track is shown in **Plate 6-9**. **Figure 6-53** identifies the marine turtle nesting locations recorded by GHD (2007b) and in the present study. Specific locations and details from the 2003 study have not bee provided as the report only summarises the total nesting activity for each species.

The proposed location of the port is not considered a high density turtle nesting beach. The nearest major rookery on Cape York is Crab Island (Limpus 2007). On Crab Island, Leis (2008) found an average of 30 nesting tracks per kilometre per day of beach surveyed during May 2008. This compares with Bell (2004) who found 0.3 turtle tracks per kilometre per day from False Pera Head to Boyd Bay and GHD (2007b) who found 0.6 tracks per kilometre per day in a similar area. The April 2008 survey of the proposed port area found 0.1 tracks per kilometre per

day. The proposed port area can be considered to have a low to medium density nesting population. .

Table 6-37 Sea Turtle Tracks and Associated Nests in the Survey Area, 2007 and April 2008

Survey Date	Coordinates (WGS 84)	Species	Nest and Track Descriptions
May 2007	S12°54'787" E141°37'978"	Green Turtle (*Chelonia mydas*)	Large body pit, single egg shell found at surface, evidence of predation of eggs.
May 2007	S12°54'693" E141°38'107"	Flatback Turtle (*Natator depressus*)	Body pit with several egg shell fragments found on sand surface, evidence of predation of eggs.
May 2007	S12°54'675" E141°38'124"	Unidentified	Large body pit, no evidence of egg predation.
May 2007	S12°54'632" E141°38'124"	Unidentified (body pit only, no tracks)	Body pit with several egg shell fragments found on sand surface, evidence of predation of eggs.
May 2007	S12°54'721" E141°38'135"	Unidentified (old track)	False crawl, no associated body pit or nest.
May 2007	S12°54'613" E141°38'110"	Unidentified (old track)	False crawl, no associated body pit or nest.
June 2007	S12°54'060" E141°40'000"	Unidentified (body pit only, no tracks)	Small body pit, shell fragments evidence of pig predation.
June 2007	S12°54'619" E141°38'128"	Unidentified (body pit only, no tracks)	Small body pit, shell fragments evidence of pig predation.
June 2007	S12°54'693" E141°38'107"	Unidentified (body pit only, no tracks)	Large body pit, several egg shell fragments found at surface, evidence of predation of eggs.
June 2007	S12°54'859" E141°37'910"	Unidentified (body pit only, no tracks)	Small body pit, shell fragments evidence of pig predation.
June 2007	S12°54'875" E141°37'852"	Flatback Turtle (*Natator depressus*)	Body pit/nest. No signs of feral pig predation.
July 2007	S12°54'598" E141°38'106"	Unidentified (body pit only, no tracks)	Small body pit, shell fragments evidence of pig predation.
July 2007	S12°54'662" E141°38'090"	Unidentified (body pit only, no tracks)	Small body pit, shell fragments evidence of pig predation.
July 2007	S12°54'836" E141°37'921"	Flatback Turtle (*Natator depressus*)	No evidence of egg predation.
July 2007	S12°54'875" E141°37'857"	Unidentified (body pit only, no tracks)	Small body pit, shell fragments evidence of pig predation.
July 2007	S12°55'095" E141°37'672"	Olive Ridley Turtle (*Lepidochelys olivacea*) or Hawksbill Turtle (*Eretmochelys imbricata*)	Small body pit and narrow alternating tracks. No signs of predation. Multiple nesting attempts.
July 2007	S12°55'209" E141°37'618"	Flatback Turtle (*Natator depressus*)	No signs of predation. Multiple nesting attempts.
April 2008	S12°55'777" E141°37'299"	Flatback Turtle (*Natator depressus*)	Very fresh tracks and nest (probably only a few hours old). No sign of disturbance or predation. Nest shallow. Track and nest shown in **Plate 6-9**.
April 2008	S12°56'513" E141°36'795"	Flatback Turtle (*Natator depressus*)	Paired gait of flippers. Nest adjacent to cliff edge. Evidence of predation by feral pigs.
April 2008	S12°55'897" E141°36'514"	Flatback Turtle (*Natator depressus*)	Reasonably old track. Paired gait of flippers. Nesting against fallen timber. Predation of nest by pigs/dogs. Quad bike tracks leading to and from nest.
April 2008	S12°56'913" E141°36'500"	Flatback Turtle (*Natator depressus*)	Old track. Straight drag pattern down the centre of the track. Paired gait of flippers. Nesting against cliff and under fallen timber. Predation of nest by pigs/dogs.
April 2008	S12°56'957" E141°36'461"	Flatback Turtle *(Natator depressus*)	Old track but with sufficient morphology to identify it as a flatback. Predation of nest by pigs.

Survey Date	Coordinates (WGS 84)	Species	Nest and Track Descriptions
April 2008	S12°56'990" E141°36'455"	Unidentified	Old track without clear morphology. Predation of nest.
April 2008	S12°59'230" E141°35'320"	Flatback Turtle (*Natator depressus*)	Paired gait of flippers with a wide plastron imprint. Nest adjacent to cliff edge. No tail drag lines down the centre of the track. No evidence of predation.
April 2008	S12°59'608" E141°35'111"	Hawksbill Turtle (*Eretmochelys imbricata*)	Fresh track most probably from previous night. Tracks are in very coarse sand, meandering and in part over rock. Several attempts made to nest on the side of a vegetated dune. No evidence of predation, but feral pig tracks abundant in the general area (Thud Point).
April 2008	S12°54'704" E141°38'047"	Flatback Turtle (*Natator depressus*)	False crawl with no associated nest.
April 2008	S12°54'635" E141°38'133"	Unidentified	Old nest with no signs of tracks but fragments of egg shell present.

2007 Survey Data from GHD, 2007b

Plate 6-9 Flatback Turtle Nest (left) and Turtle Tracks between Boyd Point and Pera Head

Available information identifies that scattered nesting of Flatback Turtles occurs along most beaches of western Cape York, including the proposed Project site. There are no concentrated high density rookeries such as those that occur on islands of the Torres Strait such as Crab Island and Deliverance Island; however, the beaches of western Cape York represents an area of low to medium density nesting activity for this species. Nesting of the Olive Ridley and Hawksbill Turtles in the vicinity of the Project site and throughout the western Cape York beaches is identified as low density. There are uncertainties regarding whether nesting of Olive Ridley Turtles is still occurring in the western Cape York region.

Incidental observations while undertaking boat-based marine ecology field work identified that, within the area surveyed, marine turtles (predominantly Flatback Turtles) were frequently observed surfacing. The qualitative observations did not reveal any apparent preference for one part of the study area over the other. No quantitative assessment of the relative importance of the area as sub-tidal feeding habitat for marine turtles was undertaken.

Marine turtles are long-lived and late maturing with maturity reached at between 30 and 50 years of age (Miller 1996). Female marine turtles emerge from the water, generally at night, and move up the shoreline to select a nesting location. Most females do not nest in consecutive years (Miller 1996). However, a female marine turtle may lay several clutches of eggs per year (Limpus *et al.* 1984). Nesting marine turtles generally demonstrate fidelity to a nesting beach and return to nest on their natal beach with a high degree of precision (Limpus *et al.* 1984). The process by which turtles select nesting sites along a beach has not been clarified (Miller 1996); however, the light regime is considered to have a significant impact on the emergence of female marine turtles from the ocean. Marine turtles may also emerge from the water and

return without attempting to excavate a nest or lay eggs – a phenomenon known as a "false crawl". Nesting generally occurs between the high water mark and the foredune; however, nests may also be laid below the high tide mark (Whiting *et al.* 2007). If inundation of nests is significant, the nest becomes unviable.

The sex ratio of turtle hatchlings is dependent on the temperature of incubation, which is a function of sand colour. Nests in darker sand incubate at higher temperatures and produce more females (Hays *et al.* 2001). For Flatback Turtles, the most numerically important nesting location, Crab Island, produces mostly male offspring while the scattered nesting in darker coloured beaches on western Cape York, such as those in the area of the proposed development, produce predominantly female offspring (Dr Colin Limpus, pers. comm.).

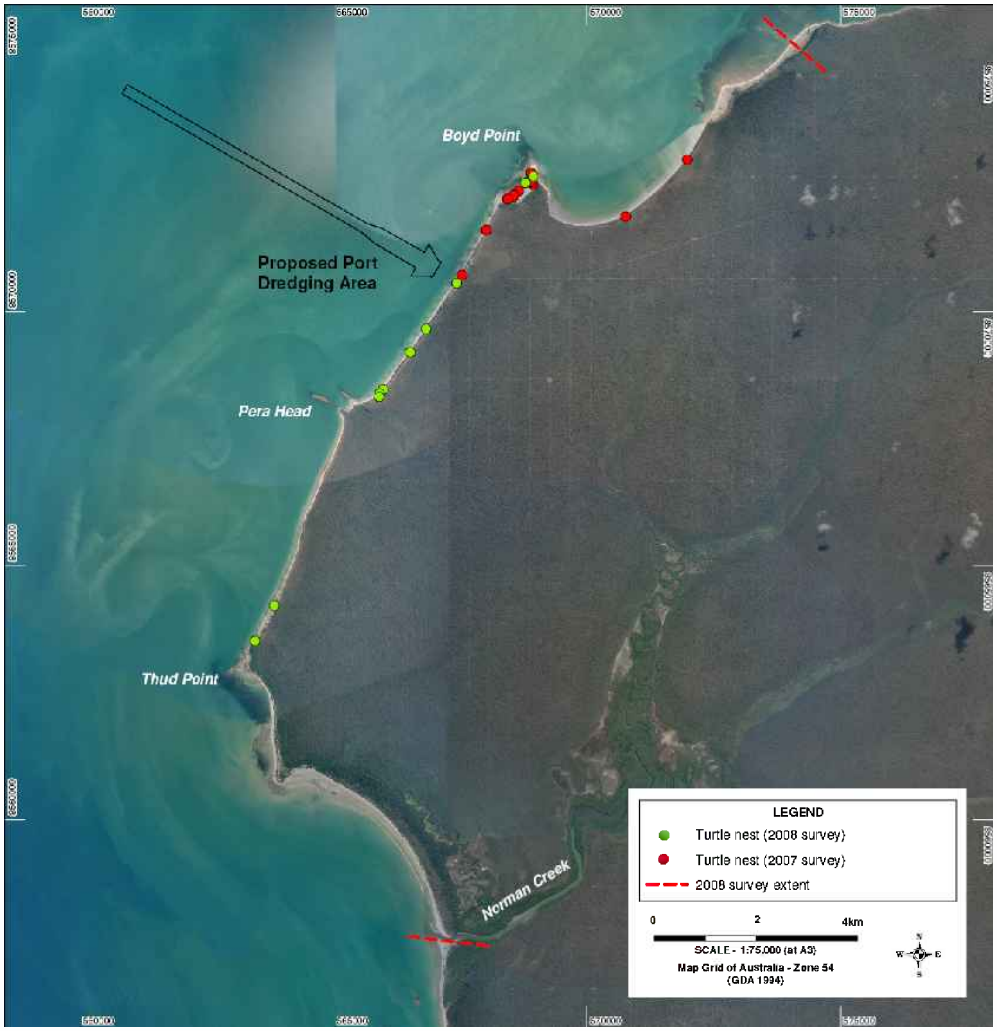

Figure 6-53 Location of Turtle Nesting Activity May – July 2007 and April 2008

Once hatched, lighting cues are identified as critical for hatchlings to move from the beach to the ocean – a behaviour known as sea-finding. In simple terms, where there are no anthropogenic light sources, hatchlings move away from the dark silhouetted shoreline towards the brighter ocean horizon. Brightness in this context, however, is a term that encompasses wavelength and intensity (Witherington and Martin 1996). The uniformity of the light regime can also act as a cue, whereby hatchlings may orientate away from a horizon that has patterns of light and shadow representing shoreline vegetation or structures. In practical terms, the

turtles would see these patterns and orientate away from the shore and head towards the more uniform light environment of the ocean horizon (Godfrey and Barreto 1995; Witherington and Martin 1996).

Altered above-water, night-time light regime can have an effect on hatchlings' attempts to find water. Lights at a nesting beach can result in turtle hatchlings heading inland rather than into the ocean, with subsequent mortality. Lights adjacent to nesting beaches can result in hatchlings entering the ocean safely, only to re-emerge closer to the light source. At Hummock Hill Island (central Queensland), lighting from the Boyne Island smelter, which is approximately 18km north of the nesting beach, was observed to disorientate nesting turtles (Hodge *et al.* 2006). This lighting source is extremely bright and lacks any measures to mitigate impacts on marine turtles. A modified lighting regime may elicit an impact, with illumination of salt spray adjacent to a nesting beach being sufficient to alter sea-finding behaviour (Dr Colin Limpus pers. comm.). Offshore lighting may result in hatchlings aggregating under the light, effectively becoming a focus for predatory fish. Flashing lights (e.g. navigation beacons) are not recorded as inducing alteration to sea-finding behaviour.

Currently, there are two major anthropogenic threats to nesting marine turtles along the beaches of western Cape York – predation by feral pigs and entanglement in discarded fishing nets (ghost nets). The former is currently considered the most significant. Feral pigs are a well-acknowledged environmental problem in Australia. They are identified as a key threatening process under the EPBC Act and a Threat Abatement Plan (TAP) is currently in place to protect marine turtles in Australia. The impact from feral pigs on turtle nesting is a significant reason for listing feral pigs as a key threat.

Field surveys identified significant destruction of turtle nests by feral pigs, at and adjacent to the area of the proposed port development. Feral pig activity within the field survey area was particularly prevalent in areas with direct access to the beach from adjacent bushland. Where cliffs extended to the water edge, feral pig activity was considerably less, or absent. The two areas where feral pig activity was most prevalent were Boyd Point and Thud Point. Extensive feral pig activity, including turtle nest excavation, was observed just above the high tide mark at Boyd Point. Although exact estimates were not possible, approximately 50 to 60 nests appeared to be disturbed on approximately 500m of beach north of Boyd Point (refer **Plate 6-10**). This count includes nests with visible track marks, and those without track marks (time of nesting is unknown).

Ghost nets are discarded or lost nets that float in the ocean until they wash up on beaches (refer **Plate 6-11**). These nests can entangle and kill marine turtles in the open ocean and/or in inshore areas. According to the Carpentaria Ghost Nets Program, which is an Indigenous community and Commonwealth Government partnership in northern Australia, most ghost nets in the Gulf of Carpentaria originate from south-east Asian countries, in particular, Taiwan, Indonesia and Korea.

Plate 6-10 Example of Feral Pig Digging North of Boyd Point (background)

Plate 6-11 Juvenile Olive Ridley Turtle Carcass in a Ghost Net near Pera Head

6.6.6 Sea Snakes

The Gulf of Carpentaria contains a diverse and abundant sea snake assemblage of at least 17 species. In the Weipa area, the numerically dominant sea snake species is *Lapemis hardwicki,* which comprises approximately 90% of the sea snake population (Redfield *et al*. 1978).

Other species recorded in the Weipa area include: *Acalyptophis peronii*; *Aipysurus duboisii*; *Aipysurus laevis*; *Astrotia stokesii*; *Enhydrina schistose*; *Hydrophis elegans*; and *Hydrophis ornatus*.

All these species have been recorded from multiple locations elsewhere in the Gulf of Carpentaria (Redfield *et al*. 1978). There are no specific studies that have examined the sea

snake fauna specifically at the sites of the proposed development. The main impact on sea snake populations in the Gulf of Carpentaria is incidental capture in the Northern Prawn Fishery.

6.6.7 Bony Fish and Nektobenthic Marine Invertebrates

Albatross Bay is recognised as extending in a straight line from Jantz Point southwards to Pera Head. Information from Albatross Bay is also relevant to areas directly adjacent. The fish assemblages of Albatross Bay have been well studied and much of this work has focussed in or directly adjacent to the Embley River estuary (e.g. Blaber *et al.* 1989, 1990a). 344 fish species have been recorded in Albatross Bay (Baker and Sheppard 2006).

No fish species listed under the EPBC Act or the NC Act have been recorded in Albatross Bay. Different fish assemblages occur in the various habitats sampled. The fish biomass estimates obtained by Blaber *et al.* (1989) for open water channels, sandy beach habitats and mangroves creeks were found to be similar to previously-published estimates from tropical estuarine areas. In contrast, the fish biomass of seagrass habitat was lower than that estimated for other tropical estuaries. The fish assemblages of Albatross Bay estuarine and shallow coastal waters are summarised in **Appendix 6-A**.

Along the foreshore, just south of the Embley River estuary, the dominant species caught by gill netting were Queenfish, Milkfish and Blue Salmon (Blaber *et al.* 1995). Overall, Blaber *et al.* (1995) found that fish catch rates along the Weipa foreshore were less than in the adjacent estuary and offshore waters. Nonetheless, Blaber *et al.* (1995) identified the area as a transition zone between estuarine and offshore waters for some species. In offshore waters, the dominant families of fish were those that occurred at similar depths and distance from the coastline throughout the eastern and south-eastern region of the Gulf of Carpentaria (e.g. Family Leiognathidae, Ponyfishes).

Although not well studied, the reef habitats in Albatross Bay support a diverse assemblage of demersal and pelagic species. Demersal species include members of the Families Serranidae (e.g. Coral Trout, *Plectropomus leopardus*), Lutjanidae (e.g. Fingermark, *Lutjanus johnii* and Red Emperor, *Lutjanus sebae*) and Labridae (e.g. tuskfish, *Choerodon* spp.). Pelagic species include mackerel (e.g. Spanish Mackerel, *Scomberomorus commerson*i) and various tunas.

Three species of sygnathids (pipefish and seahorses) that are listed marine species under the EPBC Act (section 248) – *Hippichthys heptagonus* (Big Belly Seahorse), *Hippocampus kuda* (Spotted Seahorse) and *Hippocampus whitei* (White's Seahorse) – are confirmed to occur in Albatross Bay (Blaber *et al.* 1990). As the distribution and abundance of sygnathids are poorly known, it is highly likely that other species of sygnathids also occur in Albatross Bay.

Albatross Bay is known to be an important nursery area for the juvenile tiger and banana prawns that are the principal target species in the Northern Prawn Fishery area. Banana prawns migrate from estuarine areas into the Gulf of Carpentaria for spawning from September to November and March to May. At low tide, juvenile and sub-adult prawns are most abundant in small tidal creeks and gutters that drain from mangrove forests (Vance *et al.* 1998; Kenyon *et al.* 2004).

The Brown Tiger Prawn (*Penaeus esculentus*) and the Grooved Tiger Prawn (*Penaeus semisulcatus*) are abundant in the Gulf of Carpentaria. Brown Tiger Prawns spawn throughout the year, with peak spawning occurring from August to September (Kenyon *et al.* 2004). Grooved Tiger Prawns' spawning peaks between August and October, with a minor peak in the months of January and February. Juvenile tiger prawns are generally associated with vegetated habitats (particularly large seagrass beds) in the vicinity of estuaries (Haywood *et al.* 1995; Rothilsberg *et al.* 1996). Other prawn species that occur in abundance in Albatross Bay are Endeavour Prawns (*Metapenaeus endeavouri* and *Metapenaeus ensis*) and Eastern King Prawns (*Penaeus plebejus*).

The cephalopod (squid and cuttlefish) assemblage in the Gulf of Carpentaria is diverse and abundant, with at least 21 species. The numerically dominant species of squid and cuttlefish recorded are *Photololigo chinensis* and *Photololigo edulis*, and *Sepia elliptica* and *Sepia pharaonis* respectively (Dunning *et al.* 1994). There are no specific studies that have examined the squid and cuttlefish assemblage at the sites of the proposed marine infrastructure.

Mud crabs are common in the creeks and rivers of Albatross Bay.

6.6.8 Macrobenthic Infauna

Long and Poiner (1994) examined the macrobenthic infaunal assemblage in sub-tidal areas of the Gulf of Carpentaria. Species assemblages consisted primarily of overlapping species distributions rather than highly-structured, discrete communities with well-defined groups that are characteristic of the community. Polychaete worms were identified as the numerically dominant group of animals, followed by crustaceans and bivalve molluscs. The benthic infauna assemblage has been impacted for many years by prawn trawl operations.

The structure of macrobenthic assemblages was surveyed at six locations within three sites: the proposed new disposal ground, the proposed port area and the existing disposal ground in Albatross Bay using a benthic grab to collect four replicate samples and sieving them using a 1mm mesh sieve. Remaining infauna material was preserved and identified to lowest practical taxonomic level (typically Family morphospecies level, whereby each apparently different taxonomic "species" of a family is a different "morphospecies"). The taxa richness and abundance of the assemblage, and the five numerically dominant taxa at each of the survey sites, was assessed (**Table 6-38** and **Table 6-39** respectively).

Of the three sites, it is noteworthy that the existing spoil ground in Albatross Bay had an exceptionally high abundance of the small bivalve *Gouldia* sp., which comprised approximately 90% of the total abundance (refer **Table 6-39**). The high abundance of *Gouldia* sp. at the existing disposal site is most likely a direct response of the species rapidly colonising the area after dredge spoil deposition. Although available information is limited, a similar response by populations of this genus was recorded in the United States in response to dredge disturbance and spoil deposition (Iversen and Beardsley 1974).

The majority of taxa surveyed at the three sites were previously recorded by Long and Poiner (1994).

Table 6-38 Taxa Richness and Abundance of Macrobenthic Infauna at the Three Survey Sites

Site	Taxa Richness	Abundance
New Disposal Ground (6 locations)	148	851
Port Area (6 locations)	111	504
Disposal Ground in Albatross Bay (6 locations)	97	4562

Table 6-39 Five Dominant Macrobenthic Infaunal Taxa at the Three Survey Sites

Rank of abundance	New Disposal Ground	Port Area	Disposal Ground in Albatross Bay
1	Polychaete worm – *Eunice vittata sp?*	Polychaete worm – F. Chaetopteridae	Bivalve mollusc – *Gouldia* sp.
2	Polychaete worm – F. Maldanidae	Peanut worm – *Aspidosiphon* sp.	Bivalve mollusc – *Nuculana* sp.
3	Polychaete worm – F. Capitellidae	Polychaete worm – *Eunice vittata sp?*	Bivalve mollusc – *Yoldia* sp.
4	Anemone – F. Zooanthidae	Polychaete worm – F. Maldanidae	Polychaete worm – F. Maldanidae
5	Tusk shell – F. Laevidentaliidae	Amphipod crustacean – *Apseudes* sp.	Bivalve mollusc – *Yoldia narthecia sp?*

6.6.9 Introduced Marine Species

In Australia, there are existing protocols in place to minimise the risk of marine pest incursions and to ensure the early detection of an incursion if one occurs. Pests may be introduced by ships' ballast water or hull fouling. There is a National System for the Prevention and Management of Marine Pest Incursions, which includes three major components: prevention,

emergency response, and ongoing control and management of existing pests. Since 2001, requirements have been in place for the management of internationally-sourced ballast water that apply to all ships arriving from overseas. The Australian Ballast Water Management Requirements (DAFF 2008) details the controls to minimise the risk of introducing harmful aquatic organisms into the environment. These requirements are implemented through the *Quarantine Act 1908* and are administered by the Seaports Program within the Australian Quarantine Inspection Service (AQIS). No ballast water may be discharged from internationally trading vessels in Australian waters without express written permission from AQIS as discussed in further detail in **Section 13.3.8**.

All vessels owned and contracted by RTA would manage ballast water through a Ballast Water Management Plan which would comply with Australian mandatory requirements and the International Convention for the Control and Management of Ships Ballast Water and Sediments (IMO 2004). There would be no hull cleaning at the proposed port; however, pests may still be present on ships hulls. Monitoring would be undertaken to provide a means of early detection of introduced pests (refer **Section 6.9.4.6** and **Section 13.3.8**).

Extensive surveying for marine pest species has been undertaken at the Port of Weipa and no invasive marine pest incursions have been recorded (Hoedt *et al.* 2001; PCQ 2007; PCQ 2009). While no invasive species have been found, at least two introduced species were identified in the 1999 baseline survey (Hoedt *et al.* 2001). The detailed baseline survey of the Port of Weipa has been supplemented since 2006 by inspection every three months of larval monitoring devices installed in the port and targeted surveys by DEEDI of high-risk areas in the port. This monitoring was instigated following the discovery of the high-risk species Asian green mussel (*Perna viridis*) on a non-trading vessel that had been in the Port of Weipa. No Asian green mussels or other non-indigenous species have been detected since the monitoring began in 2006 (PCQ 2009).

6.7 Marine Fisheries Resources

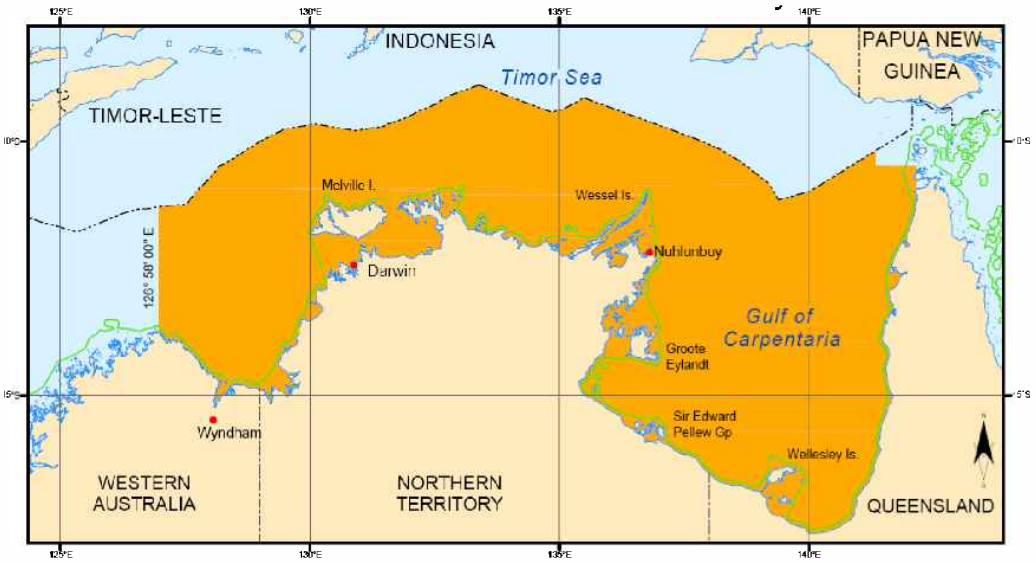
The Gulf of Carpentaria hosts commercial fisheries that are managed by the Queensland Government, Commonwealth Government, and jointly through the Queensland Fisheries Joint Authority (QFJA). The Queensland Government manages the commercial mesh net fisheries and crab fisheries through DEEDI. The Commonwealth Government manages the Northern Prawn Fishery (NPF) through the Australian Fisheries Management Authority. The line fishery is managed through the QFJA. There is also a Developmental Finfish Trawl Fishery managed through the QFJA. The recreational and charter fisheries are managed by DEEDI.

Catch information for the fisheries managed by the State and the QFJA is recorded by operators in compulsory logbooks that are submitted to DEEDI. The catch data for the fishery is recorded at a very broad spatial scale of "30 minute grids". The area of the proposed development is within reporting grid "AB8". For monitoring and assessment purposes, the NPF is divided into 15 large statistical areas, with the Weipa statistical area being relevant for the proposed development.

Recreational fishing catches are monitored through a biennial phone survey and diary program. These surveys collect information at the spatial level of the ABS statistical division (based on where an angler resides), and can only provide very broadscale information. Weipa falls within the Far Northern Statistical Division, which stretches from the Herbert River just north of Townsville, through the Torres Strait, to the Edward River on the mid-western coast of Cape York. As such, this information cannot be relied upon to provide relevant information at the appropriate spatial scale.

6.7.1 Northern Prawn Fishery

The NPF is Australia's most valuable commercial fishery, with an annual value of production averaging $95 million (1999–2007). In 2007 there were 52 operators accessing the fishery. The prawn fishing area extends across the northern part of Australia from Cape Londonderry (Western Australia) east to Cape York (refer **Figure 6-54**). In practice, fishing is focussed on a number of "hotspots", although the relative importance of these hotspots varies between years in response to climatic factors, in particular rainfall.



Source: Raudzens 2007

Figure 6-54 Permitted Fishing Area of the Northern Prawn Fishery

The main species caught in the NPF are tiger prawns and banana prawns, targeted at different times and generally in different locations. For catch and effort reporting purposes the NPF is divided into 15 statistical areas. The proposed port development area is within the Weipa statistical area, which extends from approximately Port Musgrave southwards to Thud Point. Tiger prawn fishing takes place in the western Gulf of Carpentaria from August to November, with little catch recorded in the Weipa statistical area or in the eastern Gulf of Carpentaria in general. The banana prawn season extends from April to June, with the Weipa statistical area being a significant area of production (refer **Figure 6-55**). Banana prawns are targeted in waters less than 20m deep. Areas adjacent to the proposed port site between Pera Head and Boyd Point and the potential spoil ground location are important areas within the Weipa statistical area for catching banana prawns (refer **Figure 6-56**). These species spawn offshore and give rise to larvae that migrate into 'nursery' grounds, usually seagrass beds or mangrove areas, in shallow coastal areas where they feed and grow. After three months in these nursery grounds, juveniles migrate offshore into the fishing grounds where they feed and grow for at least another three months before attaining commercial size. Peak times of migration of larvae onshore and juveniles offshore are from August to April. The potential impacts on prawn nursery grounds within the Project area are discussed in **Section 6.9.6.1**.

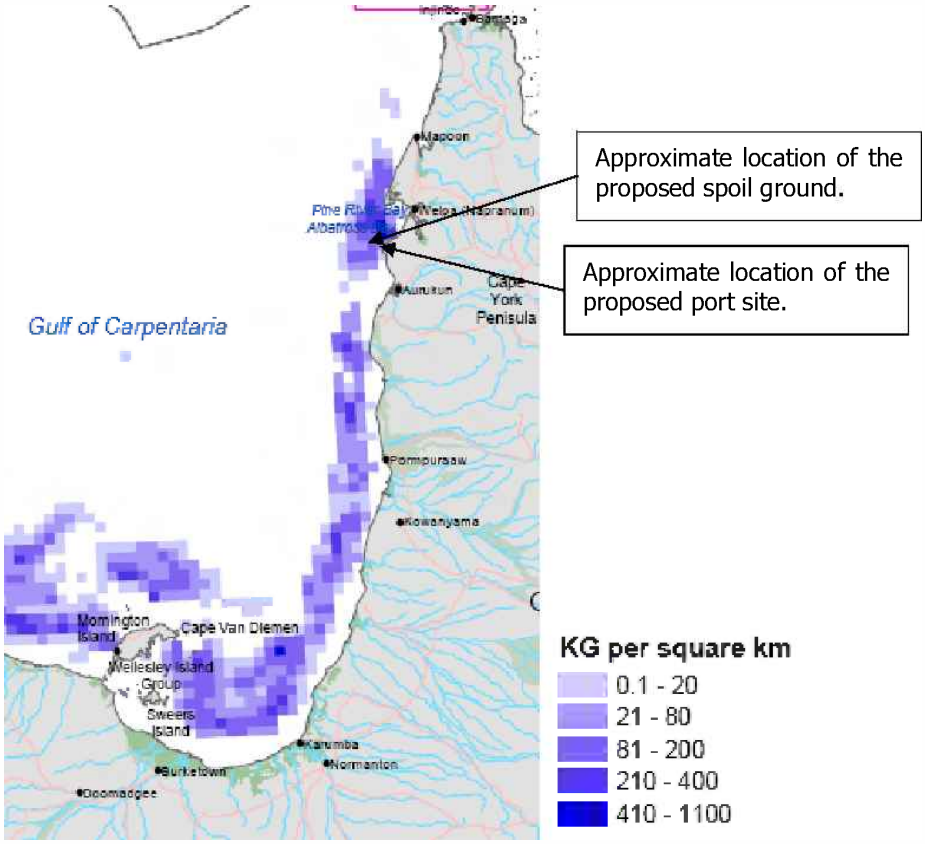

Figure 6-56 Prawn Catch – Eastern Gulf of Carpentaria Region of the Northern Prawn Fishery

6.7.2 Gulf of Carpentaria Commercial Fisheries

The Gulf of Carpentaria Inshore Finfish Fishery is a commercial mesh net fishery managed by the Queensland Government that extends from the Queensland – Northern Territory border to Slade Point on the north-west coast of Cape York Peninsula. It has an inshore component (0–7 nautical miles), targeting species such as barramundi and threadfins (*Polynemus* spp.), and an offshore component (7–25 nautical miles), targeting various shark species and grey mackerel (*Scomberomorus semifasciatus*). In 2006, 87 licensed fishers harvested 1,782 tonnes of fish with a landed gross value of production of $12.8 million. The rivers flowing into Albatross Bay are closed to the fishery, although the foreshores and sub-tidal areas can be accessed. Norman Creek can be accessed by the fishery, but the coarse spatial scale of the catch and effort data does not allow for determining the relative importance of this area for the fishery.

Production of the key target species in the inshore and offshore fishery components is reliant on intact and functioning inshore habitats such as mangroves and seagrass and the connectivity between habitats. There is a closed season between November and February to protect the spawning stock of key target species. On average, reporting grid AB8 contributes approximately 3% of the total annual catch of the Gulf of Carpentaria Inshore Finfish Fishery.

The Gulf of Carpentaria Commercial Line Fishery is managed by the Queensland Government and extends from the Queensland – Northern Territory border to Slade Point on the north-west coast of Cape York Peninsula. In 2006, 27 licensed fishers harvested 237 tonnes of fish with a landed gross value of production of $1.6 million. The main target species is Spanish mackerel, which constitutes 90% of the total catch. On average, reporting grid AB8 contributes approximately 12% of the total annual catch of the Gulf of Carpentaria Commercial Line Fishery. Commercial line fishermen recognise the reef areas in the vicinity of Pera Head, Boyd Point and Thud Point as key locations for Spanish mackerel (*Scomberomorus Commerson*) in the Weipa region. The peak season for Spanish mackerel in the Weipa region extends from August to November.

Unlike the commercial net and line fisheries discussed in the previous two sections, there is no specific fishery restricted to Gulf of Carpentaria waters for the taking of mud crab. Any licensed mud crab operator in Queensland can operate in Gulf of Carpentaria waters. At the regional level, there is a strong positive correlation between areas of mangrove forest and mud crab production. The creeks and rivers that drain into Albatross Bay are the most important mud crab harvesting areas in the Gulf of Carpentaria (Williams 2002). Mud crabbing generally focuses on areas directly adjacent to large mangrove stands, including small creeks draining such stands. The proposed port development and spoil ground is remote from these areas and therefore would not impact on mud crab populations or access to the mud crab fishery areas. Mud crabbing occurs in the Embley and Hey Rivers but the proposed barge and ferry terminal locations are not considered prime habitat for mud crabs.

Developmental fisheries are those that use new methods and/or target new and underutilised species. In the Gulf of Carpentaria there is a Developmental Finfish Trawl Fishery, extending north of 15 degrees south latitude to a distance of 25 nautical miles from the coastline. This fishery intersects the proposed Project area. The principal target species are crimson snapper (*Lutjanus erythropterus*), saddletailed snapper (*Lutjanus malabaricus*) and mangrove jack (*Lutjanus argentimaculatus*). In 2005, there were two vessels that captured 479 tonnes of fish with a landed gross value of production of $1.5 million.

6.7.3 Recreational Fishery

Recreational fishing is a popular pastime in the Project area and a range of species including barramundi, mangrove jack, fingermark, threadfins and mackerel are caught (Baker and Sheppard 2006). Common recreational fish species are identified in **Appendix 6A**. It is estimated that 9% of tourists who visit Weipa do so primarily to fish (GHD 2005). There is no information on the recreational catch and the distribution of fishing effort in the Project area.

Guided fishing supports recreational fishing tourism and attracts international tourists to Weipa. It is estimated there are eight guided fishing businesses in Weipa with a combined income of $396,000 (Fenton and Marshall 2001). Anecdotal information suggests the current income of the charter vessel fishery based in Weipa has increased substantially since 2001. The charter fishing businesses based at Weipa principally fish at the reefs in Albatross Bay, including nearby

Pera Head and Thud Point, the rivers and creeks that drain into it, and the sandflats that extend from the Embley River south to Norman Creek. Popular recreational reef fishing spots in relation to the Project marine facilities are shown in **Figure 6-57**.

6.8 Environmental Values

As identified in **Section 6.4.1**, no specific EVs or WQOs have been determined for the Western Cape York area. The marine ecosystem in the Project area is effectively unmodified and is considered of high ecological value under the EPP (Water). The EV to be protected is the biological integrity of the aquatic ecosystem. The Project area includes diverse habitat that supports species of conservation significance, and commercial and recreational fishing in water quality relatively unaffected by human impacts.

The EVs in the vicinity of the proposed port area are the diversity of habitats that support the local marine assemblages, and the use of the foreshore by nesting marine turtles. The area includes a diverse reef assemblage comprising soft and hard corals, algae, sponges and soft corals centred around Boyd Point, Pera Head, and reefs south to Thud Point. These reef assemblages occur adjacent to, but not at, the proposed port site. The importance of these reef systems (Boyd Point to Thud Point) in a regional context is considered to be high, as they support resources that are of conservation, cultural, commercial and recreational importance. Large soft sediment habitats provide habitat for macrobenthic infauna and fish species, including sawfishes, which are of conservation significance. Various fish species that support recreational, guided and commercial mesh net and line fishing occur in the reef areas and along the foreshore flats. Seagrasses are present in Boyd Bay to the north of the proposed port development and have historically been recorded in sparse isolated patches south of Thud Point.

The EVs of the proposed spoil ground include habitat for benthic infauna, fish and mobile invertebrate species that prefer sub-tidal soft sediment habitats. This type of habitat is widespread throughout the Gulf of Carpentaria. Banana prawns seasonally occur in the area and are targeted by the Northern Prawn Fishery.

The EVs of the barge/ferry terminal locations in the Embley and Hey Rivers include seagrass beds directly adjacent to the Hornibrook Terminal dredge area and isolated seagrass patches within and adjacent to the Humbug Terminal dredge area. Seagrass beds provide food and shelter for fish and invertebrates including those that support various commercial and recreational fisheries. The soft sediment estuarine area within the Embley and Hey Rivers also support macrobenthic infauna that contributes to fisheries production.

The Traditional Owners value the coastal environment for the protection of flora and fauna, for fishing and for recreation (refer **Section 16.2.2**).

6.9 Potential Impacts and Mitigation Measures – Marine

Potential impacts that may occur during the construction and operational phases of the Project are listed in **Table 6-40**.

Potential impacts and proposed management measures are discussed below in terms of: alterations to coastal processes, dredging, water quality, habitat, species, fisheries and pest species. A summary of mitigation strategies is presented in **Section 6.9.8**.

Table 6-40 Potential Impacts During Construction and Operation

Potential Impact	Port Area	New Disposal Ground	Embley River – Hornibrook & Humbug Terminals	Albatross Bay Spoil Ground	Hey River Terminal
Creation of a turbidity plume, and subsequent deposition and re-suspension of fine sediments	Construction and operation	Construction and operation	Construction and operation	Construction and operation	Construction and operation
Physical destruction to benthic habitats, including hard and soft coral communities, and fauna from dredging and construction of infrastructure	Construction and operation	Construction and operation	Construction and operation	Construction and operation	Construction and operation
Changes to coastal processes (erosion and deposition)	Construction and operation	—	—	—	—
Introduction of pollutants to marine waters and sediments	Construction and operation	Construction and operation	Construction and operation	—	Construction and operation

Introduction of pest species	Operation	—	—	—	—

— = Limited potential for impacts

6.9.1 Altered Coastal Processes

The proposed open-piled wharf jetty and berth pockets have a low potential to impact the alongshore transport of sediment. There is a greater potential for impact to the longshore beach profile and cliffs due to the increased depth of the proposed berth and departure area allowing higher wave energy to reach shore during a storm. Any impacts would be limited to a reasonably short distance both sides of the wharf trestle structure. Potential impacts would be monitored and mitigation undertaken if cliff erosion is exacerbated.

Cross-shore transport of sediment occurs during storm events and alters the nearshore morphology by forming storm sand-bars. This is a natural beach response. Modelling indicates migration of the coarser sands as bed forms would not extend far enough offshore to pose infill issues with the proposed dredged berths. However, there may be a low potential for the finer beach sands to infill the proposed dredged berth area, although the effects of this process are limited due to the small volume of this fraction of sediment in the upper beach material. Furthermore, there is a reduction in transport potential of suspended cross-shore sediment with increasing water depth towards the berth pocket.

The influence of the proposed dredging inshore on the local tidal current pattern is determined by the following:

- berth and channel dimensions (length, width and side wall slope);
- angle between the main axis and direction of approaching current;
- strength of local current; and
- local bathymetry.

The existing peak spring tide current at the location of the proposed berth pockets, averaged over depth, is 0.33m/s. After dredging, this peak current speed would reduce to an average of 0.15m/s. Current speed would decrease over the extent of the berth but would increase again when the depth reverts to the normal profile.

The primary risk that reduced currents over the proposed dredged berth would increase silt within the proposed dredge area is addressed in discussion regarding maintenance dredging in **Section 6.9.2.11**.

6.9.2 Marine Water Quality Impacts

The potential marine impacts associated with dredging and operational activities are discussed below in terms of water quality. A review of the proposed development has identified the following key sources of possible marine water quality impacts:

- port area capital dredging and disposal plume generation at proposed new spoil ground;
- dredge spoil re-suspension at the proposed spoil ground;
- inshore sediment deposition;
- capital dredging at barge and ferry terminals;
- Albatross Bay spoil ground disposal plume generation;
- introduction of contaminants during operational ship loading; and
- maintenance dredging requirements and turbid plume generation.

The key potential impacts of dredging and spoil disposal on water quality are:

- possible mobilisation of contaminants into the water column;
- generation and migration of turbid plumes;
- reduction in benthic light regimes; and
- increased local sediment deposition.

Water quality at the proposed port, new spoil ground, and proposed ferry and barge facilities all exhibit significant natural fluctuations in suspended sediment and turbidity (refer **Section 6.4.4**). The extent of this natural variation buffers water quality impacts associated with dredging, disposal, construction and operation to some extent. Generally, these habitats may be described as being more resilient to short-term water quality changes.

Periodic alterations in chemical water quality are currently experienced during event-based elevations in ambient turbidity. As fine sediments are mobilised throughout the water column, nutrient and metal concentrations naturally increase. Seasonal alterations in chemical water quality are also experienced during the monsoon and cyclone periods.

Analysis of the sediments to be dredged from the proposed port area and the barge/ferry terminals have not identified any constituents present at levels of environmental concern that would persist in the water column during dredging or sea disposal at respective spoil grounds (refer **Section 6.5.4.3** and **Section 6.5.6**).

Proposed works within the Embley River and Hey River are likely to generate turbidity concentrations that fall within the natural turbidity range. The rivers and estuaries of Cape York are subject to high ranges in turbidities over both the dry and wet seasons. The method of dredging in the Embley and Hey Rivers is likely to be by bucket or grab dredgers, which generate relatively low levels of turbidity. This is because there is no significant return of waters via overflow such as would occur through suction dredging methods. The turbidity generated would be substantially lower than that generated during routine maintenance dredging

campaigns at the Port of Weipa using the TSHD Brisbane. These campaigns so far have not demonstrated a causal link with changes in seagrass density or meadow area in the estuary. As seagrass are the most sensitive receivers, this result is a good indicator of whether dredging activities are causing significant changes in turbidity levels. The short duration of dredging in each barge/ferry terminal area (1-2 weeks) would further limit potential for impacts. Potential impacts to water quality and coral health associated with dredging activities are discussed in detail in **Section 6.9.3.1.**

The migration and dispersion of turbid plumes during major capital dredging at the proposed port area and disposal at the proposed new spoil ground has been predicted through modelling due to the significant volume of material to be dredged.

6.9.2.1 Turbid Plume Generation Modelling

The Inner Gulf hydrodynamic Mike21 model coupled with the software's mud transport module (MT) has been used to predict the fate of dredge plumes and assist in determining the potential impacts for the port area capital dredging and disposal activity.

Plume modelling included the following methodology and assumptions:

- modelled concentrations are based on suspended sediments caused by dredging and represent expected increases above background;
- the entire nine-month period estimated for the dredging works is simulated;
- dredging commenced at the most seaward location for each cut, with the berth pockets dredged last;
- simulations are based on average tide and wind conditions;
- average wind conditions, derived from the long-term record at Weipa, are used for seasonal conditions (wet, dry and transitional seasons);
- dredging works are to commence in early May at the start of the dry season and continue until work is completed; and
- two dredge time series are used to represent the operations of the cutter suction dredge (CSD) and trailing suction hopper dredge (TSHD) (discussed further below).

The tidal conditions within the simulation cover the range of tidal states experienced under normal conditions in the Project area. Modelling of worst-case wind and tide scenarios (e.g. cyclonic events) was not undertaken as dredging would not be undertaken under such conditions due to safety risks.

To predict the behaviour of the plume resulting from dredging and spoil disposal activities, fine quadrangular elements were used to resolve the berth/departure area and departure channel. Detail of the mud transport module domain (Inner Gulf model) and hydrodynamic verification is provided in **Section 6.1.2**. Wind forcing is included and based on available records at the nearby Weipa Airport Gauge.

Based on recent PSD and settling tube test information, sediment particle size distribution and settling velocities have been established for the three sediment types representing the vertical sediment profile to be dredged and incorporated within the model (refer **Table 6-41**).

Table 6-41 Dredge Material Characteristics Used in Plume Modelling

Fraction	Material	Size (mm)	Particle Size Distribution (%)			Settling velocity (mm/s)
			Layer 1 (unconsolidated marine sediments and sandy clay)	Layer 2 (stiff sandy clay)	Layer 3/4 (siltstone)	
1	Clay	<0.002	44	11	13	0.03
2	Silt	0.06–0.002	35	50	10	1
3	Fine Sand	0.2 – 0.06	10	20	47	15

The spill rates from the dredging activities vary dependent on the sediment layer, as a result of the variable sediment composition and density of the layers (**Table 6-42**). Four layers have been identified for dredging. The adopted spill rate from the TSHD during overflow for the first dredge layer is 25kg/s and has been estimated by considering the results of loss estimation undertaken for recent dredging for the Port of Melbourne Channel Deepening Project, and the material structure/density variance in the sediment profile at the proposed SoE Project port. Dredging consultants for the Project identified that the losses found from the Port of Melbourne dredging are considered consistent with other findings in the dredging industry and applicable to the South of Embley Project port dredging study. The method of dredging and size of equipment is generally consistent with that which would be applied to the developing the proposed port. A reduced spill rate of 20kg/s adopted for the second dredge layer has been interpolated from these results, and again factors in the different physical properties of the material to be dredged. The spill rate adopted for the third and fourth dredge layers has been reduced to 10kg/s. Whilst this spill rate is not supported by actual measurements, it is based on the third and fourth dredge layers representing a hard siltstone, and being of differing physical properties to the clays above.

Table 6-42 Adopted Spill Rates (kg/s) for the Dredging Scenario

Activity	Dredge parameters		Spill Rates (kg/s)		
	Production Rate	Activity time per cycle	Layer 1 (unconsolidated marine sediments and sandy clay)	Layer 2 (stiff sandy clay)	Layer 3/4 (siltstone)
CSD redepositing via near bed diffuser	1,720 m^3/hr (berths and departure area) 1,420 m^3/hr (departure channel)	2hrs (over 3hr cycle) *	1	0.8	0.4
TSHD overflow	5,000 m^3/cycle	1hr40min (over 4hr10min cycle)	25	20	10
TSHD draghead and propeller disturbance	5,000 m^3/cycle	2hrs10min (over 4hr10min cycle)	4	3.2	1.6
TSHD disposal	n/a	15min (over 4hr10min cycle)	60	60	60

CSD = Cutter suction dredge; TSHD = Trailing suction hopper dredge (TSHD)
* Remaining time in cycle spent moving the dredge and repositioning the cutter

The adopted spill rates decrease with layer depth because material strength increases with depth resulting in more large clumps and less release of fine material during dredging. Given the physical differences in material within the vertical sediment profile, as documented by PSD and core inspections, these reductions in fine material release have been extended to apply to spill rates for the CSD, and TSHD drag head and propeller disturbance.

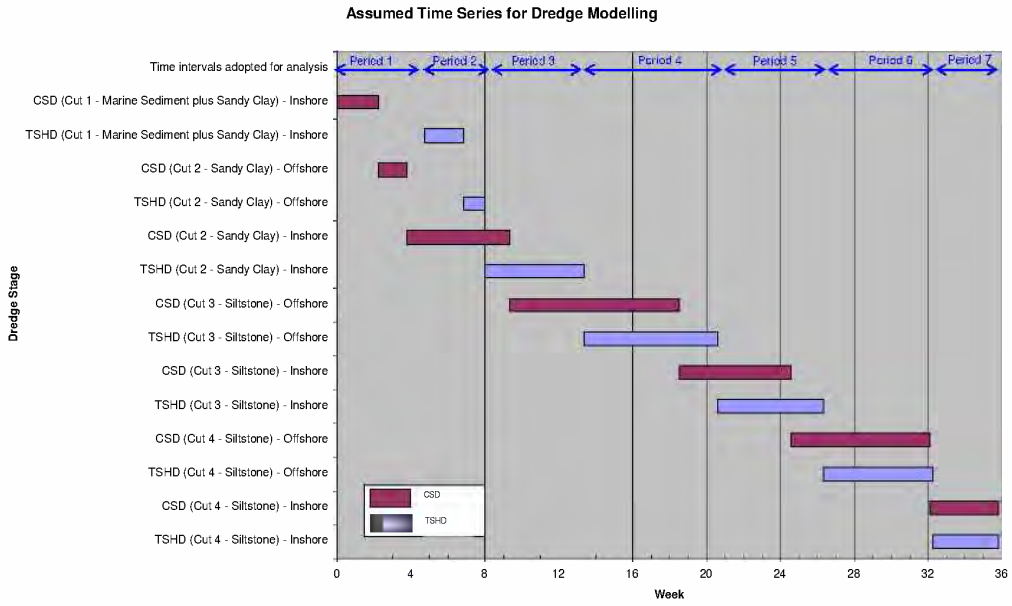
Resuspension is not included within the model predictions on the basis that there currently exists a layer of relatively fine unconsolidated material that covers a wide area of the nearshore area, and that is regularly suspended under natural conditions. Fines released from dredging will add to the unconsolidated material available for resuspension. However, the net change in material available for suspension is not considered significant.

The extent of geotechnical investigations are limited to the nearshore area surrounding the trestle and berth pockets. For areas to be dredged seaward of the extent of survey, the main assumption has been that the siltstone unit continues seaward at a similar level as identified by the nearshore boreholes (refer **Section 6.5.4.2**). This is a reasonable assumption based on the geology of the region (pers comm, Iain Turner, Coffey Geotechnics).

The dredge operation is simulated assuming the combined use of a CSD and TSHD. Approximately 6.5 million cubic metres of material is to be dredged within a 36-week period starting at the beginning of the dry season (early May) and continuing until work is completed (January). This 36-week dredging period does not allow for any delays such as for breakdowns

or maintenance, which would extend the duration of dredging but also interrupt suspended sediment plume generation. Based on *Boyd Point Facility for Cape-Size Vessels Review of Options for Dredging and Disposal of Dredged Materials* (SKM 2010) and in consultation with Pro Dredging & Marine Consultants, the adopted time series of the two dredges is shown in **Figure 6-58**. The dredging schedule has been divided into seven distinct periods. The TSHD has been assumed to commence dredging 33 days after the CSD in order for the two dredgers to complete the operation at approximately the same time.

A turbid plume would eventuate as material is released to the water column during the operation of the CSD and TSHD dredgers. The plume would be reasonably uniform over the local water depth due to the well-mixed tidal hydrodynamics and the predominantly fine silt and clay bed material. Clay and silt with a lower settling velocity may remain in the water column for long periods (days) and a low concentration plume may disperse for several kilometres in the direction of the tide.



Legend: CSD = Cutter suction dredge; TSHD = Trailing suction hopper dredge

Figure 6-58 Dredge Time Series Adopted for Mud Transport Model Runs

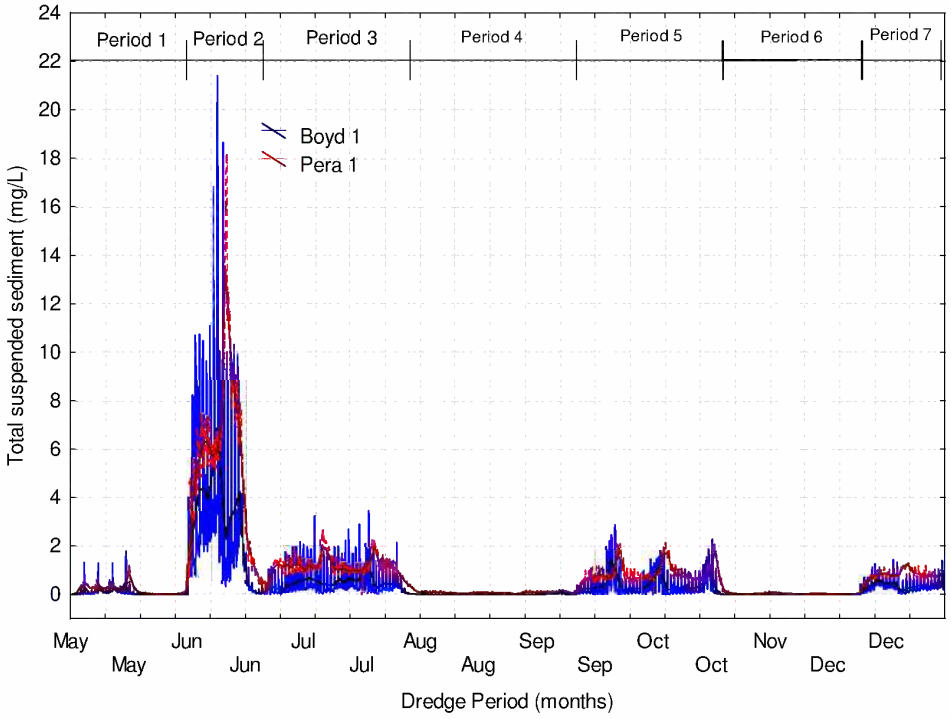
Plumes are advected by current strength and direction; therefore the individual flood and ebb tide phases influence their shape and trajectory, as do spring and neap tide phases. Model results of the dredge plume during approximately 36 weeks of continuous dredging were examined.

6.9.2.2 Port Area Capital Dredging Turbid Plume Generation

Model outputs identify that during flood tides the turbid plume generated by port area capital dredging extends parallel, along the coast from the dredge location to beyond Pera Head. During the flood tide phase, Boyd Point experiences relief from the increased TSS concentration. During the ebb tide the dredge plume extends along the coast extending from Pera Head to Boyd Point. In contrast to Boyd Point, Pera Head does not experience total relief from the increased TSS concentration. This is due to the net south-west tidal current direction causing suspended material to accumulate between the proposed port and Pera Head.

Modelled TSS time series data from Pera 1 (Pera Head) and Boyd 1 (Boyd Point) have been divided into the seven distinct dredging periods (refer **Table 6-43**) and are shown in **Figure 6-59**). Refer to **Figure 6-61** for locations. Periods of high TSS concentration generally coincide with the TSHD operating in the inshore area (i.e. in the berths and departure area). Period 1

represents an initial phase of inshore and offshore dredging of layer 1 using just a CSD, and as a result TSS concentrations remain relatively low throughout this period. The remaining six periods all include both CSD and TSHD operation with the spill rates varying depending on which layer is being dredged and the location of the dredges. Following dredge cut 1, the CSD makes a relatively minor contribution to the overall TSS concentrations. Period 2 represents dredging of layer 1 in the inshore area by the TSHD, while Period 3 represents dredging of layer 2 in the inshore area by the TSHD. Periods 4 and 5 represent dredging of layer 3 by the TSHD in the offshore and inshore areas respectively, while Periods 6 and 7 represent dredging of layer 4 by the TSHD in the offshore and inshore areas respectively.



Note: Bold lines represent rolling daily averages

Figure 6-59 Above Background TSS Concentration Time Series Extract at Pera 1 and Boyd 1

Table 6-43 Dredge Event Duration and Median Plume TSS Concentration Above Background at Pera 1

Plume Period	Dredge Event Duration (days)	Median Plume TSS (mg/L) above background – Pera 1
1	33	0.2
2	25	5.3
3	36	1.1
4	54	0.1
5	39	0.8
6	40	0
7	25	0.8

The median and 80th percentile of the TSS concentrations from the dredge plume dispersion model have been plotted spatially for Periods 2, 3 and 4 (**Figure 6-60 a, b and c respectively**) as representing inshore and offshore dredging for sediment layers 1, 2 and 3, respectively. Periods 5-7 are not shown to avoid duplication as their TSS concentrations are suitably represented by periods 3 and 4 (refer **Figure 6-59**). Dredge plumes may not cover the

entire dredge footprint as the different periods reflect different locations of dredging (inshore versus offshore) as described in **Section 6.9.2.1**. Summary statistics from key locations (refer **Figure 6-61**) for all seven periods are shown in **Table 6-44**. These locations include extract points from Pera Head, Boyd Point, Thud Point and the Boyd Bay beach area.

Modelling results indicate the Boyd Point reef area will experience greater respite from dredge plume migration than Pera Head and locations south (refer **Figure 6-59** and **Figure 6-60a-c**). Under ambient conditions, Boyd Point and Pera Head reef areas demonstrate a high variation in turbidity, driven primarily by local wind and associated wave events. Pera Head data loggers deployed during 2007–2008 recorded turbidity event periods of 9 and 24 days duration at median event concentrations of 248 and 127mg/L respectively (refer **Figure 6-33** in **Section 6.4.4**). Data captured from Boyd Point (GHD 2008) reported ambient events of 23 and 25 days duration, recording median event TSS concentrations of 163 and 184 mg/L respectively (refer **Figure 6-34** in **Section 6.4.4**). Respite between these events for both locations was approximately 13 days.

Median plume concentrations from all periods remain below event based ambient ranges reported from reef habitats (refer **Table 6-44**). Summary of plume duration and concentrations above background (ambient median TSS = 15mg/L) at Pera 1 is provided within **Table 6-43**. Modelling results indicate Thud Point locations south of Pera Head will experience similar patterns of TSS increases as predicted for Pera Head and Boyd Point during the seven periods but with a significant reduction in scale (refer **Figure 6-62**).

The durations of TSS plume concentrations at or above 5, 10 and 15mg/L above background (ambient median TSS = 15mg/L) have been extracted from the model for plume Periods 2 and 3 (refer **Figure 6-63a-c** respectively**)**. This is a duration-based plot based on percentage occurrence of concentrations for Periods 2 and 3. The 5mg/L case extends to 1-2km north of Thud Point during Period 2, while during Period 3 it remains local to the dredge. The 10mg/L case during Period 2 extends from Pera Head to Boyd Point, while during Period 3 it is restricted to within the immediate location of the area to be dredged. Results show that concentrations in excess of 15mg/L are not predicted to occur beyond Pera Head or Boyd Point for any of the periods for over 5% of the time. It is only during Period 2 that TSS concentrations in excess of 15mg/L occur for more than 5% of the time, and these concentrations do not occur for more than 20% of the time. Period 4 TSS concentrations do not exceed 5mg/L, so an exceedance figure is not presented.

Given a predicted peak plume period of approximately 25 days (approximately the same as natural event durations of 30 days), only areas identified within **Figure 6-63** as having a duration exceedance approaching 100% may be described as approaching the currently understood limits of natural conditions. Given this comparison, plume duration effects at the 15mg/L concentration beyond that encountered during ambient events are not experienced throughout any of the dredge periods.

6.9.2.3 Proposed Spoil Ground Turbid Plume Generation

Modelling of turbid plumes at the proposed new spoil ground identified a median TSS concentration of less than 1mg/L above background and a maximum of 13mg/L above background (refer **Table 6-45**) over the dredging and disposal period of 36 weeks. These concentrations at the proposed new spoil ground are relatively low due to an increased dilution within the water column (i.e. depth averaged concentration), low duration (disposal approximately every four hours) and prevailing southerly currents providing dispersion.

The disposal plumes tend to disperse along a south-south-east trajectory due to tidal currents and are not predicted to impact Nine Mile Reef, which is located approximately 6km south-south-west of the spoil ground (refer **Figure 6-60a-c**). Modelling has predicted that a median TSS of less than 0.2mg/L and maximum of 1.2mg/L above background would occur over Nine Mile Reef (refer **Table 6-45**). These increases are negligible given background TSS characteristics at offshore areas, as represented by existing conditions at the proposed spoil ground where recorded TSS concentrations had a median of 33mg/L, mean of 135mg/L and maximum of 1056mg/L during the Project's in-situ logger program (refer to **Section 6.4.4.1**).

6.9.2.4 Dredge Spoil Re-suspension at the Proposed Spoil Ground

The composition of in-situ bed material at the proposed spoil ground is 20% gravel, 57% sand, and 23% fines (silt and clay fractions) (refer **Section 6.5.5**). A substantial proportion of the material to be dredged is anticipated to be present in the dredge hopper as chunks of clay and siltstone. The silt clay fraction in the material to be dredged decreases with depth, with silts and clays representing approximately 79% in unconsolidated clays near the sediment surface, 61% in lower stiff sandy clays and 23% in the deeper siltstone material (refer **Section 6.5.4.2** and **Table 6-41**). Because of their mass, these chunks of material would not be easily remobilised by normal tidal currents and waves, and are unlikely to be mobilised in storm events. The hydrodynamic model predicts that maximum currents are not strong enough to transport substantial amounts of material from the spoil area during the disposal process. Although the flood tide current (peak value 0.3m/s) is the same as the ebb tide current, it lasts longer, resulting in a net drift towards the south-west.

Stronger currents associated with tropical cyclone activity, together with wind driven currents, are important to the long-term fate of spoil ground sediments. Currents may reach 2m/s or more in a severe storm that could track across the proposed new spoil ground from a wide range of directions.

Large waves may occur at the proposed new spoil ground site due to the depth of water. However, the percentage exceedance curves from the DERM wave buoy data in Albatross Bay indicate large waves only occur for brief periods, usually in the summer months. Significant wave heights, greater than 3m, occur only 0.1% of the time.

Sediment transport calculations were undertaken to assess the potential for spoil ground remobilisation based on the following:

- spoil ground characteristics;
- dredge material to be disposed of; and
- current and wave conditions specific to the site.

Results show the transport of the sand fraction increases with increasing current speed and wave height.

Spring and neap tide currents, less than 0.3m/s at the proposed new spoil ground site without wave action, do not transport sand because bed-stresses are too low. Sand transport, in combination with normal peak spring tide currents, is predicted to occur only under larger significant wave heights (greater than 2m) at the proposed spoil ground.

A current speed of 1.4m/s at the proposed spoil ground, combined with 3m significant wave heights (6 hour storm duration), has a capacity to transport approximately 4% of the sand material disposed during capital dredging. This remobilisation is considered to have a low potential impact because of the quantity involved and the limited extent of migration due to the short duration of the higher energy conditions.

The fine material deposited at the site would be resuspended under moderate to high wave and current conditions when critical bed-shear stresses for these fractions are exceeded, similar to the in-situ clays and silts presently at the site (36%). The extent of migration can be substantial for the deposited fine materials as they remain in suspension for long periods and deposition of sediment flocs starts to occur only once the critical bed-shear stress falls below a critical value (1.5N/m^2). The sediment direction of movement would be governed by storm-generated currents from any sector.

Benthic habitats within and adjacent to the proposed spoil ground are sparsely colonised, open muddy-sand substrates. Significant epibenthic habitats, such as seagrass or hard coral, were not observed in the disposal area during field investigations and are highly unlikely to occur there due to the depth of –23mLAT and resulting low light availability for photosynthesis. The soft coral – sponge dominated benthic habitat at Nine Mile Reef located 6km south-south-west of the proposed new spoil ground would not be impacted by remobilisation of sediments. Modelling undertaken in **Section 6.9.2.3** has identified currents and associated plumes occur along a south-south-east trajectory, thereby largely skirting Nine Mile Reef. During the dredge spoil disposal process, negligible increase in TSS was predicted at Nine Mile Reef (refer **Section 6.9.2.5)**. On that basis, it is expected that risks from resuspended sediments from the spoil ground post-disposal are similarly negligible. Should dredging-related turbidity be identified at Nine Mile Reef an investigation would be undertaken and appropriate mitigation measures implemented.

6.9.2.5 Inshore Sediment Deposition

Outputs from sediment deposition modelling have been plotted over the study area (refer **Figure 6-64**). These figures represent dredge Periods 2, 3 and 4 utilising theoretical settling velocities for particles using Stokes Law. The distribution of fine particle sizes used in the modelling was determined using geotechnical borehole material via hydrometer tests with a solution of 35g/L seawater. The use of seawater in the hydrometer tests provides a more realistic assessment of "effective" particle sizes since it takes into account the flocculative effects of seawater on clay particles. The flocculation of clay particles in seawater results in increased "effective" particle sizes and correspondingly faster settling rates.

The settling rates adopted for fine sediment fractions in turbid plume and deposition modelling are as follows:

- clay = 0.03mm/s
- silt = 1.0mm/s
- fine sand = 15.0mm/s

Ambient sediment deposition rates reported from Pera Head are compared with the predicted deposition regime within the footprint of the plume (refer **Table 6-46**). This table includes the modelled mean deposition predicted in mg/cm^2/day for representative dredge periods for model reef locations at Boyd Point, Pera Head and Thud Point (refer **Figure 6-61** for locations).

These results predict that mean deposition rates will remain less than 5% above background levels over key reef habitats. Locations adjacent to Pera Head are expected to experience the highest deposition rates and these are predicted to occur during Periods 2 and 3. Deposition rates during intervening periods are negligible compared to the ambient conditions, being less than 0.1mg/cm^2/day above background concentrations.

Based on the modelled sediment deposition rates and the duration of the dredging program, deposition impacts to reef systems between Boyd Point and Thud Point may be experienced. It should be recognised, however, that a complex relationship exists between deposition and actual impact within reef environments, driven by both physical and biological processes.

The process of remobilisation would act to limit deposition stress over coral habitats. However, given that dredge derived sediments are likely to be of a different physical and chemical nature to naturally derived materials, ambient water movements may be insufficient to fully remobilise these additional deposits.

Ambient fine sediments available for re-suspension and deposition can be described as existing in a complexed state, binding with organic particles which alter their behaviour (propensity for settling and remobilisation). The readily mobilised sediments can be described as a floc, moving into and out of suspension very easily. Sediments lost to the dredge plume are comparatively 'fresh', and mobilised to the plume relatively quickly once recovered from the seabed. They lack the complexing with organics and may demonstrate an increased cohesiveness, resulting in sediment deposits of a butter-like consistency, developing greater shear stresses after a period of compaction than ambient materials can obtain. These differing physical processes are important to consider when defining potential impact.

When plume derived sediment loads deposit with complex reef structures, the prevailing hydrodynamics of inter-reef spaces may not facilitate its complete remobilisation during 'average' events. This may lead to a scattered buildup of sediments within the reef, perhaps remobilised only during peak event periods (i.e. cyclones). Therefore, some storage of fine sediments within reef habitats can be expected for a period post dredging. Conversely, open reef surfaces over the corals themselves may be considered more open to remobilisation. These features result in a mosaic of sedimentation risk within the reef system.

* model summary statistics indicate that mean and median values are consistent.

Mean modelled sediment deposition rates have been plotted over key habitat areas (refer **Figure 6-64**). Statistical analysis shows that the median modelled sediment deposition rate remains consistent with the mean (typical of the modelling processes when dealing with many small values). The following colour codes have been used to represent modelled sediment deposition rates presented within **Figure 6-64**:

- Mean modelled deposition 20% above median ambient (~0.5 – 1.0 mg/cm^2/day) – blue;
- Mean modelled deposition 40% above median ambient (~1.0 - 1.5 mg/cm^2/day) – green;
- Mean modelled deposition 60% above median ambient (~1.5 - 2.0 mg/cm^2/day) – brown;
- Mean modelled deposition 80% above median ambient (~2.0 – 2.5 mg/cm^2/day) – yellow; and
- Mean modelled deposition 100% above median ambient (~2.5 + mg/cm^2/day) – red.

Yellow and red represent a higher risk associated with deposition, brown and green moderate risk and blue, low risk. De'ath and Fabricius (2008) recommend a mean annual sediment deposition rate of 3mg/cm^2/day, and daily maximum of about 15mg/cm^2/day, to guard against excessive coral recruit mortality.

The median ambient sediment deposition rate recorded over Pera Head Reef was approximately 2.4mg/cm^2/day. During Period 2, reefs at Pera Head are predicted by the model to receive median above-ambient deposition rates approaching 1.5 to 2.0mg/cm^2/day (refer **Figure 6-64**), which represents an increase of 63% to 85%. Therefore the total rate of deposition may increase to a median of 3.9 to 4.4mg/cm^2/day for the duration of Period 2 dredging (approximately four weeks).During the same period, reef systems south of Pera Head to Thud Point are predicted to experience an increase in sediment deposition of 0.25 to 1mg/cm^2/day, a 10%-50% increase over ambient conditions. This would equate to an approximate median daily exposure of 2.7 to 3.4mg/cm^2/day. Therefore the total rate of deposition during Period 2 may represent a potential risk of mortality to coral recruits based on the recommended mean annual concentration of 3mg/cm^2/day. However the predicted sediment deposition rates remain much lower than the recommended daily maximum of about 15mg/cm^2/day. Corals already established on the reef are likely to be more resilient than recruits as demonstrated by colony survival following natural events where deposition rates would be significantly higher than the recommended daily maximum level recommended by De'ath and Fabricius (2008).

Similar deposition distributions are experienced during Period 3, though the extent of affect is markedly reduced. During Period 4, the footprint of deposition above 0.25mg/cm^2/day above ambient rates remains relatively localised around the dredge channel. Deposition at rates outside those readily accommodated by corals may lead to lethal or sublethal responses over a period of days to weeks. Evidence of fine sediment deposition from recent dredging programs in Queensland demonstrate a preferential deposition of sediments over hollows and indentations of at-risk corals, such as encrusting species of *Montipora* and massive species such as *Porities*. Other reef elements to experience deposition include uncolonised sand and silt patches and 'inter reef spaces' between live coral structures.

While the reef may be exposed to sediment deposition from the plume, the risk of deposition incurring damage is not consistent across coral habitats. In addition to the varying hydrodynamic features of the corals, some species exhibit larger polyps which physically remove sediment from the tissues by constant movement of their tentacles. Other corals such as branching *Acroporid* species maintain very limited surfaces open to deposition, being cylindrical in shape. Fungid corals observed within a fines deposition zone surrounding acute dredging disposal on the Great Barrier Reef survived within an area affected by approximately 5cm of fine silts and clays by a combination of hydrodynamic forces (scouring) and activity of the corals tentacles (the coral itself was only 4–5cm in height, and located almost totally beneath the deposition profile) (Pers. obs. T. Koskela 2002). Although species are variably designed to cope with a wide range of deposition regimes, the resulting stress caused from extended periods of deposition exposure may lead to a drain on general biological functions (mucus production, reproductive resources etc).

An important consideration when determining the fate of plume-derived deposition is the prevailing sea state. For example, under calm conditions the role of sedimentation as an impactor can be expected to increase. Relatively rapid increases in coral mortality have been observed (Pers. obs. T. Koskela 2002) from fringing reefs near Townsville during dredging in calm conditions, with rapid small scale deposition causing coral tissue necrosis over a five to seven day period. It is possible that periods of calm sea conditions over reef habitats during dredging may provide an increased level of risk to reef communities which would require considered management and monitoring to prevent long to medium term damage to corals within the deposition footprint.

The supply of additional fine sediment loads via the dredging process also has the capacity to induce chronic changes to those areas susceptible to the accumulation of fine sediments. The remobilisation of dredge derived sediments following the completion of dredging, particularly from shallow waters, is likely to persist for several years following dredging activity. However, the active nature of the coastline, and frequent passage of cyclones and tropical storms, is likely to limit such effects and favour a rapid rehabilitation phase as sediments are resorted to appropriate depositional environments.

As described above, the effects of deposition are not often experienced as a blanket of sediment within the far field plume environment. The implementation of a reactive monitoring program – designed to capture changes, define significance and respond with suitable management measures – is considered an important control mechanism during dredging operations.

6.9.2.6 Capital Dredging at Barge and Ferry Terminals

Minor volumes of material would be dredged at Hornibrook Terminal (18,680m^3), Humbug Terminal (10,670m^3) and Hey River Terminal (17,300m^3) to obtain sufficient draft for Project support vessels at the barge and ferry facilities. Dredge spoil would be disposed of at the existing Albatross Bay spoil ground.

Annual maintenance dredging activities have been undertaken in the Embley River by North Queensland Bulk Ports Corporation Limited (NQBP), formerly Ports Corporation of Queensland (PCQ), for more than 30 years and are a regular feature of port operations. As part of these activities, NQBP has undertaken aerial surveillance and turbidity monitoring during dredging campaigns. PCQ (2009) report that aerial surveillance and turbidity measurements during dredging campaigns suggested there were no significant adverse impacts from dredging on key marine resources in the area such as the seagrass meadows. The capital dredging proposed for the ferry and barge terminals represents a small proportion (5-10%) of the volume dredged regularly by NQBP. It follows that the minor dredging proposed by RTA would have a lesser impact than the NQBP dredging.

On the basis of the minor volumes of dredging required and results of previous monitoring undertaken for dredging projects in the Embley River, turbidity modelling at the three proposed barge/ferry terminal areas was not undertaken.

6.9.2.7 Albatross Bay Spoil Ground Disposal Plume Generation

The material to be dredged from the barge/ferry terminals has physical characteristics similar to Weipa shipping channel (South Channel) sediments. GHD (2005) has previously carried out an impact assessment study in relation to capital dredging of the shipping channel and placement of the material at the Albatross Bay spoil ground. The study examined impacts from capital dredging campaigns involving a much larger volume (greater than 3,000,000m^3) of maintenance and capital material. It concluded that the impacts to sensitive areas, such as seagrass meadows to the north-east, from migration of material would be low because the material is predicted to migrate south towards the South Channel. Modelling of turbidity plumes identified that turbidity generated at the spoil ground following release would travel a maximum of 3km within 11 hours of placement and that this would not extend to sensitive areas.

The combined volume of material to be dredged from the Embley and Hey River dredge areas is very small (<10%) compared to routine maintenance dredging at the Port of Weipa. Since the material to be placed at the spoil ground would likely migrate towards the existing shipping channel and plumes not extend to sensitive habitats, it is concluded that the potential for impact on sensitive habitats is very low. Consequently, modelling was not undertaken as part of the present study.

6.9.2.8 Capital Dredging Mitigation Measures

The most effective control strategy to minimise negative effects of dredging on adjacent habitats is to minimise dredging time, allowing sensitive receptors to enter a recovery phase as quickly as possible. It is anticipated the port area would be dredged over up to 10 months. However, there would be periods of respite as the dredging operations move between inshore and offshore locations. Dredging at barge/ferry terminals should take only one to two weeks, each representing short dredging campaigns.

It is likely that silt curtains would not be a suitable physical control measure at Boyd Point or Pera Head due to high current movements in those areas. Such measures are also not proposed for the Embley and Hey River sites as currents are likely to be problematic and the duration of dredging is short.

The proposed method of undertaking capital dredging works for the port area, using a self propelled cutter-suction dredger that deposits cuttings on the cut seabed area followed up by a trailing suction hopper dredge, was selected to minimise the turbidity generated through overflow, particularly for large dredging projects. Water entrained and subsequently overflowed during suction of pre-cut and deposited dredge material would be significantly less than that entrained during cutting and pumping of sediments to a waiting hopper barge.

To further minimise potential turbidity impacts at the dredge spoil disposal sites, the following measures to reduce loss of bulk material into the marine environment during dredging operations would be considered:

- Specifying that the trailing suction hopper dredge used during port development dredging includes a low-wash hull design, below keel discharge and electronic positioning systems.
- Specifying that hopper barges used in Embley River and Hey River dredging must have hopper door seals that are in good condition.
- Taking loaded hopper barges or hopper dredge to spoil disposal areas and discharging material as soon as possible to minimise clays settling and adhering to the hopper lining. (Removing the settled clays within a hopper barge's lining generally requires sailing the barge at full speed across the spoil grounds when disposing, causing unwarranted turbidity.)
- Where possible, placing a sandy silt lining (from dredge material) on the bottom of the barge before loading clays to facilitate clay discharge.
- Developing a spoil dumping plan to aid the even distribution of material over the spoil grounds.

Each spoil placement would be logged using both satellite navigation and standard bridge equipment, and would be electronically fixed using a differentially corrected global positioning system (GPS). Electronic track plots will mark the start of each placement process (hopper open), and the end of the process (hopper closed). Placement tracks usually show an arc, which the dredge follows to ensure that dredged material is placed within the designated spoil ground boundary. Position would be determined with an accuracy of at least 10m.

Maintenance dredging environmental management procedures and monitoring requirements for the port facility would be developed within a Long Term Management Plan that would be required for any long-term dredging and spoil disposal approval issued under the *Environmental Protection (Sea Dumping) Act 1981* (Cwlth) or *Environmental Protection Act 1994* (Qld).

6.9.2.9 Introduction of Contaminants During Operational Ship Loading

The process of conveying bulk material from shore to ship provides a mechanism through which bauxite material can enter the marine environment in the immediate vicinity of the port. Bauxite material that enters the marine environment during the loading process would primarily be in non-bioavailable solid form and would enter a typically turbid water body. It is expected that turbidity impacts arising from bauxite would be minor given the high degree of water movement within the bay between Pera Head and Boyd Point, relatively minor rate of dust generation, and existing turbid nature of the inshore waters. It should be noted that larger granular bauxite naturally occurs in the port development area sediments, having been derived from the adjacent cliff areas through natural erosion processes. These naturally deposited bauxite materials do not appear to have any impact on the marine environment.

The conveyor and ship loader would be designed and operational procedures adopted to minimise dust generation and spillage to the surrounding environment, particularly in the vicinity of transfer points. These measures would include the following:

- A catch tray would be positioned under the ship loader tripper to catch spillage from the inclined section of belt. The material collected from the tripper catch tray would be directed to the head end sump and then pumped onshore to a sediment holding pond.
- Three stage belt scraping with water sprays would be positioned at the conveyor head pulley to clean the belt. The scrapings and the water used for belt cleaning would be directed into the head end sump for pumping onshore into sedimentation dams.
- The wharf conveyor would be designed with variable speed drives to provide controlled belt starting, thereby minimising the potential for bauxite spillage.
- Belt drift switches would be installed on the wharf and ship loading conveyor that shuts down the conveyor drives if a belt moves from the designed position. Training idlers that track the belts would also be installed.
- When loading ships, the product reclaimer would be stopped and the conveyor allowed to empty before the ship loading boom travels between hatches to prevent bauxite spillage onto the deck of the ship.
- A sealed maintenance area would be provided at the end of the wharf so the ship loading boom can be serviced and cleaned within a bunded area. Runoff from this sealed maintenance area would report to the head end sump for pumping back to shore.
- No fuel or chemicals would be unloaded at the proposed wharf facilities.

6.9.2.10 Turbidity from Port Area Operational Shipping Movements

Turbidity is generally elevated immediately adjacent to port facilities as propeller wash and vessel movement/handling by tugs continually mobilise fine sediments. The absence of significant light dependent benthic habitats immediately adjacent to the proposed port would limit any effects of ship movements.

The nearest benthic habitats recorded from the vicinity of the port included sparse sponge and soft coral communities established on outcropping hard substrates located 150 to 800m from the proposed wharf. Such organisms are tolerant of variable sedimentation regimes so no significant impact is predicted. The more significant reef habitats located at Boyd Point and Pera Head are considered to

be too far away to be affected by operational increases in turbidity from vessel movement and are subject to naturally varying turbidities.

6.9.2.11 Maintenance Dredging Requirements and Turbid Plume Generation

Port Area

Considerable sediment is mobilised under current and higher wave conditions (refer **Section 6.1.5**). There is a high potential for the proposed berth pockets to accumulate the clay and silt fractions present in the surrounding seabed. Fine sand fractions would also be transported as bed load and suspended load during larger wave events.

The potential siltation depth for the proposed berths has been calculated using the percentage exceedance curves for wave heights from records at the Weipa wave buoy. Average annual siltation depth has been conservatively estimated to be 1.15m for the berth and departure apron area and 0.35m for the departure channel. This equates to approximately 890,000m^3 per year of material requiring dredging to maintain the design depths (refer **Table 6-47**). This includes 540,000m^3 from the berth and departure apron area and 350,000m^3 from the departure channel.

Table 6-47 Annual Siltation Depth of Port Area Based on Wave Exceedance

Per Cent Exceedance (All Data)	Exceedance (days)	Occurrence (days)	Significant Wave Height Hs (m)	Peak Energy Wave Period Tp (s)	TSS (mg/L)	Silt Depth (m)	
						Berths and Departure Area	Departure Channel
20%	73.0	58.40	>0.5	5	100	0.642	0.204
4%	14.6	7.30	>1	6	200	0.139	0.040
2%	7.3	5.48	>1.5	7	400	0.200	0.060
0.5%	1.8	1.53	>2	8	1000	0.131	0.039
0.1%	0.3	0.26	>3	10	1500	0.031	0.009
0.01%	0.0	0.04	>4	12	2000	0.006	0.002
Total						1.150	0.350

The potential siltation depth was also estimated based on two high energy wave events recorded with the ADCP at Boyd Point between late 2007 and early 2008 and has been calculated as 1.41m and 0.42m for the respective areas (the equivalent of approximately 1,000,000m^3 of infill). This result indicates the average annual siltation depths of 1.15m and 0.35m may be exceeded over a relatively short period following two or more significant events during a single wet season. Significant annual infill variability may be expected at the study site and is expected to be closely related to the timing, duration, and magnitude of events.

It is expected that this maintenance dredging would take approximately six weeks. This assumes that the dredging would be undertaken by a TSHD such as the *Brisbane*, which services many ports around Queensland, including the Ports of Karumba and Weipa in the Gulf of Carpentaria. Of the six-week dredging program, dredging would occur in the inshore berth and departure areas for approximately three to four weeks while dredging of the departure channel would take about two to three weeks, based on calculated siltation volumes in each area.

Modelling of maintenance dredging plumes has not been undertaken, but it is expected that the spatial extent of plumes would not exceed those generated during capital dredging works since turbid plume generation from both campaigns is primarily due to overflow dredging from the TSHD. Maintenance dredging would likely have higher concentration of fine sediments in the overflow, but this would be largely balanced by significantly lower overflow rates. Dredging plume generation would likely be similar to that of Period 2 in the capital dredging campaign.

The volume of annual maintenance dredging for the port would add approximately 0.4m height, on average, to the proposed new spoil ground prior to any consolidation or remobilisation of sediments.

Once Stage 2 of the port was developed to include an additional two berths, an extra 280,000m^3 per annum of maintenance dredging would be required, increasing the annual total of maintenance dredging for the port from 890,000m^3 to approximately 1,170,000m^3.

Embley and Hey River Barge/Ferry Terminals

The maintenance dredging for the ferry and barge terminals is expected to add approximately 7,000m^3 of material annually to the 400,000-900,000m^3 of material dredged from the Embley River and entrance channel for the Port of Weipa by North Queensland Bulk Ports.

Future maintenance dredging and disposal for the port site, and Embley and Hey River facilities would follow testing and reporting procedures outlined within the NAGD (Commonwealth of Australia 2009) or subsequent guideline.

6.9.3 Marine Habitat Impacts

Various impacts on marine habitats are likely to occur during construction and operational phases of the Project. The key habitats potentially impacted include:

- reef assemblages in the vicinity of the proposed port;
- soft sediment habitat in the vicinity of the proposed new spoil ground; and
- marine plant (seagrass and mangrove) habitat near Embley and Hey River barge/ferry terminals.

Impacts to these areas would arise either directly through removal or deposition, or indirectly through water quality impacts described in **Section 6.9.2**, particularly light attenuation.

Dredging at the Embley and Hey River barge/ferry terminals would not affect oyster banks on the Hey and Embley Rivers.

6.9.3.1 Inshore and Offshore Reef Habitat Turbidity

There are no reefs within the proposed port development footprint that need to be removed for dredging or wharf construction purposes.

The creation of a turbidity plume from dredging, and subsequent deposition and re-suspension of fine sediments, can result in potential indirect impacts on reef assemblages. This is particularly important for reef hard corals which require sunlight for photosynthesis. Small patches of sponge reef nearest the proposed Port facility may experience significant deposition during the dredging process. Some loss of habitat at these locations may be expected which may locally affect feeding preferences in marine turtles, however regional impacts are not predicted. The potential for impact to turtle feeding habitat is discussed further in **Section 6.9.4.3**.

Hard coral is present from Pera Head south to Thud Point and at Boyd Point (refer **Figure 6-18**). Due to their inshore location, hard corals on these reefs are presently exposed to naturally high deposition and turbidity and corresponding low light levels, a situation which can persist for several weeks at a time particularly during the wet season. Modelling of deposition over reef habitats is discussed in **Section 6.9.2.5**. Light availability, which correlates with depth and ambient suspended sediment regimes, restricts coral reef distribution. Based upon validation of reef distribution using video assessment, the maximum extent of reef development is though to occur between –8m and –12mLAT. Loggers situated at Pera Head were located 0.5m above the seabed at approximately –8m LAT, with data considered to represent conditions approaching the limits of coral tolerances. Analysis of TSS and PAR light data at Pera Head supports the development of light attenuation coefficients for varying TSS conditions to allow prediction of light regimes for the majority of shallow water reef habitats between Boyd Point and Thud Point.

Table 6-9 in **Section 6.4.4** presented three light regimes related to coral sustainability based on the relationship between TSS and light. These regimes were:

- Favourable – green:
- Light limited – orange; and
- Unsustainable – red.

Using the range of TSS values and depth profiles developed within **Table 6-9** a prediction of impact based on benthic light availability has been completed for reef habitats of the study area between Boyd Point and Thud Point. The following provides a summary of the analysis process:

1. Median TSS plots were extracted from the model for Periods 2, 3 and 4, as representative of the seven periods identified within the model (refer **Section 6.9.2.1**) and model TSS results (refer **Section 6.9.2.2**).
2. Reef habitats were mapped based on a combined analysis of bathymetric data, infield drop camera video assessment and aerial photograph interpretation.
3. Reef habitats were depth classified from available bathymetric survey provided by RTA.
4. Habitat, depth and modelled TSS concentrations were then cross-referenced against the predicted light attenuation regimes developed using spatial analysis tools.

The results of this assessment have been mapped in the categories of "favourable" and "light limited" (analysis of an "unsustainable" class was assessed but returned null results during assessment). Light availability predictions comparing the ambient case against dredging Periods 2, 3 and 4 are presented for Boyd Point and Pera Head (**Figure 6-65a**), and reefs south of Pera Head to Thud Point (**Figure 6-65b**). Analysis incorporates TSS results from median case plume dispersion modelling. Impacts to near shore hard coral habitats are summarised within **Table 6-48**, which presents predicted changes in area (hectares and percentage) for favourable and limited light availability.

Overall, dredging is predicted to reduce the area of favourable light conditions over hard coral habitat by approximately 14%. This remains generally static over the dredging program. Pera Head is predicted to exhibit the greatest changes, with a reduction in favourable light condition habitat of approximately 33% during Period 2, reducing to approximately 16% for the remainder of dredging. The area of favourable light conditions at Boyd Point is predicted to reduce by approximately 11% during dredging, with no discernable difference between the dredge periods. A similar response is reported from reefs south of Pera Head to Thud Point (reduction in area of favourable light conditions of 11-12%).

Period 2 presents the peak affect on light attenuation, driven primarily by the increased clay and silt fractions within the first layers of material to be dredged using TSHD. The duration of the Period 2 dredging approaches 30 days, similar to ambient light reduction events recorded at Boyd Point during field investigations (23-30 days). However, the predicted plume TSS concentrations remain well below reported maximum ambient concentrations. Within the **Table 6-46**, light regime classification areas for Periods 3 and 4 remain consistent. This is a result of the differences in median TSS being up to about 1mg/L (refer **Table 6-44**).

Given the relatively short duration of light attenuation, and general respite provided to coral reef systems after Period 2, these predicted light reductions are not thought to be a driver of acute impact associated with the dredging process. Rather, a moderate proportion of coral habitats (11-14%) would enter an extended period of reduced light availability, approaching conditions presently experienced by corals living nearer the local limits for coral growth. Despite this, it is important to note that the analysis did not identify any coral habitats entering "unsustainable" light regimes, as described within **Section 6.4.4** (based upon median TSS concentrations within the plume).

Significant impact to coral resulting from light attenuation is not predicted. However, RTA would develop a reactive monitoring program which incorporates sub-lethal indicators of light stress, including bleaching. Modelling results indicate that, following the peak plume period (Period 2), receiving habitats enter a four to five week cycle of minor light reduction/increased TSS (Periods 3, 5 and 7), followed by four to five week periods of respite (Periods 4 and 6). Given that some level of stress is likely to occur during the first peak dredge plume period (Period 2), via light reduction and increased deposition, the recurring periods of respite are considered important to minimising overall coral stress. These periods provide an opportunity for corals to return to light dependent primary productivity and regenerate energy stores.

	Light Limited	3.9	17%

d) Thud Point Reefs

Dredging Period	Light Regime Classification	Area (ha)	Area (%)
Ambient	Favourable	137.8	88%
	Light Limited	19.3	12%
Period 2	Favourable	118.5	75%
	Light Limited	38.8	25%
Period 3	Favourable	118.5	75%
	Light Limited	38.8	25%
Period 4	Favourable	118.5	75%
	Light Limited	38.8	25%

Habitats that enter the "light limited" range as a result of the dredge plume are likely to undergo a period of photo adaptation, or acclimatisation, where corals increase photosynthetic pigments, improve photo efficiency and partition an increased portion of their energy budget to heterotrophy. Whilst not considered of sufficient change to initiate an acute response, the rate at which impacted corals can acclimatise is not well defined, and they remain at risk of developing sub-lethal responses to reduced light regimes. The additional processes of sediment deposition, such as lost photosynthetic area due to smothering and associated lost energy budgets also requires consideration (i.e. possible additive affects of light reduction and deposition).

Experimentation undertaken by Anthony *et al* (2007) under a range of manipulated temperature, light and turbidity regimes, identified responses in coral survivorship for *Acropora intermedia*. While response in low temperature regimes (28°C) did not demonstrate a pronounced change in survivorship, reduced light and increased sediment regimes influenced sub-lethal responses by way of reductions in chlorophyll-a and lipid content to some degree. These responses appeared more pronounced via light reduction than sediment increases, appearing to reach a process of decline after 10–20 days (sub lethal response – Lipid content). The duration of Period 2 exposures (25-30 days) exceed the 10–20 day threshold identified by Anthony *et al.* (2007), providing some indication that corals may begin to exhibit sub-lethal responses to light attenuation during the first peak plume period. Reactive monitoring designed to track sub-lethal responses in coral condition is considered an important management commitment over the entire dredge program.

Habitats maintaining a "favourable" light regime are not considered to be at risk over the dredge program. This represents approximately 86-89% of the reef systems inferred within the study area.

Maintenance Dredging Impacts

Maintenance dredging of approximately 890,000m^3 annually is expected, with 540,000m^3 from the inner port area (berths and departure area) and 350,000m^3 from the long departure channel (refer **Section 6.9.2**). Inshore dredging is estimated to take about three to four weeks and offshore dredging about two to three weeks.

The inshore reef areas of Pera Head and Boyd Point naturally experience extended periods of high suspended solids/turbidity and low light availability for three to four weeks in a single event (refer **Section 6.4.4.5**). Given that turbid plumes from maintenance dredging are expected to be well within natural ranges (refer **Section 6.9.2.11**), and duration of dredging plume generation is not more than that which occurs naturally, there is not predicted to be any significant impact to inshore reefs.

Reef Habitat Monitoring

For port area capital dredging, monitoring of turbidity, deposition and PAR is proposed to be undertaken at Boyd Point, Pera Head and Thud Point reef areas and at a control location outside the extent of the modelled dredge plume. Trigger levels would be developed for these water quality parameters primarily as alerts for coral health reactive monitoring. These levels would be identified within a Dredge Management Plan that would require approval from DSEWPaC.

TSS would be estimated based on the relationship between NTU-e and TSS (refer **Section 6.4.4.3**). The objective of this monitoring is to validate the turbid plume modelling and assist in identifying extended periods of high turbidity, high TSS and low PAR availability which can lead to coral stress. In-situ water quality loggers, like those used to collect background data for the present study, would continue to be used during the proposed monitoring program. Monitoring would begin a minimum of a month prior to dredging and extend until two months after the completion of dredging. Loggers would be either downloaded fortnightly or telemetry linked to allow for remote download so that data can be regularly reviewed.

Monitoring of hard corals is proposed at Boyd Point, Pera Head and reefs south to Thud Point. The objective of this is to identify when corals become stressed due to low light conditions or are being impacted by sediment deposition. Key parameters and response levels would be confirmed through a pilot program but would likely focus on a gradient of stress indicators such including coral colour, photosynthetic efficiency, sediment coverage, bleaching, injury and partial mortality, and mortality. These biological triggers focus on a range of sub-lethal indicators to best facilitate management response (although lethal response also to be recorded).

Due to the presence of potentially dangerous marine life, common coral monitoring techniques such as divers swimming fixed line transects for assessing changes in coral cover are not viable. Alternatively, it is proposed to use boat-based methods, including repeated measures of a range of individual corals attached to trays that can be extracted from the water and studied on-board the vessel. Some initial in-water work would be required to collect coral specimens and establish the monitoring sites, however ongoing risk to divers is minimised.

Should signs of unacceptable coral stress become apparent, opportunities for the manipulation of dredging operations (for example, relocation of the TSHD operations to offshore areas) would be reviewed to best allow inshore corals a period of respite and a return to more favourable conditions.

The final design of the reactive monitoring program would be prepared in consultation with DSEWPaC and DERM and incorporated into a Dredge Management Plan (refer **Section 6.10** for an outline of the Dredge Management Plan). The Dredge Management Plan would include:

- validation of plume dispersion modelling predictions (first six to eight weeks);
- marine water quality monitoring (loggers – TSS, light (PAR) and deposition); and
- coral health monitoring (fixed impact and control sites).

A monitoring response protocol, including management triggers, would be developed as part of the Dredge Management Plan.

Monitoring requirements for future maintenance dredging would be developed as part of the maintenance dredging approvals process and would be subject to the conditions of future sea dumping permits. This would be informed by outcomes from the monitoring undertaken during capital dredging.

Although modelling predicts that the turbidity plume generated by the spoil ground would not impact Nine Mile Reef (refer **Section 6.9.2.3** and **Section 6.9.2.4**), turbidity plume monitoring would be undertaken for the purposes of model validation of spoil disposal and will be described within the Dredge Management Plan. If monitoring determines that there are unacceptable impacts to Nine Mine Reef due to the turbidity plume associated with the spoil ground, then appropriate management measures would be developed and implemented in consultation with DSEWPaC. If the model is identified as validated, then no further turbidity monitoring would be proposed at Nine Mile Reef.

6.9.3.2 Mangrove Habitat

While scattered stunted individuals of *Avicennia marina* exist within the upper tidal range on rocky shores at Boyd Point, seagrass and mangrove marine plants are not present in the immediate area of the proposed port development.

The only proposed marine infrastructure location with mangroves in the immediate vicinity is the Hey River barge/ferry terminal. The mangrove communities have established within marginal, gravel habitat at the base of a small bauxite cliff. The area that would be disturbed by the Project is a very small proportion of the area of mangroves in the Albatross Bay assemblage and therefore there is unlikely to be significant impact on the environment. The clearing of 400m^2 of mangrove habitat to facilitate pontoon access and barge transfer represents 0.008% of the associated RE (3.1.1a) within the Project area and 0.003% of total mangrove communities within the Project area (refer **Section 8.6.1.5**). The proposed dredging and operation of the facility is not considered a significant ongoing threat to the viability of the adjacent mangrove system, or to fisheries values or habitat essential to significant fish species, such as juvenile sawfish or *Glyphis* species.

Approval is required under the *Fisheries Act 1994* to remove or destroy marine plants (such as mangroves). In line with the Fish Habitat Management Operational Policy (FHMOP005) *Mitigation and Compensation for Works or Activities Causing Marine Fish Habitat Loss* (DPI 2002), a condition of approval under the *Fisheries Act 1994* for removing mangroves may include a requirement to provide a compensatory measure as an offset. The types of compensatory measures include:

- best practice methodologies;
- habitat productivity enhancement;
- restoration or replacement of fish habitat;

- fisheries resource research and education support;
- the payment of bonds (held towards ensuring impacts are minimal);
- fish habitat creation;
- fish habitat acquisition/exchange (relinquishment of private tenure); or
- fisheries stock enhancement.

Any such compensatory measure would be discussed with DEEDI and could include restoring mangrove habitat elsewhere or contribution to a State-wide Compensation Program to fund research or extension on fish habitats.

6.9.3.3 Seagrass Habitat

Water quality conditions at the proposed port location between Boyd Point and Thud Point do not favour seagrass establishment. However, seagrass has been recorded from subtidal meadows between the headlands of Boyd Bay, to the north of Boyd Point, and from locations south of Thud Point (Norman Creek and meadows near Aurukun) (refer **Figure 6-20**). Turbidity plume modelling indicates that these seagrasses would not be subject to any appreciable change in TSS concentrations, with predicted median and 80th percentile concentrations being less than 0.25mg/L above ambient (refer **Figure 6-60**).

The Hornibrook Terminal dredge footprint does not contain seagrass, however, aggregated patches of *E. acroides* seagrass may be located adjacent to it. Similarly, seagrass is not present in the dredge footprint at the proposed Hey River Terminal; however, it may occur in the wider vicinity as isolated patches.

Isolated patches of *E. acoroides* have been identified at the spring low tide level within or immediately adjacent to the proposed dredge footprint at Humbug Wharf. A conservative estimate of less than 1.84kg dry weight seagrass biomass may be directly extracted during the dredging process, based on seagrass area of 1250m^2 within the dredge area and most recent biomass estimates for monitoring meadow A6 (1.47g dry weight per m^2). The 1250m^2 area represents about 0.003% of the seagrass meadows within the Weipa region and approximately 0.13% of the meadows monitored within the Intensive Monitoring Area, based on most recent (2008 2009) data (Chartrand and Rasheed 2009; McKenna and Rasheed 2010).

As noted in **Section 6.3.4.2**, DEEDI has identified that *E. acoroides* meadows in Weipa have experienced biomass losses, which is largely a response to regional and local climate conditions, driven particularly by tidal exposure, temperature and solar irradiance. In particular, the aggregated patches *E. acoroides* bed opposite Lorim Point (monitoring meadow A2) has experienced "burning" and is considered to be vulnerable to further cumulative impacts. While DEEDI considers that *Enhalus* biomass change is driven by climatic conditions, it does not discount that other natural and anthropogenic factors may contribute, including dredging operations and vessel movements (McKenna and Rasheed 2009).

Erftemeijer and Lewis (2006) collated information regarding critical thresholds of light availability, survival duration below those thresholds, and critical annual sedimentation thresholds for a range of seagrass species around the world. Significant differences were found between species in their respective critical levels and duration tolerances. No critical light availability or survival duration information was available for *E. acroides*; however, a critical sedimentation threshold of 10cm per year was reported for *E. acroides* from an experimental burial study by Vermaat *et al.* (1997) in the Philippines.

Variation between different seagrass species in their ability to tolerate and recover from periods of reduced light is related to their differing morphological and physiological characteristics (Erftemeijer and Lewis 2006). These characteristics represent different strategies for survival in response to stress or disturbance. Smaller, short-lived species (e.g. several *Halophila* spp.) do not survive long once environmental conditions are outside their environmental tolerance; however, they tend to recolonise rapidly following an impact. Conversely, larger seagrass species, including *E. acroides*, survive longer during periods of low light due to their greater stored reserves which can be mobilised to sustain the plant. Larger species tend to be slow growing, long-lived and therefore represent a resilience strategy, being more resistant to short-term to medium-term disturbances. However, if the impact persists to the point where the seagrasses have exhausted their stored reserves, they would die and recover

slowly or not at all (Erftemeijer and Lewis 2006). This slow recovery is consistent with the slow recovery from "burning" (aerial and subaerial exposure to increased irradiance) being exhibited in the A2 *E. acoroides* dominated meadow at Weipa (refer **Section 6.3.4.2**).

At each of the barge/ferry terminal facilities in the Embley and Hey Rivers, dredging is likely to take only one to two weeks and involves only minor dredge volumes ranging from 10,700m^3 to 18,700m^3. The dredging activity proposed at Hornibrook Point and Humbug Wharf in the Embley River is located on the opposite bank to the *E. acoroides* seagrass bed (A2) previously "burned" and considered vulnerable to cumulative impacts. Any turbidity generated by the backhoe dredge operating on the northern bank of the Embley River would be unlikely to migrate over the vulnerable meadow due to the strong tidal exchange in the channel separating the banks.

Given the minor scale and short duration of dredging, it is unlikely that sediment loads would be generated over the aggregated *E. acroides* patches adjacent to the proposed infrastructure at a thickness that would approach critical levels. Further, any reduction in light levels would be short-term and the large-structured *E. acroides* would likely have sufficient stored reserves to provide resilience to the predicted low impact.

The location of the proposed barge and ferry terminals is within the intensive seagrass monitoring area monitored at least annually by DEEDI. Any impacts from the initial dredging or ongoing vessel movements should be notable within the intensive monitoring undertaken.

Movement of the ferry through the water may generate waves, which result in increased turbidity and erosion. The magnitude of the waves is related to speed, size of the ferry, depth of water, and the distance between the ferry and receptor (e.g. shoreline, seagrass).

The ferry would operate from Hornibrook Terminal to Hey River Terminal approximately four times a day, increasing to six times per day with production increases above 15Mdptpa. The average ferry speed would be 25 knots when travelling in open water, with much lower speeds when departing and arriving at dock. The deepest section of the ferry route is off Hey Point at 17m and the shallowest is at the half-way point of approximately 6m. The estuary ranges from 2,200 to 3,550m wide along the proposed ferry route.

There could be some impact to the shoreline environment from the waves created by propeller wash. However, the impact on seagrass and mangroves, as well as oyster banks and cultural heritage sites on the Hey and Embley Rivers, is anticipated to be minimal as the ferry would slow to a low speed when departing and arriving at dock, it would only operate an anticipated four to six round trips per day, and the estuary is very wide.

In addition, turbidity generation from barge and ferry movements is expected to be minor but cumulative over that from vessel movements in adjacent areas including tug and bulk carrier vessels at Hornibrook Point and supply barges at Humbug Wharf. There currently are no regular vessel movements in the vicinity of the proposed terminal in the Hey River. It is possible that background turbidity may increase locally to the barge and ferry terminal locations, possibly impacting the isolated or aggregated patches of seagrass in the immediate vicinity.

Overall, the proposed Project poses a low risk to seagrass and mangrove habitat.

6.9.3.4 Soft Sediment Habitat

It is anticipated the spoil ground would receive 3–4m thickness of dredge spoil from capital dredging, and an annual maintenance dredging load of about 0.4m, so localised smothering of sediments would be significant. Unvegetated sediments of the Gulf of Carpentaria are not considered to be sensitive marine habitats. The areas proposed to be impacted would be extremely small relative to the area of unvegetated sedimentary habitats in the region.

6.9.4 Marine Fauna Impacts

Potential impacts on marine fauna and proposed management measures are discussed below, particularly with respect to listed species identified in **Section 6.6**. In some instances no impact is identified because the range of identified impacting processes cannot plausibly result in a measurable impact. Impacts may also be beneficial (e.g. increased species richness); where applicable this is also identified. The main potential impacts are summarised in **Table 6-49.**

Consideration of threatened and migratory species under the EPBC Act occurs in discussion of faunal groups in sections below and EPBC Act Significance of Impact Assessments for threatened and migratory fauna are presented in **Section 6.9.5**.

Table 6-49 Summary of Main Potential Impacts on Marine Fauna

Fauna	Potential impact	Project phase	Project component
Dugong and cetaceans	Disturbance from boating and shipping activities including alienation from habitat. Acoustic impacts from pile driving and vessel movement. Boat strike.	Construction and operation	Proposed new spoil ground, existing Albatross Bay spoil ground, barge/ferry terminals and port facility.
Marine turtles	Altered night-time light regime. Disturbance from boating and shipping activities including alienation from habitat. Acoustic impacts from pile driving and vessel movement. Boat strike. Offshore turbidity plume. Introduction of artificial hard substrate.	Construction and operation	Proposed new spoil ground, existing Albatross Bay spoil ground and port facility.
Macrobenthic infauna assemblage	Creation of a turbidity plume from dredging activities, spoil deposition and subsequent deposition re-suspension of fine sediments. Physical disturbance.	Construction	Proposed new spoil ground, existing Albatross Bay spoil ground, barge/ferry terminals and port facility.
Fish assemblage (including sharks and rays)	Creation of a turbidity plume from dredging activities, spoil deposition and subsequent deposition re-suspension of fine sediments.	Construction and operation	Proposed new spoil ground, existing Albatross Bay spoil ground, barge/ferry terminals and port facility.
Introduced marine pest species	Shipping, through ballast water and hull fouling, is a known source of introduced pests.	Operation	Shipping and port facility.

6.9.4.1 Dugong

The following aspects of the proposed Project may affect Dugong:

- loss of foraging habitat from dredging activities;
- creation of a turbidity plume from dredging activities, and subsequent deposition and re-suspension of fine sediments;
- boat strike;
- direct impact from dredging activities;
- disturbance from boating and shipping activities including alienation from habitat; and
- acoustic impacts.

There is current scientific evidence suggesting that death and injury caused by boat strike has a significant impact on Dugong populations in Queensland (Grech and Marsh 2008). It is commonly accepted that vessel speed and water depth are the main factors affecting the risk of boat strikes. The risk of boat strike is higher in shallower water. A recent study has found that the reaction time of Dugongs does not change in accordance with the speed of an approaching vessel and therefore faster moving vessels have a greater probability of causing Dugong mortality (Hodgson and Marsh 2007).

The Project involves operating a ferry from Hornibrook Terminal to Hey River Terminal. The ferry would operate at an average speed of 25 knots in shallow water. The operation of the ferry is predicted to pose a moderate risk to Dugong in the Embley estuary where seagrass beds are present. Transit lanes would be defined to reduce the overall area of disturbance from vessel activities. Where possible, these transit lanes would follow greatest water depths to avoid significant meadows of seagrasses.

Slow moving displacement vessels such as bulk carriers, barges and tugs do not pose a boat strike risk and as such are not considered a risk in the operational phase of either the port area or in the Embley and Hey Rivers. TSHDs are similarly slow moving however in accordance with typical permit conditions for dredging and sea disposal, RTA will ensure that before beginning TSHD dredging and

dumping activities during daylight hours, a check will be undertaken, using binoculars from a high observation platform, for Dugongs (and whales) within a monitoring zone (approximately 300 metres of any point on the dredging/dumping run about to be commenced). If any Dugong (or whales) are sighted in the monitoring zone, dredging/dumping activities will not commence until after the last Dugong (or whale) is observed to leave the monitoring zone; or alternatively the dredge will to move to another area of the dredge or disposal site to maintain a minimum distance of 300 metres between the vessel and any Dugong (or whale). CSDs are essentially stationary during dredging, and so do not pose a risk to Dugong. Any injury or death of a Dugong from dredging would be documented and reported within 24 hours of the incident to DERM and DSEWPaC and further monitoring and/or management requirements discussed.

As well as direct impacts from boat strike, boating activities have been implicated in the disturbance and alienation of Dugong from their feeding habitats along the Queensland east coast (Hodgson and Marsh 2007). There is no Dugong feeding habitat in the vicinity of the proposed wharf and shipping channel, so the risk of strike by bulk carriers at the port and the risk of alienation from habitat is low. While Dugongs may move through the proposed port area when periodically migrating between feeding areas, the proposed port and port activities do not represent a barrier to migration that is likely to result in any meaningful impact on Dugong populations in the region. Overall, Project-related vessel movements are likely to have a low risk of impact on Dugongs in the vicinity of the proposed port.

Seagrass is absent from both the proposed port site and proposed new spoil ground location. Therefore Dugong foraging habitat would not be directly disturbed by port dredging and spoil disposal nor affected by turbidity plumes from port dredging. At the barge/ferry terminals, minor capital dredging is proposed. The area of seagrass to be disturbed is not significant in terms of a Dugong foraging resource (**Section 6.3.4.2**). Given the minor scale and short duration of dredging, at each of the barge/ferry terminals it is unlikely that Dugong foraging areas would be significantly affected by turbidity plumes.

Dugongs are potentially sensitive to underwater noise and construction activities, such as pile driving, have the potential to temporarily drive Dugongs from the area or cause physical damage to the auditory system or cause temporary changes in behavioural patterns (refer **Section 10.2.5**). As discussed previously, the proposed port area is not suitable Dugong habitat; as such, it is predicted that an avoidance response to underwater construction activities would pose a low risk of impact to Dugongs at this site. Seagrass beds are typically present in the lower reaches of the Embley River (refer **Section 6.3.4**), therefore, an avoidance response to construction activities in the Embley estuary pose a moderate risk of impact to Dugongs. However, pile driving would be a one-time event of short duration (approximately 15 days). Risk from physical damage to the auditory system from pile-driving activities would be minimised where possible through a "soft-start" approach and the monitoring of an exclusion zone (refer **Section 10.5**). "Soft-start" refers to the increasing of pile energy gradually over a period of time.

6.9.4.2 Cetaceans (Whales and Dolphins)

Four cetacean species are known to frequent the Project area: Indo-pacific Humpback Dolphin, inshore and offshore Bottlenose Dolphins, and Australian Snubfin Dolphin. Bryde's Whale (*Balaenoptera edeni*) inhabits inshore tropical waters, so it may occur sporadically in the vicinity of the port area, but not in the shallower estuarine areas of the Embley and Hey Rivers.

The following aspects of the proposed Project may affect dolphin and whale species in the vicinity of the Project activities:

- boat strike;
- direct impact from dredging activities;
- disturbance from boating and shipping activities including alienation from habitat; and
- acoustic impacts.

In Australia, dolphin species in particular co-exist with coastal development including extensive port facilities (Hale *et al.* 1998). The most important area for Indo-Pacific Dolphins in Moreton Bay is the Port of Brisbane (Hale *et al.* 1998). Indo-Pacific Humpback Dolphins and Australian Snubfin Dolphins are also associated with port infrastructure at Cleveland Bay, Townsville (Parra 2006). Bottlenose

Dolphins also inhabit inshore areas where significant amounts of recreational vessel and commercial water-based activities occur including Moreton Bay (Chilvers *et al.* 2005), Richmond and Clarence Rivers (NSW) (Fury and Harrison 2008), and Port Stephens and Jervis Bay (NSW) (Möller *et al.* 2002).

The potential for boat strike on whales would be similar for Dugong in the coastal waters of the Gulf of Carpentaria given their size and similar mobility. Whales do not inhabit the estuarine areas of the Embley and Hey Rivers. The slow moving displacement vessels that would operate in the proposed port area do not pose a boat strike risk to whales.

As indicated for Dugong in **Section 6.9.4.1**, despite TSHDs being slow moving displacement vessels, visual checking would be undertaken during daylight hours for whales in an approximately 300m monitoring zone, and if they were present, the dredging location would be changed or operations suspended until after the last whale has left the monitoring zone. CSDs are essentially stationary during dredging, and so do not pose a risk to cetaceans. Any injury or death of a cetacean from dredging would be documented and reported within 24 hours of the incident to DERM and DSEWPaC and further monitoring and/or management requirements discussed.

The potential for boat strike on dolphins would be less than for Dugongs and whales overall due to their greater mobility and ability to quicker response to disturbances. The slow moving displacement vessels operating in the proposed port area and Embley and Hey Rivers do not pose a risk to dolphins. The ferry that would operate in the Embley and Hey Rivers presents a low risk compared to the moderate risk for Dugong on the basis that dolphins are more agile and able to better react to and avoid approaching vessels. Following from this low risk of boat strike, the potential for disturbance from boating and shipping activities and possible alienation from habitat is considered minor, particularly given preferred pelagic foraging habitats are not located in the Embley and Hey Rivers where the ferry would provide transportation services.

A number of human-caused marine noises can be highly intensive and detectable at ranges of several kilometres (Gordon and Moscrop 1996). Cetaceans have been found to avoid some human sound sources for ranges of several kilometres, abandoning valuable habitat in the process (Tyack 2008).

Jefferson *et al.* (2009) identified that Indo-Pacific Dolphins avoid areas during pile driving but return once construction ceases. Such short-term responses by dolphins to pile driving and other construction activities are expected from the proposed Project, but no significant long-term impacts are predicted. While no significant impacts are expected, risk of acoustic impacts from pile-driving activities would be minimised where possible through a "soft-start" approach and the monitoring of an exclusion zone (refer **Section 10.5**).

6.9.4.3 Marine Turtles

The primary factor currently impacting sea turtle nesting success at the proposed Port site is predation by feral pigs (refer **Section 6.6.5**). The intensity of nest disturbance by feral pigs is very high, particularly at Boyd Point immediately to the north of the proposed port area where there are no cliffs impeding beach access.

The following aspects of the Project may affect marine turtles:

- altered above-water, night-time light regime;
- boat strike;
- disturbance from boating and shipping activities including alienation from habitat;
- direct impact from suction dredging activities;
- creation of a turbidity plume from dredging activities, and subsequent deposition and re-suspension of fine sediments on feeding habitats;
- introduction of hard substrate (e.g. piles); and
- acoustic impacts from pile driving activities on turtles.

These factors are discussed below in terms of management.

Altered Above-Water Night-Time Light Regime

Altered above-water night-time light regime can affect nesting adult female turtles and hatchlings (refer **Section 6.6.5**). Design and operational guidelines for mitigating lighting impact on turtle

hatchings associated with coastal development have been developed (Witherington and Martin 1996). These guidelines are designed more for residential developments and roads than the proposed development type, but some general principles are relevant and would be utilised where applicable for the proposed port. Australian examples exist where the impacts of artificial lighting on turtles have been mitigated in part. At Thevnard Island (North West Shelf) light impacts were mitigated from offshore petroleum production by minor shielding, re-positioning and, in some cases, time-switching of the lights. It is difficult, however, to mitigate the impacts of a changed lighting regime in its entirety. A lighting plan for the port is considered an important part of both construction and operation environmental management. Turtle sensitive lighting approaches would also need to consider safety requirements, navigation requirements and the need to minimise light spill on turtle sensitive areas. A lighting plan has been developed with consideration of the following:

- ensuring lighting is minimised overall to that which is essential for safe and efficient operation of the facility;
- ensuring non-essential lighting will be switched off or dimmed when there are no ships at berth or being piloted in the area;
- shielding and/or recessing of lights to minimise light spill;
- installation of long wavelength lights; and
- any other lighting options that further reduce impacts to marine turtles while allowing for the safe and efficient operation of the port facility.

The lighting plan is detailed in **Table 6-50**. RTA proposes an adaptive approach to work with the Traditional Owners and DERM to minimise the impacts of changes to the light regime during both the construction and operation phases of the proposed port on marine turtles, while still allowing a safe working environment. An altered above-water night-time light regime without mitigation is anticipated to cause the largest single potential threat to marine turtles. In addition to the lighting plan, a feral pig control program would be implemented between Pera Head and Boyd Point to reduce nest predation and enhance turtle population survivorship. It is considered that this measure would produce an overall increase in hatchling numbers and therefore there would not be an overall significant adverse impact on threatened marine turtles.

Boat Strike, Boating, Shipping Disturbance and Habitat Alienation

There is the possibility of impacts on marine turtles from both boat strike from fast moving vessels and alienation from habitat by boating activity. These impacts are relevant primarily at the proposed port site. The barge/ferry terminals are not in areas that have habitat likely to be frequently utilised by marine turtles. Therefore the operation of the ferry is predicted to pose a low risk.

Review of the Queensland Marine Wildlife Stranding and Mortality Database annual reports from 1999-2004 (most recent), does not indicate that there are any significant number of dead turtles with boat strike markings from the Weipa or Western Cape York region. Most incidences are from Moreton Bay and Townsville. This situation is unlikely to change as a result of Project construction or operation.

Unlike the Dugong, there is no available information to demonstrate that boating activity alienates marine turtles from their habitat although this cannot be discounted. Marine turtles are known to co-exist in areas with very high levels of boating activity (e.g. southern bay islands of Moreton Bay).

Direct Impact from Dredging Activities

The use of self propelled trailing suction hopper dredgers has the potential to entrain marine turtles during dredging activities. The use of turtle exclusion devices on the suction heads is now standard equipment on such dredgers and minimises the potential for entrainment. Any TSHD contracted for the port area dredging (and future maintenance dredging) would be required to have turtle exclusion devices fitted. Entrainment by cutter suction dredges is less likely due to the slow rate of progress of dredging. Bucket type dredges, such as those potentially used for Embley and Hey River dredging activities, do not pose an entrainment hazard to turtles. Any injury or death of a turtle from dredging would be documented and reported within 24 hours of the incident to DERM and DSEWPaC and further management requirements discussed.

Table 6-50 Lighting Plan

Facility	Description	Mitigation measures
Phase: Design		
Shiploader	Only in use when shiploading. Only equipment would be lit. Lighting required to enable worker to enter cabin. When in use light would be required for conveyor belts, transfer shoots and discharge point to hull. Shiploader height about 8–10m above top of wharf level.	• Long wave length lighting (low pressure sodium or equivalent) • Turn off unnecessary lights when not in use and minimise usage to that required for safe operation
Wharf deck	Light access walkway and conveyor bends as needed	• Long wave length lighting (low pressure sodium or equivalent) • Turn off unnecessary lights when not in use and minimise usage to that required for safe operation • Shielding, height (keep low) and direction to minimise light spill
Jetty	Light access walkway and roadway as needed	• Long wave length lighting (low pressure sodium or equivalent) • Turn off unnecessary lights when not in use and minimise usage to that required for safe operation • Shielding, height (keep low) and direction to minimise light spill
Dolphin walkway	Light access walkway as needed	• Long wave length lighting (low pressure sodium or equivalent • Turn off unnecessary lights when not in use and minimise usage to that required for safe operation • Shielding, height (keep low) and direction to minimise light spill
Tug berth	Light access berth and walkways as needed	• Long wave length lighting (low pressure sodium or equivalent) • Turn off unnecessary lights when not in use and minimise usage to that required for safe operation • Shielding, height (keep low) and direction to minimise light spill
Tug boat	Required for safe movement around deck of tug	• Limit usage to that required for safe operation
Bulk carrier (decks)	Required for safe movement around deck of bulk carrier	• Limit usage to that required for safe operation
Navigation lights	Must meet the requirements of Queensland Transport; however RTA would work to implement mitigation measures wherever possible	• Flashing lights
Emergency lighting throughout wharf / tug berth area	Only used as needed	• Turn off unnecessary lights when not in use and minimise usage to that required for safe operation
Stockpile area	No lighting required, machine (stacker/reclaimer) would be sufficient	• No tower flood lighting (stacker/reclaimer mounted lights are sufficient)
Stacker/reclaimer	Stacker would operate continuously – machinery to be lit. Reclaimer would operate when ship loading – machinery to be lit	• Long wave length lighting (low pressure sodium or equivalent) Turn off unnecessary lights when not in use and minimise usage to that required for safe operation • Shielding, height (keep low) and direction to minimise light spill • Vegetation buffer of *Eucalyptus tetradonta* forests estimated at 25–30m high at 200m width (between stacker/reclaimer and port)
Beneficiation plant	Operate continuously – machinery and work area to be lit	• Shielding, height (keep low) and direction to minimise light spill • Vegetation buffer of *Eucalyptus tetradonta* forests estimated at 25–30m high at over 200m width (between beneficiation plant and port)
Phase: Construction and Operation		
All	Administrative controls to minimise the potential for impact	• Standard ground clearing management procedures to retain vegetation buffer • Training workforce regarding potential impacts and management measures • Limit access to beach areas • Standard incident reporting procedure for sea turtle incidents, hazards or near misses • Lighting requirements as per design would be maintained • Reactive monitoring for deposition and light

Note: Embley River and Hey River are not nesting areas for turtles, so lighting impacts from barge/ferry terminals is not a potential impact.

Turbid Plume Generation and Sediment Deposition/Re-suspension on Feeding Habitat

The creation of a turbidity plume from dredging activities, and subsequent deposition and re-suspension of fine sediments, can potentially impact foraging habitat of marine turtles. The diverse reef assemblages provide a food source for marine turtles, particularly Hawksbill Turtles which prefer sponges, seagrass and algae. Approximately 71ha of sponge/soft coral habitat occurs between Boyd Point and Pera Head (inclusive) (refer **Section 6.3.2**). It is predicted that sediment deposition would be at its greatest between these two locations (refer **Section 6.9.2.5**) and may locally affect feeding preferences in marine turtles. It is estimated that 117ha of similar habitat occurs between Pera Head and Thud Point (refer **Section 6.3.2**), with more likely to occur at inshore reef areas south of Thud Point and north of Boyd Point, so regional impacts to feeding habitats are not predicted.

At the barge/ferry terminals in the Embley and Hey Rivers, minor capital dredging is proposed. The area of seagrass to be disturbed is not significant in terms of a marine turtle foraging resource (**Section 6.3.4.2**). Given the minor scale and short duration of dredging at each of the barge/ferry terminals it is unlikely marine turtle foraging areas would be significantly affected by turbidity plumes from barge/ferry terminal dredging. The overall risk to marine turtles from restriction of food availability then is low.

Introduction of Hard Substrate

The width of the jetty structure that crosses the beach would be 10.9m which is a very small proportion of the beach length (5.81km between Boyd Point and Pera Head). Once the jetty is constructed, turtles would still have access to the area under the jetty, except where the foundations for the two piles on the beach (81m^2 each) are located. Therefore the impact from the construction and operation of the jetty related to removal of habitat for nesting of turtles is considered minor. Bell (2003) also identifies that marine turtles co-exist with port infrastructure, with green and flatback turtles nesting within port limits of Lucinda and Abbot Point.

The introduction of hard surfaces such as jetty pilings would provide a long-term surface upon which a range of sessile flora and fauna may establish and present local feeding opportunities to turtle species, particularly those that prefer reef-type foraging habitats. Sessile organisms likely to establish include solitary and colonial ascidians, sponges, soft corals and macroalgae, which present possible food sources for Hawksbill and Flatback Turtles.

Establishment of sessile organisms on the artificial surfaces is likely to take several years and experience successional development of different assemblages over time, beginning with a few pioneering species before increasing in complexity. While this may provide local benefits in the long-term it would not compensate for localised reduction in food resources over the reef areas in the short to medium term during port development capital dredging.

Acoustic Impacts from Pile Driving Activities on Turtles

There is limited data on the potential underwater noise impacts to marine turtles from pile driving activities, however SVT (2009) conducted underwater noise modelling and assessment for pile driving activities proposed for the Cape Lambert Port B Development in Western Australia. The following conclusions were made regarding marine turtles:

- physical injury would be likely to occur at peak pressure levels greater than 222dB re 1µPa at a sound exposure level (SEL) of 198dB re 1µPa^{2}s;
- hearing damage may occur at peak pressure levels greater than 222dB re 1µPa;
- avoidance behaviour was estimated to occur at peak pressure levels greater than 120dB re 1µPa based on the auditory bandwidth of turtles; and
- there is no supporting literature to establish acceptable levels of continuous noise to prevent threshold shift in marine turtles.

While no significant impacts associated with pile driving activities on marine turtles are expected, the risk of underwater acoustic impacts from pile-driving activities would be minimised where possible through a "soft-start" approach and the monitoring of an exclusion zone as discussed below.

Management Measures

RTA is committed to working with the DERM to reduce threats to marine turtles, particularly in the proposed port area, and assist with marine turtle research programs. RTA has placed sand temperature loggers near Boyd Point as part of a DERM research project to examine the potential impacts of climate change on marine turtle populations. RTA would document any strandings of marine turtles (e.g. animals entangled in ghost nets) and report these to DERM for inclusion in the Wildlife Stranding and Mortality Database and would remove ghost nets in the vicinity of the proposed port development.

RTA would work with Traditional Owners and DERM to develop and implement measures to reduce feral pig numbers in the Pera Head to Boyd Point area. Currently feral pigs are the primary factor reducing the success of sea turtle reproduction (hatchling emergence). The Recovery Plan for Marine Turtles in Australia (Commonwealth of Australia, 2003) identifies the major significance of predation by pigs on turtle nests. Data from some similar programs is provided below to indicate the success a feral pig control program can have on reducing predation on turtle nests and increasing the chances of hatchling survival.

Based on observations, NPWS and DPI (2003) states that if feral pig predation continues and remedial action is not taken, nesting by sea turtles in the Western Cape will cease by 2030. This report also notes that, on average, 90% of marine turtle nests that have been observed in the area have had some form of disturbance by feral pigs.

GHD (2007b) notes that of the 15 nests observed, 10 of these nests showed evidence of predation by feral pigs.

Bell (2003) notes that of the 236 nests observed between Aurukun and Marpoon (to the south and north of the proposed port area), there was evidence of predation by feral pigs in most nests.

Bell *et al* (2004) shows that all nests that were protected by Feral Pig Control Devices had not been subject to predation, while the majority of nests that were not protected by the devices showed evidence of predation by feral pigs.

The Cape York Weeds and Feral Animal Control Program's marine turtle conservation program has managed to eradicate approximately 28,000 feral pigs in areas of Cape York since June 2006. This has resulted in predation levels on turtle nests dropping to 30% from 90% (67% reduction) prior to the commencement of the program. This has also resulted in a significant increase in the amount of turtle hatchlings reaching the water. The program has included beach areas north and south of the Project area, but not beaches within the Project area itself.

The above evidence suggests that feral pig control programs would provide a significant benefit to the marine turtle population's breeding success that use the beaches within the Project area for nesting.

A review of the Queensland Marine Wildlife Stranding and Mortality Database annual reports from 1999-2004 (most recent), indicates that, on average, 11-15% of all turtles found dead had evidence of boat strike markings. Extrapolation for the Western Cape during this period indicates that on average 1-2 dead turtles per year would be attributed to boat strike.

The 2008 EIS turtle nesting survey (carried out over 3 days) reported predation of 5 nests. Limpus (2007) reports that Flatback Turtle nests on Crab Island contain approximately 55 eggs, and Limpus presents data showing that of those eggs not subject to predation, there is relatively high emergence (85.8%) and low mortality on the beach (14%). A 67% reduction in predation would result in 135 additional turtle hatchlings expected to have made it to the water from these 5 nests. This is therefore expected to result in a net benefit to the turtle population as the increase in hatchling emergence (135 per 5 nests) would far outweigh the potential incidence of boat strike on turtles (1-2 per annum) within the vicinity of the Project.

RTA would work with DERM to evaluate whether relocating nests is appropriate. A monitoring program would be developed in conjunction with Traditional Owners and DERM with consideration of turtle nesting activities (number, type, predation, success), behaviour (hatchling activity) and incident reporting.

To minimise the potential underwater noise impacts on marine turtles during pile driving activities, it is proposed that a "soft start" approach be used to disperse marine fauna (including marine turtles) in the vicinity of these activities prior to normal pile driving. The "soft start" involves commencing pile

driving with a partial capacity strike, or giving a warning with an underwater airgun prior to normal pile driving. It is proposed that an exclusion zone surrounding pile driving activities be established and monitored by an observer prior to normal pile driving commencing and during normal pile driving. Normal pile driving activities would not commence or be temporarily suspended if marine turtles or other threatened marine fauna are observed within the exclusion zone. Normal pile driving activities would not recommence until marine turtles or other threatened marine fauna are considered to be outside the exclusion zone. The extent of the exclusion zone would be defined based on further literature review and quantitative analysis of the potential underwater noise impacts from pile driving relating to marine turtles or other threatened marine fauna. The final extent of the exclusion zone would be defined in consultation with DSEWPaC.

6.9.4.4 Macrobenthic Infauna

Macrobenthic infaunal assemblages are temporally and spatially highly variable at several different scales. Macrobenthic infaunal assemblages are likely to be affected at the site of the proposed port facility, new spoil ground, the barge/ferry terminals and the Albatross Bay spoil ground. Dredging and spoil deposition has impacts as a result of:

- physical disturbance of sedimentary habitats and fauna from dredging; and
- creation of a turbidity plume, and subsequent deposition and re-suspension of fine sediments.

As identified in **Section 6.9.3.4**, there would be deposition of 3–4m over the spoil ground during capital dredging and approximately 0.4m during ongoing annual maintenance dredging. Despite the potentially significant local impact on the infauna assemblage through smothering during capital dredging spoil disposal, physical disturbance of the dredge sites, deposition of spoil, and the re-suspension of disturbed and deposited sediment poses a low risk on a regional scale.

Macrobenthic infaunal assemblages can recover over time from the impacts of dredging and spoil disposal. Recovery of the macrobenthic assemblage from spoil deposition at the current Weipa spoil ground in Albatross Bay is considered to be rapid (GHD 2005). Macrobenthic infaunal assemblages in the region are exposed to periodic but significant physical disturbance and elevated turbidity occurring during extreme weather events.

Monitoring of infauna is proposed be undertaken at the new spoil ground location following capital dredging and at the proposed port to identify the extent of smothering impact, spoil migration and recovery over time. Collection of infauna was undertaken in June 2010 from 15 sites within and adjacent to the proposed new spoil ground. Identification and enumeration of these samples would provide a baseline for post-dredging impact assessment.

The spatial survey design is represented in **Figure 6-66** and is based on the bulk of the disposed material remaining within the proposed spoil ground, with a primary impact zone constrained to within the spoil ground boundary (i.e. 0.5nm radius). Sample collection would occur at the following locations:

- Four samples from each of five sites within the spoil ground (centre (SG1), north (SG2), west (SG3), south (SG4), east (SG5));
- Four samples from each of five sites with distance 125m (E1), 250m (E2), 500m (E3), 1000m (E4), 2000m (E5) on an easterly axis from the boundary of the spoil ground. This axis acts as a reference area, being perpendicular to the direction of plume travel;
- Four samples from each of five sites with distance 125m (S1), 250m (S2), 500m (S3), 1000m (S4), 2000m (S5), on a southerly axis from the boundary of the spoil ground approximately in line with the direction of current (and hence plume) travel;

Samples are collected using a grab deployed from a boat. Samples would be sieved using a 1mm mesh sieve and the retained infauna material, preserved, identified and enumerated. One sediment sample per site would be analysed for particle size distribution (to 63µm) as this can have a major influence on benthic community composition. Univariate and multivariate statistical techniques would be used to test for temporal and spatial differences in abundance, diversity and infauna assemblage composition.

This sampling design has been used successfully in spoil monitoring programs at the Ports of Bundaberg and Cairns. The design is based on monitoring programs commonly undertaken in relation

to monitoring of offshore oil and gas wells. The design has previously been reviewed and approved for use in the context of spoil ground monitoring by the DSEWPaC (then DEWHA) in 2004 (in relation to monitoring at the Port of Bundaberg spoil ground). It has been proven to be effective in identifying impacts within and outside spoil grounds.

Monitoring is also proposed for the ongoing maintenance dredging campaigns at a frequency of five years, consistent with that required for long-term maintenance dredging for the Port of Weipa.

Monitoring at the Albatross Bay spoil ground is not proposed due to the minor dredge volumes involved, particularly in comparison to far larger volumes disposed there regularly from routine maintenance dredging of the Port of Weipa.

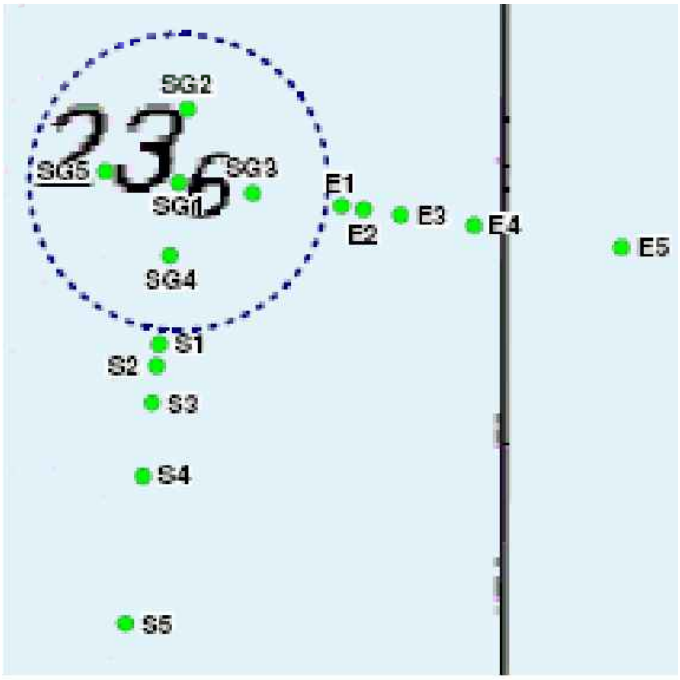

Figure 6-66 Infauna monitoring locations at the proposed offshore spoil ground

6.9.4.5 Fish Assemblages (including sharks and rays)

Fish assemblages may be affected by:

- introduction of hard artificial substrata (e.g. piles) into the marine environment;
- physical disturbance of sedimentary habitats and fauna from dredging and from construction of infrastructure; and
- creation of a turbidity plume, spoil deposition and re-suspension of fine sediments.

It is well documented that the introduction of piles and other port structures act as de-facto artificial reefs that attract many species of fish and this generally leads to an increased species richness and abundance of the fish assemblage at the local scale (Clynick *et al*. 2008). At the proposed port location, species richness and overall abundance of the fish assemblage is predicted to increase in response to the addition of piles. The addition of hard artificial substrata may also result in impacts of minor magnitude on the structure of fish assemblages. That said, the predicted impact on the fish assemblage, namely increased abundance and species richness, is generally considered by the public as beneficial and the science of artificial reefs is predicated on it.

The fish assemblage is exposed to periodic but significant physical disturbance and elevated turbidity during extreme weather events. Fish species are also mobile and as such can move away from any local areas that are affected by a disturbance (e.g. dredging and dredge spoil deposition). Physical disturbance to the dredged site, deposition of spoil, and the re-suspension of disturbed and deposited

sediment probably would have impacts of minor magnitude at the proposed port facility, the proposed new spoil ground, and the barge/ferry terminals.

Information relating to potential impact on fish assemblages in estuarine areas is provided in **Sections 8.14 to 8.17** and **Appendix 8C**.

The projected change in population (refer **Table 16-3**) is not predicted to increase recreational fishing activity in the area significantly. The projected population of Weipa would decrease from the 2007/08 population during the 15Mdptpa and 30Mdptpa scenarios. Recreational fishing activity as a result of the Project is therefore expected not to increase from levels in recent years. If the Project expands to 50Mdptpa (subject to market demand), then the population of Weipa is only projected rise approximately 400 (10%) above the peak of the 2007-2008 population. This increase at 50Mdptpa would be unlikely to significantly increase recreational fishing activity in the area or subsequently the impact of recreational fishing impacts on fish assemblages, including sawfish and shark species.

The Project is predicted to pose a low risk to sharks and rays, including sawfishes, and a low risk to bony fishes.

6.9.4.6 Introduced Marine Pests

It is likely that construction dredging for the port area would require the services of internationally sourced dredgers. RTA proposes to manage the potential for introduced marine pest incursions from this source based on a risk-based approach. Initially, this would be based on a review of the ships work and maintenance history. Where operations or duration since last maintenance period are extended or the information not provided, certification from the dredging contractor by way of hull inspection clearance would be requested. Clearance of the vessel for fouling prior to its mobilisation to Australia would be considered as an item for contract, including diver or dry dock inspection. This approach is consistent with the biofouling risk assessment framework outlined within the *National Biofouling Guidance for Non-trading Vessels* (Commonwealth of Australia 2008). Detail of the proposed management and monitoring measures will be provided in the Dredge Management Plan.

The risk of marine pest introduction from vessels during operations is likely to be similar to the current risks associated with port operations at the Port of Weipa because vessel activity associated with bauxite export would merely shift over time from the Port of Weipa to the Project port area. Currently approximately 20% of exports from Weipa are destined for China, Korea and Japan. The Project port would operate in similar export proportions and destinations to that of the current Port of Weipa.

Under the DSEWPaC-approved Port of Weipa Long Term Environment Management Plan for Dredging and Dumping Activities (SKM 2009a), the Port of Weipa is considered a low risk port for marine pests and hence there is currently no requirement to undertake a comprehensive marine pest survey of the port. However, consistent with the low risk rating, limited routine monitoring is undertaken at the Port of Weipa. Larval monitoring plates are deployed at three sites (Evans Landing, and Lorim Point Wharf east and west). These traps are retrieved and checked every three months and no pest species have been identified to date.

RTA proposes to deploy similar larval plates at two locations along the Project jetty. They would be retrieved and checked for introduced marine pest larvae every three months.

In the event of a pest incursion during either dredging or operations, RTA would advise Biosecurity Queensland immediately and work with them in planning and implementing a response. The nature of the response would be determined largely by the type of organism and its lifecycle, substrate affected and extent of incursion.

6.9.5 Summary of EPBC Act "Significance of Impact" Assessments for Threatened and Migratory Fauna

The summary "assessments of significance of impact" in this section are based on the *Significant impact guidelines* (DEWHA 2009a) and draws on discussion provided in **Section 6.9.4**.

6.9.5.1 Threatened Marine Fauna

Individual significant impact assessments are provided below for each of the EPBC Act listed threatened marine fauna species assessed as *likely* or *known to occur* in the Project area as identified in **Section 6.6.1**.

These include:

- Endangered species
    - Leatherback Turtle (*Dermochelys coriacea*)
    - Loggerhead Turtle (*Caretta caretta*)
    - Olive Ridley Turtle (*Lepidochelys olivacea*)
- Vulnerable species
    - Hawksbill Turtle (*Eretmochelys imbricata*)
    - Flatback Turtle (*Natator depressus*)
    - Green Turtle (*Chelonia mydas*)
    - Green Sawfish (*Pristis zijsron*);
    - Dwarf Sawfish (*Pristis clavata*).

Key definitions from the DSEWPaC guidelines that apply to this assessment are as follows:

- "Population of a species" is an occurrence of the species in a particular area. In relation to critically endangered, endangered or vulnerable threatened species, occurrences include but are not limited to:
    - a geographically distinct regional population, or collection of local populations; or
    - a population, or collection of local populations, that occurs within a particular bioregion.
- "Habitat critical to the survival of a species or ecological community" refers to areas that are necessary:
    - for activities such as foraging, breeding, roosting, or dispersal;
    - for the long-term maintenance of the species or ecological community;
    - to maintain genetic diversity and long-term evolutionary development; or
    - for the reintroduction of populations or recovery of the species or ecological community.

  Such habitat may be, but is not limited to:
    - habitat identified in a recovery plan for the species or ecological community as habitat critical for that species or ecological community; and/or
    - habitat listed on the Register of Critical Habitat maintained by the Minister under the EPBC Act.
- An "invasive species" is an introduced species, including an introduced (translocated) native species, which out-competes native species for space and resources or which is a predator of native species. Introducing an invasive species into an area may result in that species becoming established. An invasive species may harm listed threatened species or ecological communities by direct competition, modification of habitat or predation.

Leatherback Turtle (*Dermochelys coriacea*): Endangered

The Leatherback Turtle is a pelagic feeder, found in tropical, subtropical and temperate waters throughout the world. In the vicinity of the Project area, Albatross Bay is identified as a potential foraging area for the species. They principally feed upon soft bodied invertebrates such as colonial ascidians and jellyfish. Leatherback Turtles are considered likely to occur in the Project area, potentially using it for foraging. They are rarely found in Queensland and have not been recorded to have nested in eastern Australia since 1996.

The best available data for population size at a global level are the numbers of adult females that breed in particular years. According to the DSEWPaC (2010) SPRAT database, the most recent estimate, in 2004, was that 35,800 females bred that year. There is insufficient data to determine whether the Australian population is distinct, geographically separate or whether it moves in/out of Australia's jurisdiction. The Leatherback Turtle is the most pelagic of all marine turtles, spending much

time in the open ocean, with individuals traversing thousands of kilometres, so it is likely that the population is continuous within Australia.

Given the rarity of this species in Queensland waters and the large home ranges they may have, the Project area is not considered to be of particular importance to this species. The Project area is not considered to contain an important population, geographically distinct regional population or local population that occurs within a particular bioregion.

Will the proposed works ...	**Leatherback Turtle (*Dermochelys coriacea*)**
... lead to a long-term decrease in the size of a population?	It is unlikely that this species utilizes Project area beaches for nesting since the leatherback turtle has not been recorded nesting in eastern Australia since 1996 and they are rarely found in Queensland. The impacting processes are not of a sufficient scale or magnitude to lead to a long-term decrease in the size of a population, particularly where their occurrence is normally rare.
... reduce the area of occupancy of the species?	Globally, the Leatherback Turtle occupies a broad latitudinal range, from tropical to sub-tropical waters. The Project would not reduce the area of occupancy of the leatherback turtle in any ecologically meaningful way.
... fragment an existing population into two or more populations?	The Project development and operation would not create any barriers to movement for Leatherback Turtles.
... adversely affect habitat critical to the survival of a species?	While some feeding habitat would be disturbed as a result of proposed dredging of the port area, suitable feeding habitats are found throughout coastal areas of the Gulf of Carpentaria. The constructed jetty would provide a surface for potential food sources (e.g. ascidians) to grow.
... disrupt the breeding cycle of a population?	Nesting is not known to occur in the vicinity of the Project area, so no disruption to the breeding cycle would result.
... modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	While habitat would be disturbed as a result of dredging of the port area, the impact is not of a sufficient scale to affect the survival of any marine turtle species.
... result in invasive species that are harmful to an endangered species becoming established in the endangered species' habitat?	It is considered unlikely that an invasive species that is harmful to Leatherback Turtles would be introduced due to the development or operation of the Project marine infrastructure.
... introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is considered unlikely that a disease harmful to the Leatherback Turtle would be introduced due to the development or operation of the Project marine infrastructure.
... interfere with the recovery of the species?	There is a recovery plan in place for all marine turtle species found in Australia. Use of turtle deflectors on suction hopper dredgers would minimise potential for entrainment of turtles during development and maintenance dredging for the port area. The Project is not expected to interfere with the recovery of the species.

Loggerhead Turtle (*Caretta caretta*): Endangered

The Loggerhead Turtle has a global distribution throughout tropical, sub-tropical and temperate waters with nesting mainly concentrated on sub-tropical beaches. In Queensland nesting is concentrated in the south-east, particularly along the Bundaberg coast. It prefers a range of habitats including subtidal and intertidal reefs, seagrass meadows and soft-bottomed habitats. It has a diverse diet but typical food items include crabs and bivalve and gastropod molluscs.

Surveys have found no nests in the Project area. It is considered likely that this species would be transient in the Project area, using it for foraging or resting, but highly unlikely for nesting.

There are no concise estimates of global population or annual nesting female numbers for the Loggerhead Turtle. The Loggerhead Turtle is considered to comprise of two distinct genetic stocks in Australia—the eastern Australian genetic stock and the western Australian genetic stock. The DSEWPaC (2010) SPRAT Database identifies that in 2000 it was estimated that there were 500 nesting females per year in the eastern Australian stock. Adult females comprise approximately 20% of the population.

Loggerhead Turtles occurring in the vicinity of the Project area are not considered to constitute an important population, geographically distinct regional population or local population that occurs within a particular bioregion.

Will the proposed works ...	Loggerhead Turtle (*Caretta caretta*)
... lead to a long-term decrease in the size of a population?	The impacting processes are not of a sufficient scale or magnitude to lead to a long-term decrease in the size of a population, particularly in an area where individuals would be transient.
... reduce the area of occupancy of the species?	Globally, the Loggerhead Turtle is a circum-tropical species. The Project would not reduce the area of occupancy of the Loggerhead Turtle in any ecologically meaningful way.
... fragment an existing population into two or more populations?	The Project development and operation would not create any barriers to movement for Loggerhead Turtles.
... adversely affect habitat critical to the survival of a species?	While some feeding habitat would be disturbed as a result of proposed dredging of the port area, suitable feeding habitats are found throughout coastal areas of the Gulf of Carpentaria.
... disrupt the breeding cycle of a population?	Nesting is not known to occur in the vicinity of the Project area, being centred principally in Queensland's south-east. No disruption to breeding cycles would occur.
... modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	While habitat would be disturbed as a result of dredging of the port area, the impact is not of a sufficient scale to affect the survival of any marine turtle species.
... result in invasive species that are harmful to an endangered species becoming established in the endangered species' habitat?	It is considered unlikely that an invasive species that is harmful to Loggerhead Turtles would be introduced due to the development or operation of the Project marine infrastructure.
... introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is considered unlikely that a disease harmful to the Loggerhead Turtle would be introduced due to the development or operation of the Project marine infrastructure.
... interfere with the recovery of the species?	There is a recovery plan in place for all marine turtle species found in Australia. Use of turtle deflectors on suction hopper dredgers would minimise potential for entrainment of turtles during development and maintenance dredging for the port area. The Project is not expected to interfere with the recovery of the species.

Olive Ridley Turtle (*Lepidochelys olivacea*): Endangered

The Olive Ridley Turtle nests throughout tropic waters and migrates through tropical and sub-tropical areas of the world. They generally inhabit shallow unvegetated coastal waters where they feed on gastropod molluscs and crabs

The Olive Ridley Turtle is the most numerous of all marine turtles in the world largely due to major global nesting areas occur in Pacific Costa Rica and Pacific Mexico. The DSEWPaC (2010) SPRAT database identifies studies that estimate global annual nesting populations to be 852,000 and 2,000,000. Detailed information on the size of nesting and foraging populations in Australia is unknown although the nesting population is expected to be in the order of a few thousand. Low density nesting has been historically recorded from a number of locations including the eastern Gulf of Carpentaria; however, there is some uncertainty whether nesting still occurs on Western Cape York.

Olive Ridley Turtles occurring in the vicinity of the Project area are not considered to constitute an important population, geographically distinct regional population or local population that occurs within a particular bioregion.

Will the proposed works ...	Olive Ridley Turtle (*Lepidochelys olivacea*)
... lead to a long-term decrease in the size of a population?	The Project aspects with the greatest potential for long-term impact and decrease in local Olive Ridley Turtle activity are dredging and onshore lighting (assuming turtle nesting continues to occur on western Cape York and in the vicinity of the proposed port). The use of turtle deflectors on trailing suction hopper dredgers and implementation of a lighting plan would minimise the risk of any long-term population decline. Implementation of a lighting plan would minimise long-term impacts from hatchling disorientation. Population survivorship would be enhanced through ghost-net removal and reducing feral pig numbers which currently cause major reductions in egg and hatchling survivorship. The impacting processes are not of a sufficient scale or magnitude to lead to a long-term decrease in the population size of this species.
... reduce the area of occupancy of the species?	The Project development and operation would not reduce the area of occupancy of the Olive Ridley Turtle in any ecologically meaningful way.
... fragment an existing population into two or more populations?	The Project development and operation would not create any barriers to movement for Olive Ridley Turtles or fragment an existing population.
... adversely affect habitat critical to the survival of a species?	While some local feeding habitat would be disturbed as a result of dredging of the proposed port area, suitable feeding habitats are found throughout coastal areas of the Gulf of Carpentaria.
... disrupt the breeding cycle of a population?	There is uncertainty whether Olive Ridley nesting continues to occur on western Cape York. Implementation of a lighting plan would minimise above-water lighting disorientation to hatchlings and impacts to local breeding success, should nesting still occur in the Project area. Hatchling survivorship would be enhanced through reduction in feral pig numbers in the vicinity of the proposed port development.
... modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	While habitat would be disturbed as a result of dredging of the port area, the impact is not of a sufficient scale to affect the survival of any marine turtle species.
... result in invasive species that are harmful to an endangered species becoming established in the endangered species' habitat?	It is considered unlikely that an invasive species that is harmful to Olive Ridley Turtles would be introduced due to the development or operation of the Project marine infrastructure.
... introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is considered unlikely that a disease harmful to the Olive Ridley Turtle would be introduced due to the development or operation of the Project marine infrastructure.
... interfere with the recovery of the species?	There is a recovery plan in place for all marine turtle species found in Australia. Use of turtle deflectors on trailing suction hopper dredgers would minimise potential for entrainment of turtles during development and maintenance dredging for the port area. Implementation of a lighting plan would minimise the risks of local breeding impacts from hatchling disorientation. Recovery of turtle species occurring in the area would be enhanced through removal of ghost netting on beaches in the vicinity of the port development and reduction of feral pig numbers. The Project is not expected to interfere with the recovery of the species.

Hawksbill Turtle (*Eretmochelys imbricata*): Vulnerable

Hawksbill Turtles are found in tropical, subtropical and temperate waters in all the oceans of the world. Nesting is mainly confined to tropical beaches. There are no concise estimates of global Hawksbill Turtle population numbers; however, Australia holds the largest breeding populations of Hawksbill Turtles in the world. There are two genetically separate subpopulations: one in the northern Great Barrier Reef, Torres Strait and Arnhem Land (north-eastern subpopulation); and the other on the North West Shelf of Western Australia (north-western subpopulation). The SPRAT database identifies that 'several thousand' females nest in Queensland each year.

For the north-eastern subpopulation, the northern Great Barrier Reef, and particularly Milman Island and the inner Great Barrier Reef Cays north from Cape Grenville, are considered to be important foraging grounds and juvenile habitat. The preferred foraging habitat of the Hawksbill Turtle is rocky and coral reefs where preferred food items include algae, seagrass and sponges.

Low density nesting is recorded from a number of locations from False Pera Head to Boyd Bay in the vicinity of the port development area. Reef habitat is likely to provide significant local foraging habitat.

Hawksbill Turtles occurring in the vicinity of the Project area are not considered to constitute an important population, geographically distinct regional population, or local population that occurs within a particular bioregion.

Will the proposed works...	Hawksbill Turtle (*Eretmochelys imbricata*)
... lead to a long-term decrease in the size of an important population of a species?	The impacting processes are not of a sufficient scale or magnitude to lead to a long-term decrease in an important population of this species.
... reduce the area of an important population?	Globally, the Hawksbill Turtle is a widely distributed species. The Project development and operation would not reduce the area of occupancy of the Hawksbill Turtle in any ecologically meaningful way.
... fragment an existing important population into two or more populations?	The Project development and operation would not create any barriers to movement for Hawksbill Turtles.
... adversely affect habitat critical to the survival of a species?	While some local feeding habitat would be disturbed as a result of dredging of the proposed port area, suitable feeding habitats are found throughout coastal areas of the Gulf of Carpentaria. The creation of a turbidity plume from dredging activities, and subsequent deposition and re-suspension of fine sediments, can potentially impact diverse reef assemblages which provide a food source for hawksbill turtles. While decreased light availability from turbid plumes may have an impact on marine plants and hard corals, any reduction in their immediate availability over the reef area would be buffered by the diversity of other foods available to hawksbill turtles that are not as sensitive to light or suspended solids changes, such as sponges, seagrass and algae. The constructed jetty would provide a surface for potential food sources (e.g. algae and sponges) to grow in the long term.
... disrupt the breeding cycle of an important population?	Low density Hawksbill Turtle nesting occurs in the area but it does not represent a critical breeding area, so no significant disruption is likely. Implementation of a lighting plan designed to minimise above-water lighting disorientation to hatchlings would minimise potential disruption to local breeding success. Hatchling survivorship would be enhanced through reduction in feral pig numbers in the vicinity of the proposed port development.
... modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	While foraging habitat would be impacted as a result of dredging of the proposed port area, the impact is not of a sufficient scale to affect the survival of any marine turtle species.
... result in invasive species that are harmful to an vulnerable species becoming established in the vulnerable species' habitat?	It is considered unlikely that an invasive species that is harmful to hawksbill turtles would be introduced due to the development or operation of the Project marine infrastructure. Population survivorship would be enhanced through ghost-net removal and feral pig control measures. Currently feral pigs are the primary factor reducing the success of sea turtle reproduction (hatchling emergence). RTA would work with Traditional Owners and DERM to develop and implement measures to reduce feral pig numbers in the Pera Head to Boyd Point area.
...introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is considered unlikely that a disease harmful to the Hawksbill Turtle would be introduced due to the development or operation of the Project marine infrastructure.
...interfere substantially with the recovery of the species?	There is a recovery plan in place for all marine turtle species found in Australia. Use of turtle deflectors on trailing suction hopper dredgers would minimise potential for entrainment of turtles during development and maintenance dredging for the port area. Implementation of a lighting plan would minimise the risks of local breeding impacts from hatchling disorientation. Recovery of turtle species would be enhanced through removal of ghost netting on beaches in the vicinity of the proposed port development and reduction of feral pig numbers. The Project is not expected to interfere with the recovery of the species.

Flatback Turtle (*Natator depressus*): Vulnerable

The Flatback Turtle does not have a global distribution. It is found only in the tropical waters of northern Australia, Papua New Guinea and Irian Jaya. The population size of the Flatback Turtle is currently estimated to be approximately 20,285 nesting females (Sea Turtle Conservancy 2010a).

It is considered that nesting is confined to Australia. Nesting locations occur from the Bundaberg region, north to west of the Northern Territory – Western Australia border. Within Australia, the most significant breeding site is Crab Island in the western Torres Strait. The beaches of western Cape York represent medium density nesting habitat. Flatback Turtle nesting occurs in the vicinity of the proposed port area with nesting occurring all year round, but peaking in May through to September.

Foraging habitats for the species are shallow coastal environments including rocky reef and sedimentary habitats where they feed principally on soft bodied animals including sea cucumbers, sea pens and soft corals.

Flatback Turtles occurring in the vicinity of the Project area are not considered to constitute an important population, geographically distinct regional population or local population that occurs within a particular bioregion.

Will the proposed works ...	Flatback Turtle (*Natator depressus*)
... lead to a long-term decrease in the size of an important population of a species?	The Project aspects with the greatest potential for long-term impact and decrease in local flatback turtle activity are dredging and onshore lighting. The use of turtle deflectors on trailing suction hopper dredgers and implementation of a lighting plan would minimise the risk of any long-term population decline. Implementation of a lighting plan would minimise long-term impacts from hatchling disorientation. Population survivorship would be enhanced through ghost-net removal and reducing feral pig numbers which currently cause major reductions in egg and hatchling survivorship. No significant long-term impact to an important population is expected.
... reduce the area of an important population?	The Project development and operation would not reduce the area of occupancy of the Flatback Turtle in any ecologically meaningful way.
... fragment an existing important population into two or more populations?	The Project development and operation would not create any barriers to movement for Flatback Turtles.
... adversely affect habitat critical to the survival of a species?	While some local feeding habitat would be disturbed as a result of dredging of the proposed port area, suitable feeding habitats are found throughout coastal areas of the Gulf of Carpentaria.
... disrupt the breeding cycle of an important population?	Medium density Flatback Turtle nesting occurs in the area but does not represent a critical breeding area, so no significant disruption is likely. Implementation of a lighting plan designed to minimise above-water lighting disorientation to hatchlings would minimise potential disruption to local breeding success. Hatchling survivorship would be enhanced through reduction in feral pig numbers in the vicinity of the proposed port development.
... modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	While habitat would be disturbed as a result of dredging of the proposed port area, the impact is not of a sufficient scale to affect the survival of any marine turtle species.
... result in invasive species that are harmful to a vulnerable species becoming established in the vulnerable species' habitat?	It is considered unlikely that an invasive species that is harmful to Flatback Turtles would be introduced due to the development or operation of the Project marine infrastructure. Population survivorship would be enhanced through ghost-net removal and feral pig control measures. Currently feral pigs are the primary factor reducing the success of sea turtle reproduction (hatchling emergence). RTA would work with Traditional Owners and DERM to develop and implement measures to reduce feral pig numbers in the Pera Head to Boyd Point area.
... introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is considered unlikely that a disease harmful to the Flatback Turtle would be introduced due to the development or operation of the Project marine infrastructure.
... interfere substantially with the recovery of the species?	There is a recovery plan in place for all marine turtle species found in Australia. Use of turtle deflectors on trailing suction hopper dredgers would minimise potential for entrainment of turtles during development and maintenance dredging for the proposed port area. Implementation of a lighting plan would minimise the risks of local breeding impacts from hatchling disorientation. Recovery of turtle species occurring in the area would be enhanced through removal of ghost netting on beaches in the vicinity of the proposed port development and reduction of feral pig numbers. The Project is not expected to interfere with the recovery of the species.

Green Turtle (*Chelonia mydas*): Vulnerable

Green Turtles are found in tropical and subtropical waters throughout the world. It is estimated that globally there are approximately 88,520 nesting female turtles (Sea Turtle Conservancy 2010b). Green Turtles nest, forage and migrate across tropical northern Australia. Green Turtles forage in shallow coastal areas, in particular seagrass beds. The nearest important foraging ground to the Project is Wellesley Islands in the south-western corner of the Gulf or Carpentaria. Numerous nesting areas are identified for Australian waters including western Cape York. The SPRAT database identifies that the total Australian population of Green Turtles is estimated to be more than 70,000 individuals, distributed across seven genetically distinct regional populations.

Green Turtles are likely to forage in the Project area, including the Embley and Hey Rivers where seagrass beds occur, but do not nest in the Project area. They feed principally on seagrass and seaweeds although juveniles are also carnivorous. It is uncertain which sub-population Green Turtles in the Project area would belong to, as their reported geographic distributions do not include the Project area. They could belong to the Northern Great Barrier Reef population (containing around 41,000 individuals), or the Southern Gulf of Carpentaria population (containing around 5,000 individuals), or both.

Will the proposed works...	Green Turtle (*Chelonia mydas*)
... lead to a long-term decrease in the size of an important population of a species?	At the Project scale, Green Turtles occurring in the vicinity of the Project area do not constitute a geographically distinct regional population or local population that occurs within a particular bioregion. The Project aspect with the greatest potential for long-term impact and decrease in local Green Turtle activity is dredging. The use of turtle deflectors on trailing suction hopper dredgers would minimise the risk of any long-term population decline. Minor removal of seagrass from barge/ferry terminal berth areas would not impact Green Turtle feeding resources, with more significant seagrass meadows occurring elsewhere in the Weipa region. The impacting processes are not of a sufficient scale or magnitude to lead to a long-term decrease in an important population of this species.
... reduce the area of an important population?	The Project development and operation would not reduce the area of occupancy of the Green Turtle in any ecologically meaningful way.
... fragment an existing important population into two or more populations?	The Project development and operation would not create any barriers to movement for Green Turtles.
... adversely affect habitat critical to the survival of a species?	The Project area does not include any critical habitat areas for the species.
... disrupt the breeding cycle of an important population?	Surveys have found no nests in the Project area. No large rookeries are present in the region. Disruption to the life cycle of marine turtles is not anticipated as a result of the Project.
... modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	Minor removal of seagrass from barge/ferry terminal berth areas would not impact Green Turtle feeding resources, with more significant seagrass meadows occurring elsewhere in the Weipa region.
... result in invasive species that are harmful to a vulnerable species becoming established in the vulnerable species' habitat?	It is considered unlikely that an invasive species that is harmful to Green Turtles would be introduced due to the development or operation of Project marine infrastructure.
...introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is considered unlikely that a disease harmful to the Green Turtle would be introduced due to the development or operation of Project marine infrastructure.
...interfere substantially with the recovery of the species?	There is a recovery plan in place for all marine turtle species found in Australia. Use of turtle deflectors on trailing suction hopper dredgers would minimise potential for entrainment of turtles during development and maintenance dredging for the proposed port area. The Project is not expected to interfere with the recovery of the species.

Green Sawfish (*Pristis zijsron*): Vulnerable

No quantitative data are available on global population size of the Green Sawfish. Green Sawfishes were once widely distributed in the northern Indian Ocean, westwards to South Africa, around South and Southeast Asia and around northern Australia. However, this species may now be virtually extinct in Southeast Asia, and northern Australia may be the last region where significant populations of green sawfish exist. There are no quantitative data regarding the Australian Green Sawfish population, but it is evident that there has been a significant decline in population number around the 1960s and 1970s, corresponding to an increase in commercial fishing.

The Australian population of the Green Sawfish is considered to be unfragmented and occurring throughout northern Australia. It is presumed that since it is a large species, and presumably is capable of long distance movements along the coast, they should form a continuous population (Stevens *et al.* 2005). On that basis, Green Sawfish within the Project area are not considered to represent an important population.

Green Sawfish inhabit estuaries, river mouths, embayments and along muddy and sandy beaches. This species may move into marine waters after the wet, and during the wet season enter estuarine or less saline environments (though not freshwater) to breed (Peverell 2005 and DSEWPaC 2010). They feed primarily on shoaling fish, baitfish, prawns, molluscs and small crustaceans.

This species has not been recorded in surveys of the Project area but it has been recorded from Albatross Bay. The Project area, including the port development area and barge/ferry terminals in the Embley and Hey Rivers, contain suitable habitat for the species. Further information relating to listed threatened Sawfish species in estuarine areas is provided in **Section 8.17** and **Appendix 8C**.

Will the proposed works...	Green Sawfish (*Pristis zijsron*)
... lead to a long-term decrease in the size of an important population of a species?	The impacting processes are not of a sufficient scale or magnitude to lead to a long-term decrease in an important population of this species given there is abundant suitable habitat available to it.
... reduce the area of an important population?	Given the extent of suitable habitat in northern Australia, the Project development and operation would not reduce the area of occupancy of the Green Sawfish in any ecologically meaningful way.
... fragment an existing important population into two or more populations?	The Project development and operation would not create any barriers to movement for Green Sawfish.
... adversely affect habitat critical to the survival of a species?	While some local habitat would be impacted as a result of proposed dredging activities in the Embley and Hey Rivers, suitable habitats are found throughout coastal areas of the Gulf of Carpentaria and northern Australia.
... disrupt the breeding cycle of an important population?	Development and operation of the barge/ferry terminals would not be at a sufficient scale or magnitude to lead to significant disruption to the Green Sawfish population, which is considered to occupy much of coastal northern Australia. Pupping is believed to occur in coastal or estuarine areas.
... modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	While habitat would be impacted as a result of dredging of the barge/ferry terminals, the impact is not of a sufficient scale to affect the survival of the Green Sawfish.
... result in invasive species that are harmful to an vulnerable species becoming established in the vulnerable species' habitat?	It is considered unlikely that an invasive species that is harmful to Green Sawfish would be introduced due to the development or operation of the Project marine infrastructure.
... introduce disease that may cause the species to decline?	It is considered unlikely that a disease harmful to the Green Sawfish would be introduced due to the development or operation of the Project marine infrastructure.
... interfere substantially with the recovery of the species?	Globally the threats to the Green Sawfish include fishing pressure, shark finning, habitat degradation and Australian Indigenous harvesting. The low reproductive rate and late maturation of Green Sawfish limits the ability of the species to recover from listed threats (Stevens *et al.* 2005). The Project would not result in any substantial interference with the recovery of this species.

Dwarf Sawfish (*Pristis clavata*): Vulnerable

There are no confirmed records of the Dwarf Sawfish outside of Australian waters. The extent of distribution is considered to be from Cairns around Cape York Peninsula, across northern Australian waters to the Pilbara coast in Western Australia; however there have been no records of the species from the eastern coast of Cape York Peninsula. The DSEWPaC (2010) SPRAT Database identifies that there are insufficient data available to estimate the total numbers of mature individuals of Dwarf Sawfish in Australian waters.

Dwarf Sawfish inhabit shallow (2–3m) coastal waters and estuarine habitat, moving into marine waters after the wet season. The species prefers highly turbid environments (DSEWPaC, 2010) and are only usually found in silt sections of an estuary which are completely devoid of instream structure (Thorburn *et al.* 2003). However DSEWPaC (2010) does note that this species may rest either side of high tide in inundated mangrove forests. During the wet season enter estuarine or brackish waters to breed. Juveniles are more commonly encountered in coastal foreshores and embayments; adults in marine waters (DEEDI, 2009). Estuarine habitats are used as nursery areas by Dwarf Sawfish, with immature juveniles remaining in these areas up until three years of age (Thorburn *et al.* 2007). Adults are known to seasonally migrate back into inshore waters (Peverell 2007). They feed principally on schooling fish, particularly mullet. Individuals appear to move only small distances and occupy only a relatively restricted area.

This species has not been recorded in surveys of the Project area but are considered likely to occur in the estuarine and lower brackish reaches of the Project area's main drainage systems. Further information relating to listed threatened Sawfish species in estuarine and freshwater areas is provided in **Section 8.17** and **Appendix 8C**.Any population within the project area is likely to be locally important on the basis that individuals occupy restricted areas and travel only short distances.

Will the proposed works...	Dwarf Sawfish (*Pristis clavata*)
... lead to a long-term decrease in the size of an important population of a species?	The Project is unlikely to result in a long-term decrease in the size of the local dwarf sawfish population. The only shallow water (2–3m) development relates to the barge/ferry terminals where minor dredging would be required to a depth of approximately 2m. The proposed port area works in those shallow depths may relate only to piling as dredging starts at –11m LAT depth.
... reduce the area of an important population?	The minor works proposed in the shallows of the Project area would not cause any significant reduction in the area of a local population.
... fragment an existing important population into two or more populations?	Barges and ferries docked within the terminal areas may present temporary blocks to movement but this would not likely result in fragmentation as vessels would move several times per day.
... adversely affect habitat critical to the survival of a species?	The minor works proposed in the shallows of the Project area would not adversely affect habitat to the extent that it significantly impacts the local population or survival of the species as a whole.
... disrupt the breeding cycle of an important population?	The development and operation of the port and barge/ferry terminal areas is unlikely to disrupt the breeding cycle of the Dwarf Sawfish, which is believed to move into marine waters after the wet season, and during the wet season enter estuarine or fresh waters to breed. The infrastructure or activities are unlikely to present a significant barrier to movement.
... modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	While habitat would be disturbed as a result of dredging and operation of barge/ferry terminal areas, the impact is not of a sufficient scale to significantly decrease the availability or quality of shallow muddy habitat as there is abundant similar habitat in the Project area.
... result in invasive species that are harmful to an vulnerable species becoming established in the vulnerable species' habitat?	It is considered unlikely that an invasive species that is harmful to dwarf sawfish would be introduced due to the development or operation of the Project marine infrastructure.
... introduce disease that may cause the species to decline?	It is considered unlikely that a disease harmful to the Dwarf Sawfish would be introduced due to the development or operation of the Project marine infrastructure.
... interfere substantially with the recovery of the species?	Threats to the Dwarf Sawfish include fishing pressure, habitat degradation and Australian Indigenous harvesting. The low reproductive rate and late maturation common to sawfish likely limits the ability of the species to recover from listed threats. The Project would not result in any substantial interference with the recovery of this species.

6.9.5.2 Migratory Marine Fauna

Individual significant impact assessments are provided below for each of the EPBC Act listed marine migratory fauna species that are not threatened species and are assessed as *possible, likely* or *known to occur* in the Project area as identified in **Section 6.6**. These include:

- Indo-Pacific Humpback Dolphin (*Sousa chinensis*);
- Australian Snubfin Dolphin (*Orcaella heinsohni*);
- Bryde's Whale (*Balaenoptera edeni*); and
- Dugong (*Dugong dugon*).

Key definitions from the DSEWPaC guidelines that apply to this assessment are as follows:

An area of "important habitat" for a migratory species is:

- habitat utilised by a migratory species occasionally or periodically within a region that supports an ecologically significant proportion of the population of the species; and/or
- habitat that is of critical importance to the species at particular life-cycle stages; and/or
- habitat utilised by a migratory species which is at the limit of the species range; and/or
- habitat within an area where the species is declining.

Listed migratory species cover a broad range of species with different life cycles and population sizes. Therefore, what is an "ecologically significant proportion" of the population varies with the species (each circumstance would need to be evaluated). Some factors that should be considered include the species' population status, genetic distinctiveness and species-specific behavioural patterns (for example, site fidelity and dispersal rates).

"Population", in relation to migratory species means the entire population or any geographically separate part of the population of any species or lower taxon of wild animals, a significant proportion of whose members cyclically and predictably cross one or more international jurisdictional boundaries including Australia.

Indo-Pacific Humpback Dolphin (*Sousa chinensis*) and Australian Snubfin Dolphin (*Orcaella heinsohni*)

Two species of dolphins – Indo-Pacific Humpback Dolphin (*Sousa chinensis*) and the Australian Snubfin Dolphin (*Orcaella heinsohni*) – that are listed as cetaceans and migratory species under the EPBC Act are known to occur in the Project area from incidental sightings during field work for the present marine study.

Both the Indo-Pacific Humpback Dolphin and the Australian Snubfin Dolphin usually inhabit shallow coastal waters of less than 20m depth and are often associated with rivers and estuarine systems, enclosed bays and coastal lagoons (Corkeron *et al*. 1997, Hale *et al*. 1998, Parra 2006).

Parra (2006) examined habitat use of both Indo-Pacific Humpback Dolphins and Australian Snubfin Dolphins in Cleveland Bay (Townsville). While there was significant overlap in habitat use by the two species, differences were also found. Australian Snubfin Dolphins preferred slightly shallower (1–2m) waters than Indo-Pacific Humpback Dolphins (2–5m). Shallow areas with seagrass ranked high in the habitat preferences of Australian Snubfin Dolphins, whereas Indo-Pacific Humpback Dolphins favoured dredged channels.

It is noted that the listed Bottlenose Dolphin species (*Tursiops aduncus* and *Tursiops truncatus*) may occur in the Project area; however, neither of these are threatened or migratory. The Arafura / Timor Sea sub-population of *T. aduncus*, which is migratory, does not have a distribution extending to the Project area. There are no *Significant impact guidelines* criteria for listed cetacean species that are not threatened or migratory; however, the potential for significant impacts from the proposed marine works and activities to these Bottlenose Dolphin species would be no greater than for the other migratory cetacean species considered.

Bryde's Whale (*Balaenoptera edeni*)

Bryde's Whale occurs in pelagic temperate to tropical waters, principally in continental shelf waters, but also extending into coastal and inshore waters. There are considered to be two forms of Bryde's Whale: inshore and offshore.

Insufficient information exists as to how Australian Bryde's Whales use their habitat, as no specific feeding or breeding grounds have been discovered off Australia. The inshore form appears to be resident in waters containing suitable prey stocks of pelagic shoaling fishes, while the offshore form appears to undergo extensive migrations between subtropical and tropical waters during the winter months.

Bryde's Whale is considered to be a fairly opportunistic feeder, readily consuming whatever shoaling prey is available, with inshore coastal forms feeding on schooling fishes such as pilchard, anchovy, sardine, mackerel, herring and others. Little is known regarding breeding in Australian waters but the inshore form is considered likely to breed all year round. There is no evidence of large-scale movements of the inshore form of Bryde's Whales, which contrasts with seasonal migration of the offshore form.

The recording of Bryde's Whale from inshore tropical waters makes it possible that the species could occur sporadically within the Project area, but the area would not represent preferred habitat. It is highly unlikely they would venture into estuarine habitats of the Embley and Hey Rivers.

The following assessment considers the whale and dolphin species together, as the impacting processes are the same and the likely responses are similar.

***Will* the proposed works ...**	**Indo-Pacific Humpback Dolphin (*Sousa chinensis*), Australian Snubfin Dolphin (*Orcaella heinsohni*), Bottlenose dolphin (*Tursiops aduncus)* and Bryde's Whale (*Balaenoptera edeni*)**
... substantially modify, destroy or isolate an area of important habitat for a migratory species?	Cetaceans may be impacted by: disturbance from boating and shipping activities including alienation from habitat, acoustic impacts, boat strike and creation of an offshore turbidity plume during dredging. The construction of the wharf would involve pile driving. The underwater noise generated by the hammer hitting the top of the pile is of short-term duration and therefore can be described as impulsive noise. The time taken to drive each pile would depend on the hardness of the seabed in each location. There is potential for marine animals in an area close to the piling to incur hearing damage as a result of the piling. It is anticipated the construction activity would deter most marine mammals from the immediate area; however for precautionary purposes, it is proposed that a "soft-start" approach would be used to disperse animals in the vicinity prior to normal pile driving. The "soft-start" involves commencing pile driving with a partial capacity strike, or giving a warning with an underwater airgun prior to normal pile driving. Construction of the proposed port, operation and spoil disposal are not anticipated to substantially modify important habitat for the migratory species confirmed as known or possible to occur within the Project area.
... result in an invasive species that is harmful to the migratory species becoming established in an area of important habitat for the migratory species?	The Project is unlikely to lead to the introduction of any invasive fauna that could affect migratory species. RTA would conduct routine monitoring of the port for marine pests, similar to that currently undertaken for Port of Weipa high-risk areas.
... seriously disrupt the lifecycle (breeding, feeding, migration or resting behaviour) of an ecologically significant proportion of the population of a migratory species?	There is the potential for alienation of cetaceans in the immediate vicinity of the port and barge/ferry terminal areas primarily during construction activities, particularly during pile driving for the bulk loading wharf. "Soft-start" pile driving procedures are proposed to limit disturbance during pile driving activities. The proposed port development would not present a barrier to migration as there is large coastal area for transit and avoidance of any underwater noise. Disturbance in estuarine areas would be minor and not represent any substantial barrier to movement of dolphins. They are highly unlikely to occur in the Embley and Hey Rivers. Dolphins present within the Project area are not identified as representing a significant proportion of the population of their respective species. No significant impact to the lifecycle of dolphins is likely. No meaningful disruption to the lifecycle of Bryde's Whale would occur as a result of the Project given the Project area is not preferred habitat and any occurrence would be sporadic.

Dugong (*Dugong dugon*)

The Dugong has a large range across tropical and subtropical coastal and island waters from east Africa to Vanuatu. A significant proportion of the world's Dugongs are found in north Australian waters from Shark Bay in Western Australia to Moreton Bay in Queensland. The Torres Strait region is the most important Dugong habitat in the world. Within the Gulf of Carpentaria, the Sir Edward Pellew Islands on the Northern Territory coast and the mouth of the Limmen Bight River are the most important areas and represent the fourth most important site in Australia (Marsh *et al* 2002).

Dugong almost solely consume seagrass and are associated with seagrass beds in the Weipa region, but the region is not identified as supporting large populations of these animals. Dugongs are known to occur in low densities in Albatross Bay (Saalfield and Marsh 2004) and are closely associated with the seagrass beds in the Embley estuary.

Dugongs prefer seagrasses that are early or "pioneer" species, particularly species of the genera *Halophila* and *Halodule* (DEWHA 2010). The long, strap-like seagrass *Enhalus acoroides*, which dominates the seagrass beds of the Embley and Hey Rivers, is not a preferred species in the Dugong diet.

Traditional Owners report that Dugong migrate through the Boyd Bay region. The species is highly migratory and would traverse coastal waters between seagrass beds.

Will the proposed works...	Dugong (*Dugong dugon*)
... substantially modify (including by fragmenting, altering fire regimes, altering nutrient cycles or altering hydrological cycles), destroy or isolate an area of important habitat for a migratory species?	The construction of the wharf would involve pile driving. The underwater noise that is generated by the hammer hitting the top of the pile is of short-term duration and therefore can be described as impulsive noise. The time taken to drive each pile would depend on the hardness of the seabed in each location. There is potential for marine animals in an area close to the piling to incur hearing damage as a result of the piling. It is anticipated the construction activity would deter most marine mammals from the immediate area, however for precautionary purposes, it is proposed that a "soft-start" approach would be used to disperse animals in the vicinity prior to normal pile driving. The "soft-start" involves commencing pile driving with a partial capacity strike, or giving a warning with an underwater airgun prior to normal pile driving. The minor area of seagrass that may be impacted by dredging at the Humbug Terminals not significant in terms of a Dugong foraging resource and is not considered to be an area of important Dugong habitat.
... result in an invasive species that is harmful to the migratory species becoming established in an area of important habitat for the migratory species?	It is considered unlikely that an invasive species that is harmful to Dugong would be introduced due to the development or operation of the Project. RTA would conduct routine monitoring of the port for marine pests, similar to that currently undertaken for Port of Weipa high-risk areas.
... seriously disrupt the lifecycle (breeding, feeding, migration or resting behaviour) of an ecologically significant proportion of the population of a migratory species?	See above for management of potential acoustic impacts during construction. Of all potential impacts, boat strike from operation of the ferry from Hornibrook Terminal to Hey River Terminal is anticipated to represent the highest risk. RTA would operate the ferry to minimize the impacts to Dugong. Transit lanes would be defined to reduce the overall area of disturbance from vessel activities. Serious disruption to the life cycle of an ecologically significant population of Dugong within the Project area is not anticipated.

6.9.6 Marine Fisheries Resources Impacts

The Project may affect fisheries through impacts on the target species directly, the habitats of target species, or through changes to fishing access. Each fishery that may be affected by the proposed development is discussed in turn.

6.9.6.1 Northern Prawn Fishery

The NPF could potentially be affected by the proposed new spoil ground as a result of:

- providing habitat less suitable for banana prawns after spoil is deposited;
- changing the local distribution of banana prawns as they respond to the turbidity plume generated by spoil disposal;
- trawlers being unable to access the proposed spoil ground area due to the uneven seabed, a consequence of spoil deposition. Trawl nets snagging on an uneven seabed may lead to safety being compromised and expensive trawling equipment being lost;
- reduced nursery habitat within the Embley estuary; and
- potential disruption to prawn migration.

Dredging of the port area and spoil disposal at the proposed new spoil ground is expected to take up to 10 months. The fishery is active in the Weipa area from July to March. Hence there is the potential for an effect on the local distribution of banana prawns as a result of spoil deposition.

Overall, the area where the NPF operates is large (thousands of km^2) and there is considerable area of suitable habitat remaining in the Weipa area for banana prawns, where the fishery can still operate unimpeded if the proposed development proceeds. It is predicted that operators in the NPF would be able to, if necessary, adapt their fishing operations to avoid the spoil ground without incurring a significant financial impact. Fine scale spatial information on the actual area of operation of the fishery in the Weipa area is lacking and the actual area will vary considerably between years. However, it is predicted that the area of the proposed spoil ground represents less than 1% of the available prawn trawl habitat in the Weipa area. The spoil ground footprint has been constrained to a 0.5nm radius to minimise the area sterilised from the NPF. It is predicted that a wedge of fine sediment deposition would occur running north-north-east and south-south-west from the disposal ground to a distance of approximately 4km in each direction (**Figure 6-60a-c**). This represents the mobilisation of fine fractions (fine sands, silt and clays) as material is released at the spoil ground.

The removal of mangrove habitat in the Embley estuary would potentially reduce the area of prawn nursery habitat within the Embley estuary. However, existing information is insufficient to quantify the

impact of this disturbance on fishery production. The area of the fishery is very large and the area of disturbance is extremely small relative to available nursery habitat in the eastern Gulf of Carpentaria.

The small scale and short duration of dredging for the barge/ferry terminals in the Embley and Hey Rivers presents low risk to prawn migration and would not warrant a requirement to dredge outside the peak period of August to April.

6.9.6.2 Gulf of Carpentaria Commercial Inshore Finfish Fishery

Currently finfish can be caught commercially on the foreshores between Boyd Point and Pera Head. The proposed port would prevent access to the fishery adjacent to the wharf structures. Provisions of the *Fisheries Regulations 2008* (Qld) create an exclusion zone to mesh nets of 200m around a wharf or jetty.

The area where the fishers can operate is very large and the area around the proposed port is not considered important for the fishery. This is based on the fishers mostly operating in the rivers and the creeks draining into the Gulf of Carpentaria and the shoreline directly adjacent to such areas where the principal target species (barramundi) are abundant (McPhee 2008).

Any changes in access to the fishery as a result of the proposed port would not impact the Gulf of Carpentaria Commercial Inshore Finfish Fishery.

Mesh net fishing is prohibited in the rivers and creeks that drain into Albatross Bay so the proposed barge/ferry operations pose a low risk of impact on mesh netting activities.

Changes to the seabed at the spoil grounds, as a result of spoil deposition, would not affect access by this fishery as the nets do not touch the seabed.

6.9.6.3 Gulf of Carpentaria Commercial Line Fishery

Commercial line fishermen recognise the reef areas in the vicinity of Pera Head, Boyd Point and Thud Point as key locations for Spanish mackerel (*Scomberomorus commerson*) in the Weipa region. The proposed port development dredging has the potential to locally affect commercial line fishing over Pera Head and inshore reefs extending to Thud Point through turbid plume generation and possible avoidance of the area by target species. Boyd Reef would experience lesser impacts from turbid plumes and may present an area of refuge from the more affected areas. The duration of proposed dredging is approximately 10 months and would cover the period between August and November, which is the peak season for this fishery in the Weipa area.

While there may be localised impact during the dredging period, the risk to the overall line fishery in the Gulf of Carpentaria is minor due to the relatively minor proportion of the reef area likely to be affected.

Suitable habitats for line fish occur within spoil grounds and within the associated dredge plumes, but impacts would be localised and there would be periods of respite between spoil disposal activities. The risk to line fishing in these areas is low.

Commercial line fishers do not presently operate near the proposed barge/ferry terminals in the Embley and Hey Rivers. It is therefore predicted that the proposed terminals would not directly impact the target species habitats or the current operator access patterns, and as such pose a low risk.

6.9.6.4 Recreational and Guided Fishing

Recreational fisherman and guided fishing tour operators would likely be affected by the proposed port development in the short term. Both these sectors extensively utilise the reefs and the foreshore flats between Boyd Point and Thud Point. For those targeting reef fish, the impact on the fishery is likely to be proportional to the changes in turbidity and loss or damage to the adjacent reef areas. There are extensive foreshore flats north of Boyd Point which provide similar recreational fishing opportunities to the area between Pera Head and Thud Point. As such, it is predicted that the proposed port development poses a moderate local risk of impact on species targeted by recreational fishers.

Suitable habitat for the target species is unlikely to be abundant at the proposed new spoil ground and Albatross Bay spoil ground. It is therefore predicted that those components of the Project have a low risk of impact on recreational or guided fishing. Modelling of turbid plumes from the proposed new spoil ground predicts that turbid plumes generated at the proposed new spoil ground would not

adversely affect Nine Mile Reef and therefore no impact on recreational or guided fishing over that area is predicted.

Recreational and guided fisherman are likely to access the Hornibrook Point, Humbug Point and Hey River areas; however, it is uncertain whether these locations represent prime fishing locations.

6.9.6.5 Other Fisheries Impacts

It is predicted the Project would not affect either the commercial Mud Crab Fishery or the Developmental Finfish Trawl Fishery as no development would occur in the important habitats for these target species. The development poses a low risk of impact on these fishing activities.

6.9.7 Cumulative Marine Impacts

This assessment has considered all marine components of the Project: port facility, the proposed spoil disposal ground, existing disposal ground (Albatross Bay), and barge/ferry terminals. These Project components are generally spatially isolated from each other and not interconnected. The exceptions to this are the sites for ferry and barge facilities. However, it is not predicted that any cumulative effects between Project components would arise.

A small increase in vessel traffic would occur within the Embley/Hey River estuaries due to barge and ferry movements between the Hey River Terminal and Hornibrook and Humbug terminals. These movements are additional to existing commercial and recreational boating undertaken from Weipa, and may be considered a cumulative effect. However, the present vessel utilisation of the estuary is relatively limited, and due to its remote nature is not facing significant pressures in terms of growing recreational or commercial demands. Vessel operations within the Embley River estuary are not considered a significant cumulative threat. Vessel movements in the Port of Weipa are discussed in **Section 14.4.6**.

The proposed port is in a remote, undeveloped location. A reduced utilisation of the adjacent beaches and foreshore by recreational boats, fishermen and pig hunters is anticipated due to port security requirements.

RTA's proposed port has been designed to allow for the option of shipping bauxite produced from neighbouring projects in the event that the parties are able to reach an agreement. **Section 1.4** describes the neighbouring projects to the RTA SoE Project and discussion of any potential for co-location and/or sharing of certain infrastructure, including wharf facilities. Such arrangements would minimise cumulative impact.

The existing Albatross Bay spoil ground would be used to receive a minor volume of spoil from capital dredging activities at the barge/ferry terminals in the Embley and Hey Rivers. The proposed volume of additional spoil to be deposited at the existing Albatross Bay spoil ground is minimal compared with annual maintenance dredge volumes of the Weipa Port.

6.9.8 Summary of Impact Mitigation Strategies

A summary of management and monitoring actions proposed during construction and operation are presented in **Table 6-51** and **Table 6-52** respectively for impacts identified in **Table 6-40**.

Table 6-51 Summary of proposed construction impact management and monitoring activities

Potential Impact	Port Area	New Disposal Ground	Embley River – Hornibrook & Humbug Terminals	Albatross Bay Spoil Ground	Hey River Terminal
Creation of a turbidity plume, and subsequent deposition and re-suspension of fine sediments	Reactive monitoring program including: • Deposition and light monitoring leading up to and during dredging. • Inshore reef coral monitoring leading up to and during dredging. • Monitoring of the progress of the turbidity plume. Relocate TSHD dredger offshore if unacceptable coral impacts detected.	Uniform deposition of dredge spoil within spoil ground boundary. Below keel discharge of sediments. Turbidity model validation. Consultation with DSEWPaC regarding identification of unacceptable impacts to Nine-Mile Reef due to dredging.	Continuation of long-term seagrass monitoring by DEEDI within intensive monitoring area.	Uniform deposition of dredge spoil within spoil ground boundary.	Continuation of long-term seagrass monitoring by DEEDI within intensive monitoring area.
Physical disturbance to benthic habitats and fauna from dredging and construction of infrastructure	Inshore reef coral monitoring during dredging. Relocate TSHD dredger offshore if unacceptable coral impacts detected.	Post-construction infauna assemblage monitoring.	Continuation of long-term seagrass monitoring by DEEDI within intensive monitoring area.	Management and monitoring not proposed.	Continuation of long-term seagrass monitoring by DEEDI within intensive monitoring area.
Changes to coastal processes (erosion and deposition)	Monitor any changes to beach profile and mitigate if cliff erosion is exacerbated.	—	—	—	—
Introduction of pollutants to marine waters and sediments	Design construction conveyor and ship loader to minimise dust generation and spillage, particularly in vicinity of transfer points. Dredge Management Plan to include waste management plan and emergency spill plan.	—	Dredge Management Plan to include waste management plan and emergency spill plan.	—	Dredge Management Plan to include waste management plan and emergency spill plan.
Underwater acoustic impacts from pile driving activities and vessel movement	"Soft-start" approach for piling activities. Piling megafauna exclusion zone.	—	"Soft-start" approach for piling activities. Piling megafauna exclusion zone.	—	"Soft-start" approach for piling activities. Piling megafauna exclusion zone.
Disturbance from boating and shipping activities including exclusion from habitat	Management and monitoring not proposed.	—	Management and monitoring not proposed.	—	Management and monitoring not proposed.

Potential Impact	Port Area	New Disposal Ground	Embley River – Hornibrook & Humbug Terminals	Albatross Bay Spoil Ground	Hey River terminal
Introduction of pest species	Ballast water management as per **Section 13.3.8** Larval plate monitoring consistent with that for Port of Weipa. Work with Biosecurity Queensland in event of pest incursion.	—	—	—	—

— = Low risk of impact

6.10 Dredge Management Plan Outline

Separate dredge management plans (DMP) would be developed for the dredging of the port area at Boyd Point, and for the dredging associated with the development of the barge/ferry terminals located in the Embley and Hey Rivers.

This DMP would describe approval conditions, monitoring and management response arrangements for capital dredging and dredged material disposal to be undertaken by RTA as part of the Project. The DMP would support applications for Sea Dumping under the Commonwealth *Environment Protection (Sea Dumping) Act* (1981) and approval for capital dredging under the Queensland *Coastal Protection and Management Act* 1995.

Core operational objectives of the DMP for the Project would include:

- Providing a platform for delivering legislated approval conditions for the development as evidenced by practical and achievable action plans;
- Implementation of an adaptive management and monitoring strategy which provides data for management at suitable spatial and temporal scales to enable effective environmental management outcomes;
- Delivering monitoring systems to overcome site based logistical and safety constraints, whilst maintaining rigour of design, and applicability to decision processes;
- Establishment of an agreed framework for the management of dredging and dredged material disposal which is transparent to stakeholders; and
- Provision of guidance to RTA and its contractors with regards to dredging and disposal activities, including the process of environmental management triggers and response requirements.

The DMP would follow the assessment framework originally developed by the *Convention of the Prevention of Marine Pollution by Dumping Wastes and Other Matter* (London Convention 1972), and outlined within the *National Assessment Guidelines for Dredging* (NAGD) (Commonwealth of Australia, 2009). It would also apply the principles of environmental management as referenced within Guidance documents released from DERM. Key components include:

- Dredging and disposal management framework;
  - Commonwealth and State permits and approvals; and
  - Roll of the Technical Advisory and Consultative Committee in the overall management approach.
- Dredging and disposal Project description;
- Characterisation of materials to be dredged;
- Existing environment;
  - Habitats;
  - Significant species;
  - Existing users.
- Potential impacts;
  - Habitats;
  - Significant species;
  - Existing users.

- Receiving habitats monitoring program (proposed monitoring regime, development of triggers; and
- Management and control strategies, including;
  - Dredge management;
    - (i) Schedule of operations;
    - (ii) Dredge vessel specification;
    - (iii) Adaptive monitoring and management systems to protect receiving habitats (including triggers, decision pathways, management actions and roll of the TACC/MRG);
    - (iv) Marine mammals interaction (whales, dugong, dolphins);
    - (v) Turtle interaction;
    - (vi) Introduced marine pests;
    - (vii) Disposal ground management;
    - (viii) Noise;
    - (ix) Air quality;
    - (x) Waste management;
    - (xi) Hydrocarbons and other hazardous substances; and
    - (xii) Operational audits.
  - Monitoring programs;
    - (i) Routine monitoring;
    - (ii) Reactive monitoring; and
    - (iii) Post dredging.
  - Security and maritime safety;
  - Emergency planning and response;
  - Reporting, auditing and improvement processes;
  - Roles and responsibilities; and
  - Training.

The proposed monitoring methods and management protocols within the DMP would be selected to provide an 'adaptive' approach to dredging impact response. These responses are tiered, with increasing levels of operational intervention and monitoring evidence depending upon the conditions of receiving habitats. This approach is designed to prevent significant environmental disturbance, working through routine monitoring to reactive monitoring as stress levels increase.

Management trigger levels would be included for key physical parameters (deposition, light attenuation), and biological response of coral communities to these stressors (coral colour, photosynthetic efficiency, sediment coverage, bleaching, injury and partial mortality, and mortality etc.). These biological triggers would focus on a range of sub-lethal indicators to best facilitate management response, although mortality response would also to be recorded.

The identified monitoring program is geared towards the use of rapid response indicators, for both physicochemical/physical factors (deployed loggers with telemetry) and biological response within

receiving habitats (deployed reference coral trays). The remote nature of the area between Boyd Point and Pera Head, the presence of dangerous marine animals, and the low visibility conditions has focused attention on diver-free methods of assessment. These constants are reflected in the adopted methods of monitoring.

A process of model validation is proposed to occur early in the dredging program. This will refine the understanding of the materials to be dredged, and their fate in the receiving environment. Comparison between the EIS predictions and the updated information will refine the appreciation of potential environmental risk. Monitoring and management processes can be adjusted accordingly early in the dredge program.

Environmental Impact Statement

for South of Embley Project

Section 7

Terrestrial Flora and Fauna

7 TERRESTRIAL FLORA AND FAUNA

7.1 Biogeographic Setting

The Weipa area is located within the Cape York Peninsula Bioregion (after Stanton and Morgan 1977, and Sattler and Williams 1999) which, based on broad vegetation formations and landform, is recognised as one of the distinct biogeographic regions of Australia (Thackway and Cresswell 2006).

The Project area and wider Weipa area are located within the Weipa Plateau province (subregion) of the Cape York Peninsula Bioregion (Sattler and Williams 1999). Although the Weipa Plateau province is only one of the six provinces (or subregions) of the Bioregion, it is the most extensive, and covers a large area of the central and north-western portions of the Cape York Peninsula. This area is relatively homogenous in vegetation and landform, and is characterised by large areas of Darwin Stringybark (*Eucalyptus tetrodonta*) open forests or woodlands, dissected by smaller areas of riparian vegetation, vine thicket patches and paperbark swamps.

7.2 Protected Areas, Conservation Areas and Biodiversity Areas

7.2.1 Protected Areas

There are three protected areas located on northern Cape York comprising (refer **Figure 7-1**):

- the western section of the Mungkan Kandju National Park, located approximately 30km to the east of the lower section of the Project area;
- the Iron Range National Park, located 150km east of the Project area on the east coast of Cape York Peninsula; and,
- the Heathlands Resources Reserve and Jardine River National Park and Resources Reserve, approximately 125km to the north-east of the study area.

None of these reserves are located downstream or within the Project area.

There is currently no World Heritage Area (WHA) listed for the northern Cape York Peninsula, although the Queensland Parks and Wildlife Service (QPWS) has commissioned preliminary works investigating the extent to which parts of Cape York Peninsula satisfy the criteria for WHA listing (Valentine 2006). The report identifies several scenarios for areas to be nominated for inclusion for WHA listing but it appears that the Mining Lease areas would not be included in any of these nominations.

The Uningan Nature Reserve is located across the Embley River at Weipa approximately 10km north of the Project area.

7.2.2 Other Identified Conservation and Biodiversity Areas

Cape York Peninsula Land Use Strategy (CYPLUS)

The CYPLUS report (Abrahams *et al.* 1995) identifies 36 areas across Cape York of regional conservation significance as a result of the presence of outstanding habitat or ecological features, or high wilderness values. In this context, wilderness value comprises a measure of ecological integrity and the extent of recent human induced disturbance. Wilderness value does not ignore the fact that Traditional Owners have occupied and derived an existence from the area for many thousands of years.

Within the Project area, an area of 670ha centred on Pera Head is noted for the following natural values:

- the coast in the Pera Head area has an extensive and aesthetically prominent landscape, comprising cliffs of red bauxite overlying white kaolin;
- about 60% of the area is of very high wilderness quality; and
- representative vegetation present in the area includes patches of tussock grassland and bare saltpans with a sparse herbland.

Queensland

South of Embley Project

Fig. 7-1: Protected Areas

N

10 0 30km

Datum/Projection: GDA94/MGA Zone 54 Date: 01/04/2011

The Hey–Embley Rivers Area overlaps the northern part of the Project area and is reported to have natural conservation significance because:

- about 70% of the area is of very high wilderness quality; and
- about 40% of the area (chiefly the eastern section) is covered by vegetation areas that are amongst the best examples of their vegetation class on the Peninsula. Representative vegetation occurring in the area is predominantly types of *Eucalyptus tetrodonta* woodlands.

Reference to the eastern section of the Hey–Embley Rivers Area suggests an area lying outside of the Project area.

It is likely that re-assessment of the Wilderness values of the identified Pera Head area, the portions of the Hey–Embley area within the Project area, and the broader Boyd and Norman Creek areas would produce lower wilderness value rankings given recent exploration activity.

Rapid Appraisal of Key and Endangered Sites (RAKES) and Stanton (1976)

Stanton (1976) assessed the conservation significance of Cape York and identified key conservation areas. The rapid conservation assessment of Queensland (RAKES) undertaken by Stanton and Morgan (1977) also identified Key and Important Areas in the Cape York Bioregion. Neither of these assessments identified significant conservation areas within or adjacent to the Project area.

Biodiversity Planning Assessment

There is currently no Biodiversity Planning Assessment undertaken for the Cape York Bioregion by the Queensland Department of Environment and Resource Management (DERM).

International Significance of Cape York Peninsula Vegetation

Mackey *et al.* (2001) completed an assessment of the natural heritage significance of the Cape York Peninsula, and concluded that the savannahs of Cape York Peninsula are of global significance. Woinarski *et al.* (2007) analysed the state of the world's tropical savannahs and concluded that the largest expanses of tropical savannah woodland remaining in good condition are in Northern Australia, making Australian tropical savannahs of very high conservation value at a global level. The Mackey *et al.* (2001) and Woinarski *et al.* (2007) assessments were broad assessments of the whole Cape and did not contain particular information pertaining to the Project area.

7.3 Matters of National Environmental Significance

This section identifies the species and communities listed as "matters of national environmental significance" (MNES) under the *Environment Protection and Biodiversity Conservation Act 1999* (EPBC Act) (Cwlth) that potentially occur in the vicinity of the Project area. A search of the Department of Sustainability, Environment, Water, Population and Communities (DSEWPC) (formerly the Department of Environment, Water, Heritage and Arts (DEWHA)) Protected Matters search tool was conducted. The search area is shown in **Figure 7-2** and detailed in **Table 7-1**.

Table 7-1 MNES Search Area Coordinates

Boundary Point	Latitude			Longitude		
	degrees	minutes	seconds	degrees	minutes	seconds

Fig. 7-2: Area of Database Search (Terrestrial)

N

5 0 5km

Datum/Projection: GDA94/MGA Zone 54 Date: 16/07/2010

Table 7-2 summarises the search results with respect to terrestrial ecosystems and species. Detailed discussion of the terrestrial MNES is provided in the following respective vegetation, flora and fauna sections.

Table 7-2 MNES Terrestrial Ecosystems

Matters of National Environmental Significance (MNES)	Result for Terrestrial Ecosystems
World Heritage Properties	There are no World Heritage Properties within or near the area affected by the proposed development.
National Heritage Places	There are no National Heritage Places within or near the area affected by the proposed development.
Threatened Ecological Communities	No endangered ecological communities (EECs) were returned by the database search of the Project area. A review of the regional ecosystem types that are mapped in the Project area indicates EECs are not likely to occur in the Project area.
Threatened Species	4 plants 3 birds 3 mammals
Migratory Species	17 birds 1 reptile

It should be noted that a Protected Matters search of the pre-defined Cape York Natural Resource Management (NRM) region (accessed on the 25/03/2011) identifies the potential occurrence of the threatened ecological community '*The community of native species dependent on natural discharge of groundwater from the Great Artesian Basin'.*

The threatened ecological community does not occur in the Project area, or Cape York, as the required discharge springs are not present (see **Section 5.3.4**)

7.4 Overview of Flora Survey Methods

The main objectives of the flora survey program was to characterise the flora in the habitats present and also provide considerable coverage of threatened species listed under the EPBC Act, as these are the primary matters of national environmental significance relevant for the Project area (i.e. in the absence of threatened communities or populations). The secondary survey methodology of the Queensland Herbarium (Neldner *et al.* 2005) was used to characterise main vegetation types, together with extensive targeted survey traverses in likely habitats for threatened species.

Surveys were undertaken of vegetation communities and flora within the Project area. Preliminary surveys were undertaken in July 2006 and May 2007 with dedicated surveys for the EIS undertaken in December 2007, May 2008, December 2008 and May 2009. The spread of survey events provided survey effort over the two key seasons for detecting vegetation and floristic variability within the Project area, namely mid dry season (July) and late wet season (May). Extensive survey during the wet season was not possible due to the difficulty of access to and within the Project area at this time of heavy rainfall when most track crossings of streams and low lying areas are impassable. Nevertheless, the late wet season surveys in May 2008 and May 2009 were conducted as soon as vehicle access to the Project area was possible and most of the wet season flora was still evident.

The two preliminary flora surveys focussed on *Eucalyptus tetrodonta* dominated communities on the bauxite plateau. These are the communities that occur within the proposed mining areas. Prior to the dedicated EIS surveys, a gap analysis was undertaken to identify vegetation communities requiring further survey effort to adequately describe their structural and floristic attributes. As a result, the May 2008 and May 2009 surveys concentrated survey effort within non *Eucalyptus tetrodonta* dominated communities occurring predominantly in riparian, seasonally inundated, and beach areas and on vine forest patches occurring on the bauxite plateau. Additional surveys were also undertaken in *Eucalyptus tetrodonta* dominated communities to extend the distribution of survey sites and coverage throughout the Project area.

The location of vegetation survey sites and traverses undertaken within the Project area is indicated in **Figure 7-3**. **Table 7-3** details the survey effort employed during all surveys in the Project area. A detailed description of the flora survey methods is provided in **Appendix 7A**.

Table 7-3 Vegetation and Flora Survey Effort

Survey Effort	Survey Level	Vegetation Community and Floristics	Targeted Threatened Flora Searches
No. of survey days		41	12
No. of survey sites	Secondary	134	n/a*
	Tertiary	6	n/a*
	Quaternary	847	n/a*

* Targeted threatened flora searches comprised traverses and broad searches for target species.

7.5 Vegetation Community

7.5.1 Vegetation Units

Vegetation unit mapping for the Project area is provided in **Figures 7-4 to 7-4d**. Thirty-two of the vegetation (land) units defined by Godwin (1985) and Gunness *et al.* (1987) were mapped in the Project area, with three of these further divided into sub-units, for a total of 38 vegetation units. Subdivision was required to adequately describe the vegetation variation evident in the Project area that was not present in the Weipa area where the vegetation unit scheme was originally derived. **Table 7-4** lists the vegetation units present and indicates the mapped area of each within the Project area. Of these, unit 2b (*Eucalyptus tetrodonta / Corymbia nesophila* Tall Woodland on lateritic red earths) is clearly the most widespread vegetation unit within the Project area (85,941ha), accounting for approximately 86% of the vegetation within the Project area and occurring almost exclusively upon the bauxite plateau areas (which is the area where mining is proposed). The remaining vegetation units are of much smaller spatial extent within the Project area and associated predominantly with drainage systems and coastal complexes that are peripheral to the bauxite plateau. The vegetation units and their equivalent REs are described in **Table 7-5,** and detailed descriptions of the vegetation of the Project area relating vegetation units to REs are provided in **Section 7.5.2** and **Appendix 7B**.

Figure 7-5 illustrates the typical sequence of vegetation types from the bauxite plateau to a middle freshwater reach of one of the major streams such as Norman Creek. This sequence of vegetation units is aligned with the changes in topography and substrate that occur from the top of the plateau, through the gentle sloping surfaces on the margins of the bauxite plateau, onto colluvial/alluvial flats, and finally into the moderately incised stream channel. The length and complexity of this vegetation sequence is generally less in upper reaches of drainage systems with more complex and extensive sequences occurring in downstream areas where greater incision of the bauxite plateau has typically occurred.

One of the key determinants of vegetation pattern within the Project area is the widespread occurrence of shallow groundwater discharge at the margins of drainage lines that dissect the laterite plateau. The shallow aquifer release occurs as a result of seepage of infiltrated rainfall that passes slowly through the surface strata and discharges from the sloping surfaces between the bauxite plateau and stream channels. This discharge may occur for an extended period after wet season rainfall has ceased.

In-stream spring heads mark the commencement of riparian gallery forest, including rainforest species (units 4a2, 4a3), which extends downstream; lateral seepage of shallow groundwater onto the landward margin of drainage corridors during and following the wet season promotes a swampy low woodland vegetation dominated by *Banksia dentata* with a sedge ground cover (units 5j1, 5j2, 5j3, 5j4, 7d). The rainforest/palm vegetation patches associated with head springs are very small and have affinities with unit 4a2 (refer **Table 7-4** and **Figure 7-8**). Where discharge is most persistent and of greater magnitude (typically in lower reaches) resultant elevated streamflows and lateral discharge has given rise to semi-permanent Melaleuca wetlands with associated sedgelands (units 3b, 12a, 12b).

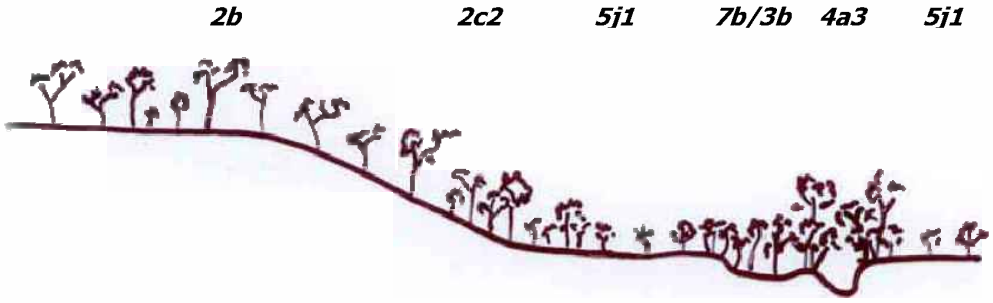
		Totals	100,372	100%

Notes:

1. A total of 100,367ha of terrestrial, wetland and estuarine vegetation was mapped within the Project area.



Note: Exaggerated vertical scale

Component Vegetation Units:	2b	Tall Darwin Stringybark woodland on lateritic red earths
	2c2	Tall Darwin Stringybark woodland on yellow earths/eroding slopes (typically on outer margins of drainage corridors)
	5j1	Bloodwood-Banksia in upper parts of broad basins with Swamp Box (*Lophostemon suaveolens*) and Lily Pily (*Syzygium angophoroides*) – outer fringe of permanent watercourses
	7b	Melaleuca/Swamp Mahogany on the outer margins of drainage depressions
	3b	*Melaleuca* swamp; zone at the most consistent water level
	4a3	Paperbark dominated riparian strip with rainforest understorey

Figure 7-5 Typical Vegetation Sequence on Edge of Plateau

A variety of wetland vegetation occurs within the Project area including freshwater, marine and brackish. The most distinctive freshwater wetlands are the typically circular, seasonal tree swamps dominated by *Melaleuca* spp. and *Lophostemon suaveolens* that occur within the bauxite plateau (units 3b, 7b, 12b). These tree swamps are not as numerous in the Project area as in the nearby Weipa area and occur predominantly in the northern part of the Project area (only six tree swamps have been identified in the Project area). More extensive freshwater and brackish treed wetland vegetation occurs along the lower reaches of the main stream systems (unit 3b), again dominated by *Melaleuca* spp. and heavily influenced by post wet season groundwater discharge flows and late dry season tidal penetration. Areas of open sedgeland (unit 12b) also occur behind mangrove systems in estuarine reaches. More detailed analysis of the ecology of these systems is provided in **Section 8**.

An array of vegetation types occur on coastal sand formations from grasslands on unconsolidated dunes (12c), shrubby Acacia dominated woodlands on hind dunes (7a), to semi evergreen notophyll vine forest on old hind dunes (3a). Dune formations do not occur along the entire coastline of the Project area as the bauxite plateau abuts the coast for the majority of the Gulf coastline and also the Hey River coastline. Consequently, vegetation communities on dune systems occur mainly as isolated pockets particularly in the vicinity of rocky headlands such as Boyd Point.

Mangrove communities occur predominantly in association with the three major drainage systems of the Project area (Winda Winda/Triluck Creek, Norman Creek, Ward River) with patches of fringing mangroves also occurring along the Embley–Hey River estuary. Within the Project area, mangrove communities attain greatest complexity and extent along Norman Creek and the Ward River. The mangrove species diversity within the Project area is typical of the tropical location. Upper estuarine areas of the three major drainage systems support a combination of mangrove, salt pan, *Melaleuca* wetland, and sedge swamp developed by topography, stream channel morphology, and highly variable salinity profiles that are determined by wet season freshwater flows and groundwater discharge.

Overall, the vegetation community of the Project area is typical of that occurring elsewhere on the western Cape on the bauxite plateau landform. Godwin (1985) described seven land systems for the Weipa region and mapped them as far south as Pera Head. The Andoom Land System is most applicable to the Project area and the most widespread, being associated with the following landform: low level plateau with sparse drainage and containing swampy sink holes and bordered by low gentle scarps (Godwin 1985). The Tullanaringa Land System of coastal beach ridges and swales is applicable to the coastal areas of the Project area where there is a more gradual topographic sequence to the coast as opposed to the bauxite cliffs. The Wenlock Land System of saline tidal flats and stream banks is apparent on the lower reaches of the Ward River, Norman Creek, Winda Winda Creek and to a lesser extent the Embley and Hey River systems. The Kurracoo Land System is described as moderately dissected undulating plains; it is largely erosional, though depositional surfaces occur along streams. Godwin (1985) mapped this system along the upper reaches of Norman Creek and its tributaries.

In contrast to the Weipa area and further north towards the Jardine River, the broad heathy swamps and drainage lines with insectivorous plants of the Jardine Land System do not occur within the Project area, apart from a small area on the northern branch of Norman Creek. Similarly, the Mapoon Land System of broad marine plains with sequences of palm forest, *Melaleuca* swamp and open sedgeland are not well developed within the Project area due to the tendency for the bauxite plateau to abut the coastline and a consequent lack of a well-developed marine plain landform.

7.5.2 Regional Ecosystems

There are a total of 28 REs within five different land zones currently appearing on the *Vegetation Management Act (1999)* (Qld) (VMA) certified mapping for the Project area (refer **Appendix 7C** for Version 6 VMA RE mapping). RE mapping is issued by DERM with caveats over the accuracy of mapping when interpreted at a property scale, and verification of RE mapping is required when used at a larger scale. RE mapping was produced at a scale of 1:100,000 and subsequently represents only broadscale mapping when considering the Project area at a scale of 1:10,000. Comparison of current RE mapping with the more detailed vegetation unit mapping prepared by ground-truthing of vegetation indicates some inaccuracies in the VMA RE mapping with respect to the complexity of REs occurring in the area, and the designation of RE types. The ground-truthed mapping undertaken for the Project identified 27 REs in the Project area. Three of the REs appearing on the VMA RE coverage of the Project area were not located during field surveys (RE 3.5.7x2a, 3.5.22a and 3.5.19x7). One RE appearing on the VMA RE mapping (RE 3.2.2a) is a variation of the main RE type and is represented on the Project RE mapping as the main RE type (i.e. RE 3.2.2). An additional three REs not included on VMA mapping were identified as present through field surveys for the Project (RE 3.1.1c, 3.3.5 and 3.3.21).

RE mapping was undertaken by assigning the existing RE type as defined by DERM that most closely described the vegetation unit identified during field surveys. In most cases, REs were a good fit for vegetation units. However, in some cases assigned REs did not accurately reflect the vegetation unit observed in the field and represent the closest available RE.

Figures 7-6, 7-6a, 7-6b, 7-6c and 7-6d are ground-truthed RE maps for the Project area using the vegetation unit mapping and equivalent REs as outlined in **Table 7-5**. A list of the 27 REs identified as occurring within the Project area is provided in **Table 7-5**. RE 3.5.2 (*Eucalyptus tetrodonta*, *Corymbia nesophila* tall woodland on deeply weathered plateaus and remnants) corresponds with vegetation units 2b and 2c1, and is the most widespread RE within the Project area comprising 87,465ha or approximately 86% of the vegetation in the Project area.

7.5.3 Threatened Vegetation Communities

Of the 27 REs occurring in the Project area, 24 are listed under the VMA as "Least concern", and three are listed under the VMA as "Of concern" (refer **Table 7-5**). There are no "Endangered" REs within the Project area.

Table 7-5 Regional Ecosystems Identified within the Project Area

RE	Description	VMA Status	Biodiversity Status	Corresponding Veg. Units		Ecological Values/ Comments	Extent in Reserves or Protected Areas in Cape York Bioregion[1]	Mapped[2] Vegetation Area in Project Area (ha)	Proportion of Vegetation in Project Area
				Main Veg. Unit(s)	Associated Veg. Units[3]				
Land Zone 1 – Marine Deposits									
3.1.1a	Closed forest of *Rhizophora stylosa* ± *Bruguiera gymnorhiza*. Occurs as outer mangroves. *Rhizophora stylosa* (Red Mangrove) often completely dominates, forming a very even, closed canopy (5–30m tall).	Least concern	No concern at present	3d	7d	Estuarine wetland	Medium representation, which includes: Cape Melville NP, Endeavour River NP, Iron Range NP, Jardine River NP, Lakefield NP.	481	0.5%
3.1.1c	Tall, buttressed trees of *Heritiera littoralis* (Looking Glass Mangrove) dominate a fairly even canopy (21–28m tall). Other tree species are frequently present in the canopy and a shrub layer (1.5–3.5m tall) is often present. In places, *Melaleuca cajuputi* (Cajuput Tree) is the most frequent canopy species.	Least concern	No concern at present	3d 3e	3b 7b 7d	Estuarine wetland	Medium representation, which includes: Cape Melville NP, Endeavour River NP, Iron Range NP, Jardine River NP, Lakefield NP.	122	0.1%
3.1.3	*Ceriops tagal* ± *Avicennia marina* low closed forest. Extensive on intertidal areas.	Least concern	No concern at present	6c 9a	7d	Estuarine wetland	Medium representation, which includes: Cape Melville NP, Endeavour River NP, Heathlands RR, Iron Range NP, Iron Range RR, Jardine River NP, Lakefield NP.	472	0.5%
3.1.5	*Sporobolus virginicus* closed tussock grassland. Occurs on coastal plains.	Least concern	No concern at present	12e		Estuarine wetland	Low representation, which includes: Lakefield NP.	4	<0.1%
3.1.6	Sparse herbland or bare saltpans. Associated with salt plains and saline flats.	Least concern	No concern at present	12e 12f 8c		Estuarine wetland	High representation, which includes: Cape Melville NP, Endeavour River NP, Iron Range NP, Jardine River NP, Lakefield NP.	633	0.6%
Land Zone 2 – Coastal sand dunes and swales									
3.2.2	Semi-deciduous vine thicket on coastal dunes and beach ridges	Least concern	Of concern	3a			No representation in protected areas on mainland within bioregion.	380	0.4%

3.7.3	*Eucalyptus cullenii* ± *E. tetrodonta* woodland on erosional escarpments and plains. Occurs on erosional escarpments and plains on the edge of the bauxite plateaus.	Least concern	No concern at present	5b 5f			Medium representation, which includes: • Mungkan Kandju NP.	245	0.2%
							Total	100,272[4]	100%

Abbreviations: RE = Regional Ecosystem; VMA = *Vegetation Management Act 1999* (Qld); NP = National Park; RR = Resources Reserve

Notes:

1. Reserved extent based on data from RE Description Database and data from Accad *et al.* (2008), which relies on 2005 remnant mapping. Note that RE mapping is incomplete for Cape York Bioregion and thus actual hectare values are not available for all REs.
2. According to revised mapping prepared for this Project (refer Figure 7-6).
3. Associated Veg. Units comprise vegetation units that can occur within more than one land zone and therefore may be attributed to more than one RE.
4. Area discrepancy from mapped vegetation within Project area due to rounding up area totals.

A RE is regarded as "Of concern" under the VMA if between 10 and 30% of its pre-clearing extent remains within the bioregion (i.e. if the majority of the RE has been cleared); or more than 30% of its pre-clearing extent remains but the remaining extent is less than 10,000ha (i.e. naturally limited distribution). Each of the "Of concern" REs occurring within the Project area has been assessed as such due to a natural limited distribution, and none have experienced significant reduction in their pre-clear extent within the Project area or elsewhere in the Cape York Bioregion. The extent to which each of the "Of concern" REs occurring in the Project area is represented in Bioregional conservation reserves is indicated in **Table 7-5**. There are no conservation reserves occurring in the main catchments making up the Project area and therefore the five "Of concern" REs are not represented in conservation reserves at the catchment level.

The Biodiversity Status of REs is also indicated in **Table 7-5**. All the REs present have a similar "No concern at present (Least concern)" or "Of concern" status to the VMA status apart from RE 3.2.2 and RE 3.2.10c which have an 'Of concern' Biodiversity Status. The Biodiversity Status scheme was developed by the DERM (formerly the Environment Protection Agency) as an alternative conservation status scheme to the VMA.

The Biodiversity Status has no regulatory power but provides an indication of conservation value of individual REs from a more ecological perspective compared to the VMA status which relies substantially on proportions of pre-disturbance and remnant areas. The three Biodiversity Status classes mirror those of the VMA and comprise:

- No concern at present (similar to "Least concern" under the VMA);
- Of concern; and
- Endangered.

The EPBC search did not identify any EECs as likely to occur within the Project area, and none were identified during the field surveys.

7.6 Flora

7.6.1 Overview of Flora

A total of 519 plant taxa has been recorded from all vegetation types within the Project area based on results of preliminary and EIS surveys. This constitutes approximately 58% of the 887 species of vascular plant taxa currently known to occur over all of RTA's Weipa mining leases. It is likely that numerous additional species known to occur within RTA's mining leases would be identified within the Project area if additional surveys were to be carried out during the wet season.

A list of the flora species recorded from the Project area is provided in **Appendix 7D**. **Table 7-6** summarises the floristic diversity at different taxonomic levels and indicates there is considerable floristic diversity within the Project area, reflecting the diversity of vegetation types and habitats present including closed forest, woodland, and a range of stream and wetland habitats. A total of 184 (or approximately 36% of the total compliment of species from the Project area) has been identified from *Eucalyptus tetrodonta* dominated vegetation (unit 2b), which is the vegetation type occurring where mining is proposed. This vegetation type comprises approximately 85% of the Project area.

The composition of plant families present reflects the variety of habitats with Lauraceae, Annonaceae, Sapindaceae, Moraceae and Clusiaceae especially indicative of vine forest and moist riparian gallery forest; Myrtaceae indicative of sclerophyllous vegetation types including eucalypt woodland, but especially boosted by a substantial diversity of Melaleuca occurring predominantly in wetland habitats; Cyperaceaea and Restionacaeae indicative of wetland habitats; Rhizophoraceae indicative of mangroves; and, Poaceae well represented across all habitats.

Table 7-6 Floristic Diversity of the Project Area at Different Taxonomic Levels

Taxonomic Level	All Vegetation Types	*Eucalyptus tetrodonta* Vegetation Types	*Eucalyptus tetrodonta* Vegetation Types as Proportion of Total
Family	110	57	52%
Genus	343	132	39%
Species	519	184	36%

Particularly well represented families comprised Poaceae (51 species), Fabaceae (38), Cyperaceae (22), Euphorbiaceae (22), and Rubiaceae (20). Particularly well represented genera comprised Melaleuca (12), Acacia (9), Ficus (7), Corymbia (5), Dianella (5), and Cryptocarya (5).

The most widespread species within the Project area were the key species associated with *Eucalyptus tetrodonta* woodland (vegetation unit 2b/2c1, RE 3.5.2), as this is by the far the most abundant vegetation type. The most widespread species comprised the trees *Eucalyptus tetrodonta*, *Corymbia nesophila*, *Erythrophleum chlorostachys* and *Parinari nonda*; the tall shrubs *Planchonia careya*, and *Acacia rothii*; and the ground cover species *Heteropogon triticeus*, *Coelospermum reticulatum*, *Spermacoce brachystema* and *Smilax australis*.

7.6.2 Threatened Flora – EPBC Act

The Commonwealth EPBC Act provides for the listing and protection of threatened flora in Australia. The threatened status categories for flora under the EPBC Act in order of increasing conservation significance are vulnerable, endangered, critically endangered or conservation dependant. **Table 7-7** lists the threatened flora species that:

- have been previously recorded from within or in close proximity to the Project area (DERM 2009c, Queensland Herbarium 2009);
- have been found during surveys for the EIS;
- could potentially occur within the Project area based on EPBC database search; and
- could potentially occur within the Project area based on previous surveys in the Weipa area for RTA.

An assessment is provided of each species' potential occurrence in the Project area based on their habitat requirements and the condition and array of habitats available. The source of records for each species is indicated in **Table 7-7** along with the preferred habitat and known occurrence in the Weipa region. **Figure 7-7, Figure 7-7a** and **Figure 7-7b** detail the location of threatened flora recorded during field surveys.

Of the 6 species identified as potential inhabitants of the Project area, all are listed as vulnerable, and:

- 2 species have been confirmed as present in the Project area;
- 1 species is likely to occur in the Project area; and
- 3 species possibly occur in the Project area.

The REs that represent potential habitat for each species are provided in **Table 7-7**. Refer to **Figure 7-6, Figure 7-6a, Figure 7-6b, Figure 7-6c** and **Figure 7-6d** for the location and distribution of these REs within the Project area. Refer to **Table 7-10** for data on the area of proposed disturbance of REs compared to the total area within the Project area, the Weipa Plateau subregion, and the Cape York Bioregion.

Table 7-7 Threatened Flora Listed Under the EPBC Act

Species **Common Name [Family] (Source of Record)**	**EPBC Status**	**Growth Form and Habitat**	**Likelihood of Occurrence within Project Area and Areas of Proposed Disturbance within the Project Area (Site)**
Calophyllum bicolor No common name [Clusiaceae] (Wild, epbc)	V	A small fire sensitive tree known to be associated with permanent groundwater seepage zones, particularly in evergreen vine forest. Potential habitats comprise RE 3.3.5 (Refer to **Figures 7-6** to **7-6d** for the locations of RE's within the Project area).	**Project Area** **Possible**: not detected during field surveys of five semi-permanent groundwater seepage rainforest patches, close to proposed mining areas, that provide suitable habitat for the species, but may occur in the Project area in groundwater-fed riparian gallery forest or seepage zones nearer the coast. Only limited areas of suitable fire retardant habitat occur within the Project area. Six other semi-permanent seepage areas surveyed outside the infrastructure footprint did not have suitable habitat present. **Mining Area** **Unlikely:** No suitable habitat exists in Darwin Stringybark woodland. **Dam C on Norman Creek and infrastructure footprint** **Unlikely:** targeted surveys of the dam area and infrastructure crossings of riparian areas indicated with a high reliability that this species is not present in these locations.
Dendrobium bigibbum (also known as *Vappodes bigibba)* Cooktown Orchid [Orchidaceae] (Wild, epbc)	V	An epiphyte that grows on trees and rocks in situations with moderate light intensity. Occurs in a range of fire sensitive habitats including coastal scrub, streambank vegetation, monsoon thickets, and gullies in open forest and woodland where fire cannot penetrate. In the Weipa area grows as an epiphyte on trees (rocks absent) and commonly encountered in coastal vine forest and vine forest on bauxite. Potential habitats comprise REs 3.1.1a, 3.1.1c, 3.2.2, 3.3.5, 3.5.4 (Refer to **Figures 7-6** to **7-6d** for the locations of RE's within the Project area).	**Project Area**: **Confirmed:** located in coastal and non-coastal vine forest, and mangrove edges at several locations within the Project area that would not be affected by mining or infrastructure. **Mining Area** **Unlikely:** no suitable habitat exists in Darwin Stringybark woodland. **Dam C on Norman Creek and infrastructure footprint** **Confirmed**: identified in pockets of riparian rainforest within the footprint of Dam C, in the vicinity of the infrastructure corridor crossings on Norman Creek, and vicinity of road crossings of Norman Creek and Winda Winda Creek.

Species **Common Name [Family] (Source of Record)**	**EPBC Status**	**Growth Form and Habitat**	**Likelihood of Occurrence within Project Area and Areas of Proposed Disturbance within the Project Area (Site)**
Dendrobium johannis (also known as *Cepobaculum johannis)* Chocolate Tea tree Orchid [Orchidaceae] (+)	V	An epiphyte that grows in open humid habitats, on slopes in open woodland, close to swamps and in pockets of monsoon forests. It has been recorded growing on Tea-tree in Melaleuca woodland and in coastal semi-evergreen vine thicket. In the Weipa area commonly encountered growing on Melaleuca and Syzygium suborbiculare on the margin of Melaleuca swamps and riparian gallery forest. Potential habitats comprise REs 3.2.3, 3.3.5, 3.3.9, 3.3.14a, 3.3.21 (Refer to **Figures 7-6** to **7-6d** for the locations of RE's within the Project area).	**Project Area** **Confirmed:** located in riparian gallery forest and Melaleuca dominated swamps particularly along major drainage lines and associated tributaries throughout the Project area, in areas not to be disturbed. **Mining Area** **Unlikely:** no suitable habitat exists in Darwin Stringybark woodland. **Dam C on Norman Creek and infrastructure footprint** **Confirmed**: occurs within the infrastructure corridor where it crosses Norman Creek.
Myrmecodia beccarii Ant Plant [Rubiaceae] (+)	V	A tuberous epiphyte known to grow in *Melaleuca* woodland and mangrove areas. Recently recorded from the Weipa area in a small groundwater seepage forest. Potential habitats comprise REs 3.1.1a, 3.1.1c, 3.1.3, 3.3.14a, 3.3.5 (Refer to **Figures 7-6** to **7-6d** for the locations of RE's within the Project area).	**Project Area** **Possible**: this species is of very restricted distribution in the Weipa area. If a permanent groundwater seepage zone was identified within the Project area, this species may occur within this zone. At present only semi-permanent groundwater seepage zones have been identified within the Project area. The species may also occur within or on the landward margin of mangroves within the Project area. **Mining Area** **Unlikely:** no suitable habitat exists in Darwin Stringybark woodland. **Dam C on Norman Creek and infrastructure footprint** **Unlikely:** targeted surveys of the dam area and infrastructure crossings of riparian areas indicated with a high reliability that this species is not present in these locations.
Solanum dunalianum Beach Nightshade [Solanaceae] (Wild, epbc)	V	An herbaceous shrub growing to 2–4m and found in or at the edge of semi deciduous vine forest. Potential habitats comprise REs 3.2.2, 3.5.2 (Refer to **Figures 7-6** to **7-6d** for the locations of RE's within the Project area).	**Project Area** **Likely**: not detected during field surveys but suitable coastal vine forest and vine forest on bauxite habitat occurs in the Project area in areas not to be disturbed. **Mining Area** **Unlikely:** no suitable habitat exists in Darwin Stringybark woodland. **Dam C on Norman Creek and infrastructure footprint** **Unlikely:** within the Project area the species is expected to be restricted to more mesic habitats, particularly coastal vine forest and vine forest on bauxite,

Species **Common Name** **[Family]** **(Source of Record)**	**EPBC Status**	**Growth Form and Habitat**	**Likelihood of Occurrence within Project Area and Areas of Proposed Disturbance within the Project Area (Site)**
Spathoglottis plicata No common name [Orchidaceae] (epbc)	V	A terrestrial orchid with flower stems to 1m that grows in or close to swamps, in seasonally inundated areas and in moist, grassy patches close to streams, in Melaleuca swamp forest and riparian gallery closed forest. Flowers during wet season, difficult to detect when not flowering. Potential habitats comprise REs 3.2.3, 3.3.5, 3.3.9, 3.3.14a, 3.3.21 (Refer to **Figures 7-6** to **7-6d** for the locations of RE's within the Project area).	**Project area** **Possible**: not detected during field surveys anywhere within the Project area but suitable stream, wetland and seepage habitat occurs extensively in the Project area in areas that would not be directly disturbed by the Project. **Mining Area** **Unlikely:** No suitable habitat exists in Darwin Stringybark woodland. **Dam C on Norman Creek and infrastructure footprint** **Possible:** potential habitat for the species occurs within the proposed footprint of Dam C and the infrastructure corridor crossing of Norman Creek, although targeted surveys did not locate the species within these areas.

Profiles of each of the 6 species are provided below.

Calophyllum bicolor

Calophyllum bicolor is currently known only from 17 populations on Cape York Peninsula (DERM 2010). It occurs on spring-fed areas that form a distinct habitat with evergreen rainforest and permanently wet substrates, but does not occur on stream banks away from the spring heads. There are four specimen records of the species from the Weipa area, but the species has not been recorded from the Project area. Permanently wet spring heads supporting vine forest have not been identified within the Project area and are therefore considered not as common within the Project area as in the Weipa area. However, five semi-permanent springs/seepage zones with suitable habitat were located and surveyed for the species close to proposed mining areas, but the species was not present. Six other seepage zones lacking suitable habitat were surveyed and the species was not present. Unsurveyed isolated habitats with these characteristics may occur at the margin of wetlands in the lower freshwater sections of drainages (Norman Creek, Ward River, Winda Winda Creek) and may support the species. Potential habitats for the species comprise:

- vegetation units 4a2, 4b; and
- RE 3.3.5.

Vegetation unit 4a2 occurs within the proposed footprint of Dam C on a freshwater tributary of Norman Creek; however, *Calophyllum bicolor* was not located in this area during targeted surveys. The species was not recorded during other surveys of the 4a2 and 4b vegetation communities.

Cooktown Orchid (Dendrobium bigibbum)

The Cooktown Orchid has been recorded from several locations in the Weipa region, particularly in notophyll vine forest on coastal dunes and on lateritic red earths. The habitat preference of this species in the Weipa region is well known, and the Cooktown Orchid is restricted to closed forest, typically as an epiphyte in rainforest or vine thicket habitats. The species is sensitive to fire and therefore is found only in situations where frequent fires do not occur. Vine forest patches on bauxite provide the required fire protection but with respect to riparian gallery forest the species is more commonly encountered inside broad occurrences of the vegetation, or where lateral seepage zones and mesic ground vegetation suppress fire frequency and scorch height.

The Cooktown Orchid was recorded within the Project area in coastal vine forest and mangroves near the mouth of Norman Creek, in mangroves on the Ward River and in areas of riparian rainforest and riparian gallery forest throughout the Project area. The species was not located in other vine forest areas on bauxite, although it may occur in these areas which occur in the Hey Point area. It is likely the Cooktown Orchid also occurs in other coastal vine forest areas that were not surveyed to the north of Norman Creek and in the Hey Point area.

Potential habitats for the species comprise:

- vegetation units 3a, 3c, 3d, 3e, 4a1; and
- REs 3.1.1a, 3.1.1c, 3.2.2, 3.3.5, 3.5.4.

The Cooktown Orchid occurs within the proposed footprint of Dam C, and in the vicinity of a proposed Mine Access Road crossing of an upper Norman Creek tributary.

Chocolate Tea Tree Orchid (Dendrobium johannis)

The Chocolate Tea Tree Orchid has been recorded from several locations in the Weipa region, including the Andoom, Weipa and Ely mining lease areas. The habitat preferences of this species are well known and the Chocolate Tea Tree Orchid is restricted to mesic habitats, typically as an epiphyte on mature *Syzygium* spp. and *Melaleuca* spp. trees in riparian gallery forest and on the margins of swamp habitats and their associated ecotones.

In the Project area the species has been located in riparian gallery forest and Melaleuca dominated swamps particularly along major drainage lines and associated tributaries. It is anticipated that the species occurs in these habitats throughout the Project area.

Potential habitats for the species comprise:

- vegetation units 3b, 4a2, 4a3, 4b, 5j1, 5j4, 5d, 7b, 7d; and
- REs 3.2.3, 3.3.5, 3.3.9, 3.3.14a, 3.3.21.

Chocolate Tea Tree Orchid occurs within the infrastructure corridor downstream of Dam C, and in the vicinity of proposed Mine Access Road crossings of Winda Winda Creek and an upper Norman Creek tributary.

Ant Plant (Myrmecodia beccarii)

The Ant Plant is known from a variety of denser canopy habitats on Cape York including mangroves, *Melaleuca* dominated wetlands, coastal scrubs, and groundwater seepage zones with swamp vine forest. The Ant Plant was recently recorded from the Weipa area in a small groundwater seepage forest but is apparently of very restricted distribution in the Weipa area. The Ant Plant was not located during extensive targeted surveys in suitable habitat but may occur within the Project area if any permanent groundwater seepage zones are present (currently only semi-permanent groundwater seepage zones have been identified within the Project area) or mangrove areas that were not inspected during surveys.

Potential habitats for the species comprise:

- vegetation units 3b, 3d, 3e, 4a2, 6c, 7b, 7c, 7d; and
- REs 3.1.1a, 3.1.1c, 3.1.3, 3.3.14a, 3.3.5.

Potential habitat for the species does not occur within proposed mining areas, and surveys of suitable habitat within the footprint of proposed infrastructure areas did not locate the species.

Beach Nightshade (Solanum dunalianum)

Beach Nightshade is known from a few records near Weipa and on Torres Strait islands, although recent surveys for known populations in the Weipa area failed to relocate the species despite targeted searching (Landsberg and Clarkson 2004). The species has generally been recorded from semi-deciduous notophyll vine forest and the edges of this community, and in the Weipa area has been recorded from vine thicket vegetation on coastal dunes between Pennefather and Duyfken areas north of Weipa and vine forest on bauxite on the north shore of the Embley River near Napranum (Jason Searle pers. comm.). The distribution of this species in the region is poorly known with only a few specimens collected, but it appears likely to be more prevalent in closed forest vegetation.

The species was not recorded during surveys for the Project. Within the Project area it is expected to be restricted to more mesic habitats, particularly coastal vine forest and vine forest on bauxite, and consequently it is highly unlikely populations of this plant would occur in areas subject to mining operations or infrastructure development within the Project area.

Potential habitat for the species comprises:

- vegetation units 3a 3c, 6a and ecotones; and
- REs 3.2.2, 3.5.2 (margins) and ecotones.

Spathoglottis plicata

Spathoglottis plicata is known from Cape York between Cooktown and the Jardine River and has been recorded from the Weipa region (DEWHA 2008e). The species was not recorded during targeted surveys in the Project area. *Spathoglottis plicata* typically occurs in or close to swamps, in seasonally inundated areas and in moist, grassy patches close to streams, in Melaleuca swamp forest and riparian gallery rainforest (Jones 1988; Dockrill 1992, Landsberg and Clarkson 2004). The species may be difficult to detect in the field if not flowering and when

aerial shoots are absent, and the potential presence of this species in suitable habitat within the Project area cannot be discounted.

Potential habitat for the species comprises:

- vegetation units 3b, 4a1, 4a3, 4b, 5j1, 5j4, 5d, 7b, 7d; and
- REs 3.2.3, 3.3.5, 3.3.9, 3.3.14a, 3.3.21.

Potential habitat for the species occurs within the proposed footprint of Dam C and the infrastructure corridor crossing of Norman Creek, although targeted surveys did not locate the species within these areas or elsewhere within the Project area.

7.6.3 Threatened Flora – NC Act

The Queensland *Nature Conservation Act 1992* (NCA) provides for the listing and protection of threatened flora in Queensland. The main threatened status categories for flora under the NCA in order of increasing conservation significance are "near threatened", "vulnerable" and "endangered. **Table 7-8** lists the threatened flora species that:

- have been previously recorded from within or in close proximity to the Project area (DERM 2009c, Queensland Herbarium 2009);
- have been found during surveys for the EIS;
- could potentially occur within the Project area based on EPBC database search; and
- could potentially occur within the Project area based on previous surveys in the Weipa area for RTA.

An assessment is provided of each species' potential occurrence in the Project area based on their habitat requirements and the condition and array of habitats available. The source of records for each species is indicated in **Table 7-8** along with the preferred habitat and known occurrence in the Weipa region.

Of the 16 NCA listed species identified as potential inhabitants of the Project area:

- 2 species have been confirmed as present in the Project area;
- 2 species are likely to occur in the Project area;
- 11 species possibly occur in the Project area; and
- 1 species is unlikely to occur in the Project area.

Profiles for these species are set out below, but also refer to profiles in **Section 7.6.2** for those species that are also listed under the EPBC Act.

Acacia fleckeri

Acacia fleckeri has been recorded from several locations in the Weipa region, including the riparian corridor of the Hey River. *Acacia fleckeri* is known from sandy creek or river banks or on shell mounds in fringing woodland with species of *Melaleuca*, *Leptospermum*, *Eucalyptus* and other *Acacia* species. In the Weipa area the species is known primarily from riparian gallery forest. This species was not recorded in the Project area; however, suitable habitats for the species are well represented within the Project area, and it is likely that the species occurs within the Project area, at least in the Hey River area.

Potential habitats for the species comprise:

- vegetation units 4a1, 4a3, 5e, 5j1; and
- REs 3.3.9, 3.3.21, 3.5.22c.

Potential habitat for *Acacia fleckeri* occurs within the proposed footprint of Dam C and the infrastructure corridor crossing of Norman Creek; however, the species was not observed in these areas during targeted surveys and is not expected to occur in these areas.

Table 7-8 Threatened Flora Listed Under the NC Act

Species **Common Name [Family] (Source of Record)**	**NCA Status**	**Growth Form and Habitat**	**Likelihood of Occurrence within Project Area**
Acacia fleckeri No common name [Mimosaceae] (Wild)	NT	A small to medium tree restricted to Cape York Peninsula. Known from sandy creek or river banks or on shell mounds in fringing woodland with species of *Melaleuca, Leptospermum*, *Eucalyptus* and other *Acacia* species. Occurs in riparian gallery forest in the Weipa area.	**Likely**: not located during field surveys but specimen record from the Hey River area. Likely to occur in the Hey Point area and possibly in other areas of fringing vegetation.
Acacia ommatosperma No common name [Mimosaceae] (Wild)	NT	A shrub or small tree known from ironstone ridges and erosional edges of the bauxite plateau in *Eucalyptus tetrodonta* open forest habitats, and also *Corymbia clarksoniana* woodland on alluvium/colluvium. Restricted to the Weipa area of Cape York Peninsula.	**Possible**: not detected during field surveys but may occur in association with ironstone outcrops within the Project area.
Albizia retusa No common name [Mimosaceae] (Wild)	NT	A small to medium tree found in *Eucalyptus tetrodonta* open forest habitats particularly near vine forest. Known from the Weipa area.	**Possible**: not detected during field surveys but may occur in *Eucalyptus tetrodonta* habitats within the Project area.
Calophyllum bicolor No common name [Clusiaceae] (Wild, epbc)	V	A small fire sensitive tree known to be associated with groundwater seepage zones particularly in evergreen vine forest.	**Possible**: not detected during field surveys but may occur in the Project area in more robust groundwater-fed riparian gallery forest or seepage zones near the coast. Only limited areas of suitable fire retardant habitat occur within the Project area.
Combretum trifoliatum Sepang [Combretaceae] (herb)	NT	A small to medium tree known from riparian gallery forest in the western Cape York area. Little known in the Weipa area.	**Unlikely**: few records in the vicinity of the Project area despite substantial survey effort, and not located in the Project area during EIS field surveys.
Dendrobium bigibbum (also known as *Vappodes bigibba*) Cooktown Orchid [Orchidaceae] (Wild, epbc)	V	An epiphyte that grows on trees and rocks in situations with moderate light intensity. Occurs in a range of fire sensitive habitats including coastal scrub, streambank vegetation, monsoon thickets, and gullies in open forest and woodland where fire cannot penetrate. In the Weipa area grows as an epiphyte on trees (rocks absent) and commonly encountered in coastal vine forest and vine forest on bauxite.	**Confirmed**: located in coastal and non-coastal vine forest, and mangrove edges at several locations within the Project area.
Dendrobium johannis (also known as *Cepobaculum johannis*) Chocolate Tea Tree Orchid [Orchidaceae] (+)	V	An epiphyte that grows in open humid habitats, on slopes in open woodland, close to swamps and in pockets of monsoon forests. It has been recorded growing on Tea-tree in Melaleuca woodland and in coastal semi-evergreen vine thicket. In the Weipa area commonly encountered growing on Melaleuca and *Syzygium suborbiculare* on the margin of Melaleuca swamps and riparian gallery forest.	**Confirmed**: located in riparian gallery forest and Melaleuca dominated swamps particularly along major drainage lines and associated tributaries.
Habenaria hymenophylla Rainforest Habenaria [Orchidaceae] (Wild)	NT	Little known species with records from the Weipa area. Occurs in vine forest.	**Possible**: difficult to predict occurrence but may occur in the Project area in vine forest habitats.
Heterachne baileyi No common name [Poaceae] (Wild, herb)	NT	A tussock grass known from *Eucalyptus tetrodonta* dominated woodlands on lower slopes of the plateau, and *Melaleuca viridiflora* woodland on floodplains.	**Possible**: not detected during field surveys but may occur in *E. tetrodonta* woodlands within the Project area.

Species **Common Name** **[Family]** **(Source of Record)**	**NCA Status**	**Growth Form and Habitat**	**Likelihood of Occurrence within Project Area**
Hoya revoluta No common name [Ascleiadaceae] (Wild, herb)	NT	A climbing or scrambling vine recorded from vine forest on coastal dunes and lateritic red earths. Record from Pennefather area north of Weipa.	**Possible**: not detected during field surveys but may occur in coastal and bauxite vine forest habitats within the Project area.
Lepturus geminatus No common name [Poaceae] (Wild)	NT	Tussock grass. Record from the Weipa area.	**Possible**: difficult to predict occurrence but may occur in the Project area.
Lindsaea walkerae No common name [Lindsaeaceae] (Wild)	NT	A terrestrial fern found near streams and in swamps. Record from the Weipa area.	**Possible**: not detected during field surveys but may occur in wetland and riparian gallery forest in the Project area.
Myrmecodia beccarii Ant Plant [Rubiaceae] (+)	V	A tuberous epiphyte known to grow in *Melaleuca* woodland and mangrove areas. Recently recorded from the Weipa area in a small groundwater seepage forest.	**Possible**: this species is of very restricted distribution in the Weipa area. If a permanent groundwater seepage zone was identified within the Project area, this species may occur within this zone. At present only semi-permanent groundwater seepage zones have been identified within the Project area. The species may also occur within mangroves within the Project area.
Sarcolobus vittatus No common name [Apocynaceae] (Wild)	V	Record from Unigan Nature Reserve at Weipa. Little known species.	**Possible**: not detected during field surveys but may occur in riparian gallery forest in lower sections of drainage lines.
Solanum dunalianum Beach Nightshade [Solanaceae] (Wild, epbc)	V	An herbaceous shrub growing to 2–4m and found in or at the edge of semi deciduous vine forest.	**Likely**: not detected during field surveys but suitable coastal vine forest and vine forest on bauxite habitat occurs in the Project area.
Spathoglottis plicata No common name [Orchidaceae] (epbc)	V	A terrestrial orchid with flower stems to 1m that grows in or close to swamps, in seasonally inundated areas and in moist, grassy patches close to streams, in Melaleuca swamp forest and riparian gallery rainforest	**Possible**: not detected during field surveys but suitable stream, wetland and seepage habitat present within Project area.

V	Vulnerable
NT	Near threatened

Acacia ommatosperma

The small tree *Acacia ommatosperma* was recently recorded in Darwin Stringybark (*Eucalyptus tetrodonta)* open forest habitat near Weipa. This tree has not been recorded elsewhere in the Weipa region, despite targeted survey effort in parts of the Weipa mining leases and in the SoE Project area. Other records for *Acacia ommatosperma* for the Cape York Peninsula bioregion indicate this species favours ironstone outcrops within Darwin Stringybark open forest. Given the occurrence of similar ironstone ridge habitat within the Darwin Stringybark woodlands of the Project area, it is considered possible that *Acacia ommatosperma* occurs in the Project area within Darwin Stringybark open forest where it grades locally into ironstone outcrops.

Potential habitat for the species comprises:

- vegetation unit 2b (small pockets where ironstone outcrops occur); and
- RE 3.5.2.

Vegetation unit 2b occurs within the proposed mining areas. The species was not recorded during the surveys of the 2b vegetation community but may occur in isolated pockets within this vegetation unit.

Albizia retusa

Records of the small tree *Albizia retusa* in the broader Cape York Bioregion indicate the species as occurring in Darwin Stringybark woodland, typically within the ecotone with adjoining notophyll vine forest. The distribution of *Albizia retusa* in the Weipa region is insufficiently known, being recorded in Darwin Stringybark open forest only in the Ely mining lease north east of Weipa (Dames and Moore 1996). Recent targeted flora surveys in this area failed to identify the tree; however, the related small tree *Albizia procera* was recorded with some regularity, and previous records for *Albizia retusa* may have been a result of taxonomic misidentification. *Albizia retusa* was not recorded during targeted surveys in the Project area. Nevertheless, ecotonal habitat between Darwin Stringybark woodland and vine forest occurs within the Project area and it is possible the species occurs in these areas.

Potential habitats for the species comprise:

- vegetation unit 2b adjoining 3c; and
- RE 3.5.2 adjoining 3.5.4.

Potential habitat for this species occurs in close proximity to vine forest on bauxite within the general mining area; however, it is likely the ecotonal area typically occupied by the species would fall within the environmental buffer area to be established around vine forest areas. The species was not recorded within these areas during targeted surveys.

Sepang *(Combretum trifoliatum)*

The distribution of this species is known from a few specimens and not well known in the Weipa region generally. Within the Weipa area Sepang is a tree of riparian gallery forest and is expected to be restricted to these types of riparian mesic habitat areas. The closest record to the Project area comes from the more substantial riparian gallery forests of the Wenlock River. Riparian gallery forest occurs throughout the Project area on the main drainages; however, this habitat type was subject to considerable survey effort and together with the lack of records of the species from the nearby Weipa Peninsula it is regarded as unlikely that Sepang occurs within the Project area.

Potential habitats for the species comprise:

- vegetation units 3a, 3c, 4a2; and
- REs 3.2.2, 3.3.5, 3.5.4.

Habenaria Hymenophylla

This is a little known terrestrial orchid species from Cape York and Torres Strait islands with a record from Weipa (Gunness *et al.* 1987). The species apparently occurs in vine forest but little

detail is available on the preferred habitats. The species was not observed during surveys of the Project area but is considered to possibly occur within vine forests in the area. It is likely that the species may be difficult to locate during field surveys at different times of the year.

Potential habitats for the species comprise:

- vegetation unit 3c, 4a2; and
- REs 3.2.2, 3.5.4.

None of the potential habitats of *Habenaria hymenophylla* occur within proposed mining or infrastructure areas.

Heterachne baileyi

Heterachne baileyi is known to occur on the lower slopes of the bauxite plateau in Darwin Stringybark woodland and on adjoining low lying areas dominated by *Melaleuca viridiflora*. The species has been recorded from the vicinity of the Aurukun Road near the eastern boundary of the Project area and possibly occurs within the Project area, although not recorded during field surveys.

Potential habitats for the species comprise:

- vegetation units 2c1, 2c2, 5e, 5j2, 5j4; and
- REs 3.3.14a, 3.3.49a, 3.3.50a, 3.5.2, 3.5.22c.

Potential habitat for *Heterachne baileyi* is located within the proposed footprint of Dam C and within the proposed infrastructure corridor crossing of Norman Creek, although the species was not recorded during targeted surveys of these areas.

Hoya *(Hoya revoluta)*

Hoya has been recorded from several locations in the Weipa region, particularly in notophyll vine forest on coastal dunes and on lateritic red earths. Hoya typically occurs as a climbing or scrambling vine and may be difficult to detect under certain seasonal conditions. The species was not recorded during targeted surveys of favoured habitat types but may occur within the Project area.

Potential habitats for the species comprise:

- vegetation units 3a, 3c; and
- REs 3.2.2, 3.5.4.

None of the potential habitats of *Hoya revoluta* occur within proposed mining or infrastructure areas.

Lepturus geminatus

Lepturus geminatus is a grass species known only to occur in northern Queensland and the Northern Territory. It is typically found growing on sand within and at the edges of evergreen vine forests and also on the inland faces of sand dunes; however, the habitat preferences of the species on Cape York are not well known. This species has not been recorded from the Project area but may occur in areas of suitable habitat.

Potential habitats for the species comprise:

- vegetation units 3a, 5c, 12c; and
- REs 3.2.2, 3.2.6a, 3.2.25.

None of the potential habitats of *Lepturus geminatus* occur within proposed mining or infrastructure areas.

Lindsaea walkerae

Lindsaea walkerae is a terrestrial creeping fern found near streams and within swamps. It has been recorded from a number of locations on northern Cape York and elsewhere in northern

Australia with a record from Weipa. This species has not been recorded from the Project area but may occur in areas of suitable habitat. Potential habitats for the species comprise:

- vegetation units 4a1, 4a2, 4a3, 4b, 4c, 7b, 12a; and
- REs 3.3.5, 3.3.9, 3.3.14a, 3.3.64, 3.3.65.

Potential habitat for *Lindsaea walkerae* occurs within the proposed footprint of Dam C and the infrastructure corridor crossing of Norman Creek, although the species was not recorded during targeted surveys of these areas.

Sarcolobus vittatus

This is a little known plant recorded from Unigan Nature Reserve near Weipa. Based on the occurrence of the species at Unigan potential habitats for the species include riparian gallery forest, coastal vine forest and possibly landward mangrove communities. The species was not recorded from the Project area but may occur in these habitats within the Project area.

Potential habitats for the species comprise:

- vegetation units 3a, 3c, 3d, 3e, 4a2; and
- REs 3.1.1c, 3.2.2, 3.3.5.

None of the potential habitats of *Sarcolobus vittatus* occur within proposed mining or infrastructure areas.

7.6.4 Introduced Flora and Weeds

No weeds or introduced flora species have been confirmed as occurring within the Project area, although there was an unverified sighting of the invasive scrambler Rubber Vine (*Cryptostegia grandiflora*) on the lower reaches of Norman Creek. The lack of weeds in the Project area is due predominantly to the limited amount of disturbance within the area, and relatively minimal visitation by vehicles potentially carrying weed propagules.

There are a number of weeds in the Weipa region that occur in similar habitats to those present within the Project area and these species could become established in the Project area if weed propagules entered the Project area. Species from the Weipa region that pose the greatest risk to the Project area in terms of alteration of natural habitat include:

- Gamba Grass (*Andropogon gayanus*);
- Rubber Vine (*Cryptostegia grandiflora*);
- Noogoora Burr (*Xanthium occidentale*)
- Guinea Grass (*Panicum maximum*);
- Stinky Passionfruit (*Passiflora foetida*);
- Parkinsonia (*Parkinsonia aculeate*);
- Hyptis (*Hyptis suaveolens*);
- Para Grass (*Urochloa mutica*); and
- Caltrop (*Tribulus terrestris*).

In Aurukun, cultivated and disturbance exotics that are known to be environmental weeds elsewhere in Australia include:

- Coral vine (*Antiogonon leptopus*);
- Neem tree (*Azadirachta indica*);
- Butterfly tree (*Bauhina monandra*);
- Golden shower tree (*Cassida fistula*);
- Centra (*Centrosema molle*);

- Poinciana (*Delonix regia*);
- Cupid's flower (*Ipomoea quamoclit*);
- Rangoon Creeper (*Quisqualis indica*); and
- Sicklepod (*Senna obtusifolia*) (Cook Shire 2007).

Other significant weed species known from northern Cape York Peninsula that may become established in the Project area include:

- Leucaena (*Leucaena leucocephala*);
- Grader Grass (*Themeda quadrivalvis*);
- Lion's Tail (*Leonitis nepetaefolia*);
- Pond Apple (*Annona glabra*); and
- Lantana (*Lantana* spp.) (CYWAFAP 2009).

Management measures to prevent the spread of weeds into the Project area are discussed in **Section 7.10.2**

7.6.5 Culturally Important Flora

Large individuals of pandanus (*Pandanus spiralis*) suitable for weaving occur most frequently in coastal areas associated with dune systems (vegetation units 5c, 5d, 7a, 7c) and sporadically in association with paperbark wetlands in lower catchment reaches (vegetation units 3b, 7b) and on high sandy bends in estuaries (small areas not mapped out). Another species known to be used for weaving, known as matrush or wallum (*Lomandra longifolia*) occurs fairly consistently in association with fringing riparian vegetation and adjacent colluvial/alluvial habitats along the freshwater reaches of larger streams (vegetation units 4a2, 4a3, 5j, 5e).

Further discussion of impacts to and mitigation measures for culturally important flora is provided in **Section 11.1.4.**

7.7 Summary of Sensitive Environmental Areas for Flora

A number of sensitive environmental areas for flora have been identified through the previous sub-sections. These comprise areas of particular local, regional or national significance with respect to habitat values, biodiversity, presence of threatened species, conservation status, refugial function, or landscape connectivity function. Sensitive environmental areas for flora within the Project area are summarised in **Table 7-9**, and mapped in **Figure 7-8**.

Table 7-9 Sensitive Environmental Areas for Flora

Flora Attribute/Area	Description
"Of concern" REs	"Of concern" REs occupy approximately 411ha (0.4%) of the Project area comprising 3.2.3, 3.2.6a, and 3.2.25. All these REs are located within Land Zone 2 which comprises coastal sand dunes and swales. Land Zone 2 would not be disturbed for mining.
Riparian gallery forest and adjoining alluvial/colluvial flats along groundwater-fed sections of freshwater streams (i.e. veg. units 4a1, 4a3, 5e, 5j1, 5j2)	This vegetation community is associated with shallow aquifer discharge at the periphery of drainage corridors (base of the bauxite plateau) and directly into streams. The floristic diversity of these areas is very high relative to their spatial extent and dependent on continued groundwater discharge. The vegetation types within these areas are also confirmed and potential habitat for a high number of threatened flora species.
Closed forest associated with semi-permanent groundwater spring/seepage areas.	These areas are of very limited spatial extent (associated springs typically 20-50m in diameter) and often provide refugia for rainforest flora and contain flora species not occurring in other vegetation units. These areas are dependent on groundwater discharges extending into the dry season. The vegetation has affinities for unit 4a2.
Vine forest on coastal sands and the bauxite plateau	Vine forest patches provide a refugial function for flora and supports threatened flora. Vine forest on the bauxite plateau is most likely indicative of an historic vegetation community where closed forest vegetation was more widespread than currently distributed.

7.8 Overview of Potential Impacts on Terrestrial Flora

Any impacts on flora would occur at the construction and operational phases of the Project. Direct impacts on vegetation would occur as a result of development clearing of vegetation within the proposed mining areas, and a much smaller area of clearing for construction of Project infrastructure. Clearing for mining would be restricted to the bauxite plateau and would affect only Darwin Stringybark woodland, while disturbance of vegetation for infrastructure would affect a variety of vegetation types including woodland, riparian and wetland vegetation types, and also some regrowth vegetation.

Secondary impacts on vegetation may occur during the operational phase of the Project, linked primarily to potential effects from altered hydrological regime due to mining activity, operation of the water supply dam on Norman Creek, and water extraction from the Ward River. The potential introduction of exotic and weed flora, and fire regimes also pose a potential mechanism for impacts on native vegetation within the Project area.

Specifically, direct impacts on vegetation and flora would occur as a result of:

- removal of Darwin Stringybark woodland within the mining area for mining and haul roads; and
- removal or disturbance of vegetation for construction of infrastructure comprising:
    - Boyd beneficiation plant, stockpiles and ship loading facility at the proposed port;
    - Boyd tailings storage facility;
    - water supply dam on a freshwater tributary of Norman Creek (Dam C);
    - infrastructure corridor from Boyd infrastructure area to Dam C on a freshwater tributary of Norman Creek;
    - pumping station on Ward River and associated pipeline corridor to Dam C;
    - Hey River barge/ferry terminal;
    - Mine Access Roads; and
    - Norman Creek beneficiation plant and tailings storage facility.

In some instances infrastructure would be located within the disturbance footprint of previously mined areas (e.g. tailings storage facilities) and would not require additional clearing of vegetation; however, the majority of Project infrastructure would be located in unmined areas. Prior to construction of each tailings storage facility cell, the bauxite from within each cell would be mined and fed into the plant if it is operating, or stockpiled for later processing if not. This approach would avoid sterilisation of economic bauxite reserves and reduce the extent of clearing of vegetation.

Potential secondary effects on vegetation may occur as a result of:

- localised effects on substrate moisture regime and vegetation community in wetland and riparian areas due to alterations to surface and shallow groundwater regimes as a result of bauxite mining;
- localised effects on wetland and riparian vegetation downstream of Dam C due to altered streamflow and any seepage, should it occur;
- localised effects on wetland and riparian vegetation downstream of the water extraction point on the Ward River;
- displacement of native vegetation and changes to vegetation communities by introduced flora or weeds;
- damage to native vegetation communities from feral pig activity; and,
- alteration to native vegetation communities due to altered fire regime, including controlled asset protection fires that burn less intensively.

7.9 Potential Impacts and Mitigation Measures – Direct Impacts on Vegetation Communities

7.9.1 Potential Impacts

The conceptual 40-year mine plan, proposed infrastructure, and vegetation mapping of the Project area are shown in **Figures 7-6, 7-6a, 7-6b, 7-6c and 7-6d**. The proposed mining areas would avoid riparian and other sensitive habitats by establishment of an environmental buffer system. **Table 7-10** summarises the areas of different REs to be directly disturbed by the Project based on interaction with the 40-year mine plan, proposed Dam C, and the location of Project infrastructure. The table also indicates the areas of each RE to be removed relative to the overall Project area, the Weipa Plateau subregion, and the wider Cape York Bioregion.

Note that version 6 of the RE mapping was used for this analysis, although the official spatial analysis of RE extents for the Version 6 RE data produced by the Queensland Herbarium is not currently available. The version 6 data has been adjusted with RTA's ground surveyed data in the vicinity of the Project area. RE mapping remains incomplete for four subregions within the Cape York bioregion. The percentage of Cape York subregions partially covered by Version 6 RE mapping is as follows:

- Weipa Plateau 85% mapped;
- Coen-Yambo Inlier 66% mapped;
- Jardine–Pascoe Sandstones 94% mapped; and
- Laura Lowlands 95% mapped.

Pre-clearing extent data are not yet available for version 6 . The pre-clearing extent data used for this analysis are based on 2006 imagery and therefore do not reflect any recent losses of REs elsewhere in the bioregion nor increased mapping areas. Consequently, the figures for areas of REs to be disturbed relative to their overall bioregional distribution that are presented in **Table 7-10** may have inaccuracies but nonetheless provide a robust indication of the spatial extent of impact of mining and Project infrastructure on vegetation.

696ha within the footprint of Dam C; and 1,360ha within the footprint of Project infrastructure established on non-mining areas (including an estimate for haul roads). The total 29,339ha of remnant vegetation to be disturbed is comprised entirely of "Least concern" REs, apart from approximately 0.3ha of RE 3.2.6a (*Casuarina equisetifolia* woodland on foredunes) to be disturbed for the ship loading facility.

Disturbance to RE 3.2.6a would occur to facilitate construction access for support structures for the approach jetty of the ship loading facility, and a support structure (bent) may also be located within the RE. A 20m construction corridor would be required through the approximately 30m wide band of RE 3.2.6a that occurs at the base of the bauxite cliff (hence the approximately 0.3ha disturbance area). Following construction, vegetation within the 20m corridor would be allowed to regenerate (subject to fire risk assessment) beneath the 12m wide deck of the approach jetty which would be approximately 12–15m above the ground surface. It is envisaged that, provided the original dune surface is reinstated, the area below the structure would still be suitable to support RE 3.2.6a.

Disturbance to REs within the Project area would comprise 27,283ha within mining areas;

RE 3.5.2 (Darwin Stringybark woodland) would be the most extensively disturbed vegetation type within the Project area as it occurs on the bauxite plateau where mining occurs. Approximately 28,967ha, or 33%, of the area of this vegetation type within the Project area would be disturbed, representing 4.3% and 3.7% of its subregional and bioregional distribution respectively. Small areas of RE 3.5.11 and RE 3.5.22c are also mapped within the mining area but occur on the lower slopes of the plateau edge and would most likely be avoided during mining.

Table 7-10 Regional Ecosystem Disturbance

RE	Description	VMA Status	Approx. area to be disturbed (ha)				Total mapped area in Project area (ha)	Proportion to be disturbed in Project area	Area in Weipa Plateau subregion# (ha)	Proportion of area in subregion to be disturbed#	Area in Cape York Bioregion# (ha)	Proportion of area in bioregion to be disturbed#	Projected remnant extent in bioregion as proportion of current extent#

Key to VMA Status Codes:

L Least concern

O Of concern

Note: Only REs likely to be disturbed are listed

All RE spatial data based on analysis of V6 RE data and adjusted with ground-surveyed mapping by RTA within and adjacent to the Project area.

With the exception of RE 3.5.2, the disturbance to most REs would be much less than 10% (0.2% to 7.5%) of their total extent in the Project area apart from RE 3.3.5 (28.8%). The total area of RE 3.3.5 within the Project area is small (28ha) but a relatively substantial proportion (8.2ha) occurs within the footprint of Dam C and associated infrastructure; however, in a subregional and bioregional context, the disturbance to RE 3.3.5 would be negligible.

While there are uncertainties as to whether the Pisolite Hills Project and Aurukun Bauxite Project will proceed, the cumulative impact of vegetation loss associated with the SoE Project together with these two projects has been considered. In the absence of publicly stated clearing rates, estimations of disturbance within RE 3.5.2 associated with the Pisolite Hills Project and the Aurukun Project were calculated using publicly available information on bauxite reserves. It is estimated that clearing of RE 3.5.2 associated with the Pisolite Hills Project and the Aurukun Bauxite Project would be approximately 2,600ha and 9,300ha respectively. In addition, total clearing (past and future) associated with the current Weipa operations is projected to total approximately 33,300ha at end of mine life.

Considering clearing associated with these current and possible future projects, total clearing within RE 3.5.2 would be approximately 74,200ha within the Weipa Plateau Subregion. If the Pisolite Hills Project and Aurukun Bauxite Project were to fully develop, the subregional extent of RE 3.5.2 would be reduced to approximately 89% of its former known distribution (2006 imagery). The Cape York Bioregional extent of RE 3.5.2 would be reduced to approximately 91% of its former known distribution (2006 imagery). The total clearing associated with current operations and proposed projects in the Weipa Plateau Subregion would not cause RE 3.5.2 to become regarded as "Of concern" or "Endangered" under the *Vegetation Management Act 1999*.

Of the remaining vegetation types to be directly disturbed by Project infrastructure only very minimal areas would be affected representing negligible reductions in subregional and bioregional extent. The reduction in spatial extent of these vegetation types within the SoE Project area as a component of a likely larger cumulative reduction across the Cape York Bioregion (from other projects) is anticipated to be minimal.

7.9.2 Mitigation Measures

The disturbance of sensitive environmental areas by mining would be avoided by the development of an environmental buffer system. The system would comprise a methodology for determining set-back distances from sensitive vegetation types and the preclusion of mining from within the designated buffers.

The sensitive vegetation to be buffered by Darwin Stringybark woodland would comprise the following vegetation types: riparian, wetland, estuarine, vine forest and coastal vegetation on sand. The relevant vegetation units and equivalent REs are listed in **Table 7-11**.

The buffer system would exceed the minimum requirements of the Queensland Government's *Regional Vegetation Management Code* as they relate to clearing set-back distances from watercourses and wetlands (DERM 2009b). In Cape York, the recommended minimum buffer distances from watercourses vary depending on stream order; from wetlands, they depend on the significance of the wetland. These buffer distances are:

- 50m buffer from each high bank of a watercourse with stream order one or two;
- 100m buffer from each high bank of a watercourse with stream order three or four;
- 200m buffer from each high bank of a watercourse with stream order five and above;
- 100m buffer from a natural wetland; and
- 200m buffer from a natural significant wetland.

A variable environmental buffer system would be implemented that takes into account factors such as sensitive vegetation type, important locations of threatened flora and fauna, stream order and hydrology when determining buffer distances. In all cases the above Code requirements would be met or exceeded.

Table 7-11 Vegetation Units to be Buffered

Veg. Unit	Description	Equivalent RE
Laterite/bauxite plateau and slopes		
3c	Notophyll vine forest on lateritic or bauxite red earths	3.5.4
Freshwater drainage lines, wetlands and streams		
3b	*Melaleuca* swamp; zone at the most consistent water level	3.3.14a 3.3.9
4a	Riparian gallery forest along permanent and semi-permanent watercourses	
4a1	Narrow mesic fringe along watercourse with Cape York red gum	3.3.9
4a2	Riparian rainforest	3.3.5
4a3	Paperbark dominated riparian strip with rainforest understorey	3.3.9
5e	*C. polycarpa/ E. brassiana* Woodland on colluvial upper reaches of broad drainage basins - yellow podzolics	3.5.22c
5j	Bloodwood-Banksia in upper parts of broad basins – A2 horizon present	
5j1	With Swamp Box (*Lophostemon suaveolens*) and Lily Pily (*Syzygium angophoroides*) – outer fringe of permanent watercourses	3.3.21
5j2	With Broad-leaved Paperbark (*Melaleuca viridiflora*) on floodplains	3.3.49a
5j3	With Swamp Box (*Lophostemon suaveolens*) and Cabbage Palm (*Livistonia muelleri*i) – on gentle low slope (e.g. western boundary of Norman Creek near estuary)	3.3.9
5j4	With Broad-leaved Paperbark (*Melaleuca viridiflora*), Lineament Tree (*Asteromyrtus lysicarpa*) +/- Hard Tea-tree (*Melaleuca clarksoniana*) on margins of sinkholes	3.3.14a
7b	Melaleuca/Swamp mahogany on the outer margins of drainage depressions	3.3.14a 3.3.50a 3.3.9
12a	Sedgeland in the drainage lines of permanent swamps	3.3.64
12b	Sedgeland in basins of seasonally flooded swamps and drainage depressions	3.3.63 3.3.65
Coastal and beach ecosystems		
3a	Semi-evergreen notophyll vine forest or thicket on coastal dunes	3.2.2
5a	Layered woodland on plains – massive sandy loams	3.2.10c
5c	Woodland on low beach dunes with horse-tail she oak	3.2.6a
5d	Paperbark woodland fringing sandy swales	3.2.3
7a	Mixed shrubby woodland (Sclerophyll vine woodland) on dunefields	3.2.5a
7c	Woodland with Paperbark on sandy swales	3.2.5a
12c	Grassland/herbland on dunefield	3.2.25
Estuary and saltpan ecosystems		
3d	Mangrove; Rhizophora zone	3.1.1a
3e	Mangrove; Landward zone, freshwater conditions (including looking glass mangrove)	3.1.1c
6c	Mangroves; Ceriops zone	3.1.3
8c	Closed scrub in saline strips in estuarine plains – yellow podzolics	3.1.6
9a	Mangrove; highly saline landward zone (mixed species)	3.1.3
12d	Grasslands on low level terraces (narrow bands)	3.2.25
12e	Saltpan, sparse herbfield	3.1.5 3.1.6
12f	Seasonally flooded saline marine plains	3.1.6

Typically, a buffer distance up to 200m would be adopted for vine forest, wetlands, estuaries, coastal vegetation on sand and riparian vegetation along watercourses of stream order three and above. Narrower buffer distances to a minimum of about 100m may be adopted for riparian vegetation along watercourses of stream order one and two, or where significant ecological attributes are absent and physical characteristics are such that a narrower buffer would still provide edge effect protection and filtering of surface runoff flows from disturbed areas.

Surveys would be carried out to define the boundaries of mapped sensitive vegetation types in the field. The field surveys would be carried out prior to clearing for drill lines (which are typically established for detailed orebody definition) and prior to clearing ahead of mining. The surveys would also assess the stream order of any watercourses and the presence or absence of significant ecological features such as springs, aquatic refugia and threatened flora and fauna in and around the sensitive vegetation types.

Buffer distances would then be set based on the findings of the surveys and, where relevant, stream order. Establishment of the buffer distance and authorisation for clearing non-buffered areas would be managed through a ground disturbance approval.

Buffer mapping would be developed using vegetation units as these provide the more detailed delineation of vegetation types compared to REs; however, in **Table 7-11** equivalent REs to the vegetation units to be buffered are provided for reference. Note that some vegetation units can be mapped into multiple RE types depending on the prevailing land zone.

The mitigation measures described above would effectively minimise the potential direct impacts of the Project on vegetation communities as outlined in **Section 7.9.1**.

7.10 Potential Impacts and Mitigation Measures – Indirect Impacts on Vegetation Communities

7.10.1 Potential Impacts

Altered hydrological regime due to removal of bauxite

Discussion of the potential interaction of mining operations on surface and sub-surface hydrology is provided in **Section 5.2.4** and **Section 5.4** respectively. From a vegetation perspective, changes to hydrological regimes have the potential to significantly affect the condition and composition of vegetation and alter the distribution of the overall vegetation community at a local scale.

No dedicated surveys or research have addressed the linkages between groundwater hydrology and vegetation communities on the laterite plateau. It is believed that at least some of the vegetation communities and groundwater hydrology are linked as the existence of 30–35m high eucalypt forest in an area of seasonally variable rainfall indicates that relatively high substrate moisture availability persists after the cessation of wet season rains. In particular the role of the shallow aquifer, which comprises kaolinitic layer and paleochannels overlain by porous bauxite (refer **Section 5.3.2**), is of significance. As a result of the capacity of the mine floor to store surface flow which ponds on the mine floor and slowly infiltrates into the adjoining soil profile of undisturbed areas, the potential effects of mine areas on interflow and vegetation in adjoining areas are likely to be minimal. Qualitative observations of the condition of Darwin Stringybark woodland and vine forest on bauxite adjacent to mine pits in the nearby Weipa mining area show no obvious adverse effects on vegetation in most instances. Isolated occurrences of canopy dieback in Darwin Stringybark woodland are evident in the Weipa mining area and may be related to hydrological change, edge effects or natural dieback. Similar isolated effects could potentially occur in close proximity to the final mine pits in the Project area.

The rainforest and palm forest associated with semi-permanent groundwater springs/seepage areas (see **Figure 7-8**) would be protected by environmental buffers. The shallow aquifer is typically hosted in the kaolinitic layer below the bauxite, apart from the peak of the wet season (see **Section 5.3.2**) where occasionally the water table rises into the bauxite. The semi-permanent seepage areas are not fed from bauxite-hosted groundwater during the dry season

and hence removal of the bauxite would be very unlikely to affect the groundwater supply to these areas.

Discussion of the potential effects of hydrological changes on riparian and wetland ecosystems is provided in **Section 8.14.** In summary, while it is not anticipated that there would be significant changes to riparian and wetland vegetation at a catchment scale, there is the potential for patchy local effects including minor adjustments to the boundaries and extent of different vegetation types in response to new surface and sub-surface hydrological regimes. Localised effects may be experienced by riparian, wetland, and estuary vegetation types.

Altered hydrological regime downstream of the water supply dam

Changes to surface and sub-surface hydrology may occur downstream of the water supply dam (Dam C) due to changes to streamflow regime below the impoundment, and potential changes to groundwater discharge rates and quality. Elevated groundwater discharge may occur immediately below the dam wall and result in elevated substrate moisture and sustained saturation of riparian, alluvial and colluvial areas, and possibly persistent low volume flows in the naturally seasonal flowing receiving streams (Norman Creek). If groundwater discharge did occur, adverse effects on vegetation may be experienced within 1–2 km downstream of the dam wall and potentially comprise:

- dieback of existing canopy vegetation (vegetation unit 4a; REs 3.3.9, 3.3.5) on stream banks due to permanent waterlogging, and development of a new equilibrium vegetation;
- lateral expansion of moisture-dependent fringing vegetation types such as *Melaleuca* swamps with sedge understorey (vegetation unit 7b; RE 3.3.12, 3.3.14a) and swamp Banksia (vegetation unit 5j; RE 3.3.54); and
- reduction in peripheral drainage line communities situated adjacent to the foot of the bauxite plateau (vegetation unit 5e; RE 3.5.22c) that are squeezed out by expansion of inner fringing communities (as per dot point above).

Altered hydrological regime downstream of the pumping point on the Ward River

The potential effects of the proposed pumping from the Ward River on stream hydrology are discussed in **Section 8.14.1**. Modelling shows that mean monthly flow to the Ward estuary is not reduced by more than 5.3% in any month except July (16.6%) as a result of pumping. Pumping would not affect downstream flows beyond that of normal seasonal variation. Wet season inundation of alluvial and colluvial vegetation areas adjacent to the stream is a key determinant of the composition of this vegetation community, which is also substantially driven by groundwater seepage at the base of the bauxite plateau which would not be affected by the pumping. Consequently, given the minimal impact on streamflows during the wet season when inundation occurs, impacts on peripheral vegetation types are not anticipated due to the pumping program.

Reduced flows may affect salinity levels and tidal penetration up the system from the estuary and result in an upstream shift in the freshwater–mangrove riparian vegetation community ecotone. As described in **Section 8.14.1**, there is the potential for upstream retraction of the freshwater–mangrove ecotonal boundary. If this occurs there may be a concomitant shift of the upper distribution of mangrove vegetation elements, such as greater colonisation by mangrove plants upstream within the new ecotone and decline of freshwater riparian vegetation such as fringing paperbarks (*Melaleuca* spp.). Overall, these changes to the ecotonal area are not anticipated to represent significant impacts on the vegetation communities involved and indeed are unlikely to be much different from natural decline and enhancement of freshwater and estuary vegetation within the ecotone due to inter-decadal streamflow and climate variation. RTA would monitor river flow at the pump station using flow meter as described in **Section 5.5.1** and the position of the freshwater–mangrove ecotonal boundary by using aerial photography as described in **Section 8.14.2.1**. .

Introduction of weeds and exotic plant species

Weeds that are known from the Weipa region pose a significant threat to vegetation within the Project area. Weeds such as Gamba Grass (*Andropogon gayanus*), Guinea Grass (*Panicum maximum*), Grader Grass (*Themeda quadrivalvis*), Rubber vine (*Cryptostegia grandiflora*), Leucaena (*Leucaena leucocephala*), Stinky Passionfruit (*Passiflora foetida*) and Hyptis (*Hyptis suaveolens*) can exclude native ground cover vegetation and significantly reduce ground cover floristic and structural diversity and affect recruitment of upper strata. Rubber Vine and Stinky Passionfruit can kill off midstorey and canopy trees with Rubber Vine most active in riparian and floodplain situations (refer also to **Section 8.9** for introduced aquatic species). Vegetation types most at risk from weed invasion include riparian, wetland, estuarine and coastal communities.

Weed invasion typically follows disturbance and it is anticipated that in the Project area, any potential weeds would most likely occur in rehabilitation areas and edges of mined areas. Based on observations of undisturbed habitat immediately adjacent to mining blocks in the Weipa mining area, it is not anticipated that weed invasion of undisturbed vegetation would occur as a result of the Project provided that appropriate weed control measures are implemented.

Altered fire regime

Fire regime is a critical determinant of vegetation condition and overall vegetation community composition, with the intensity, frequency and timing of fire important for both fire-adapted and fire-sensitive vegetation types. The current fire regime within the Project area is one of extensive, high intensity, late dry season fires with areas close to access tracks and high recreational visitation areas being intentionally burned on an annual basis (refer **Figure 7-9**).

Between 2004 and 2009 all of the Project area was burnt, with fires generally occurring three or four years out of the six-year period and some areas being burnt every year (NAFI 2010).

Fires in the Cape York region start through: maintenance of fire regimes by Traditional Owners; fire management for the purposes of biodiversity conservation and protection of the community by DERM in the National Parks; maintenance of native pastures by the pastoral industry; as well as through storms and accidental or deliberate means. This fire regime is regarded as inappropriate for both fire-adapted vegetation such as Darwin Stringybark woodland and fire-sensitive vegetation such as vine forest and riparian gallery forest. Observations of vegetation patterns and fire damage within the Project area (and consideration of faunal communities) indicate that the current fire regime is promoting a simplified woodland vegetation community with premature loss of woodland canopy trees and suppression and retreat of fire-sensitive flora and vegetation types.

Disturbance to vegetation by feral pigs

Disturbance of vegetation by feral pigs is evident throughout the Project area in all vegetation types, but with particularly extensive damage in coastal wetland areas – especially the 'Bulkuru' spike rush (*Eleocharis dulcis*) swamps (vegetation unit 12f; RE 3.3.63) that occur adjacent to the estuaries of the main stream systems (Norman Creek, Winda Winda Creek, Ward River). Pig activity also provides a potential pathway for weed establishment via the resultant disturbed ground surface and the potential for pigs to translocate weed propagules into these areas. By the end of most dry seasons many 'Bulkuru' spike rush swamps have been entirely ploughed up by pigs foraging for 'Bulkuru' spike rush tubers and invertebrates. This disturbance is likely to have a deleterious effect on the resilience of this community particularly with respect to the response of the 'Bulkuru' spike rush to re-establish in the following wet season and provide habitat opportunities for many wetland dependant species of aquatic and terrestrial fauna. Other vegetation types that suffer appreciable pig damage are *Melaleuca* wetlands, saltpan and coastal grasslands, riparian gallery forest and groundwater seepage areas. Pig damage in Darwin Stringybark woodland is usually minimal and does not have a significant impact on vegetation and flora.

The implementation of the Project would provide an opportunity to implement a pig control program in targeted locations within the Project area, which would lead to improved conditions of wetland and riparian habitats.

7.10.2 Mitigation Measures

Altered hydrological regime due to removal of bauxite

Proposed mitigation measures for changes to vegetation communities resulting from the altered post-mining hydrological regime would follow the recommendations for mitigation of hydrological effects detailed in **Section 8.14.2**. In summary, these measures comprise designing post-mining drainage to emulate as far as possible the pre-mining regime of surface and subsurface flows. This would be achieved by a combination of surface drainage features and detention basins that recharge the shallow aquifer.

The environmental buffer system as described in **Section 7.9.2** would also be a primary mitigation measure for edge effects and hydrological effects on sensitive vegetation. The retained tract of undisturbed land within the buffer between mined bauxite areas and nearby riparian and wetland ecosystems would minimise changes to the groundwater hydrology and limit effects on nearby vegetation.

These mitigation measures would be supported by a selective vegetation monitoring program. Results of the monitoring program would be used to identify any effects on vegetation from edge effects and altered hydrological regime (and any other causes) and investigate measures to minimise similar future impacts.

The vegetation monitoring program would have the following attributes:

- Monitoring sites would be established in representative areas of sensitive vegetation units occurring adjacent to mining areas and in downstream areas (both in terms of surface and groundwater hydrology). The monitoring sites would include seasonally stratified sampling data prior to mining or development (i.e. one late wet / early dry season and one pre wet season survey event);
- Specimens would be collected for herbarium identification if a plant cannot be identified;
- Control sites for each vegetation unit would be established within the Project area in areas well away from proposed mining or infrastructure that are unlikely to experience surface or groundwater modification; and
- Monitoring would be undertaken periodically at an interval that would allow effective remediation should significant adverse impacts become evident.

The mitigation measures described above would effectively minimise the potential impacts as outlined in **Section 7.10.1** associated with the alteration of the hydrological regime due to bauxite removal.

Altered hydrological regime downstream of the water supply dam

Mitigation of the effects of water supply dam seepage on downstream riparian and fringing vegetation can be addressed at both the design and operational phases of the Project. With respect to possible elevated surface flow and groundwater inputs downstream of Dam C, further detailed geotechnical investigations and engineering design would be undertaken to select the wall position and structural format for a low seepage dam structure (within other design constraints and specifications).

Secondly, an environmental flow program with appropriate water release structures would be implemented to provide a streamflow regime that maximises similarities with the natural regime of streamflow duration throughout the year. Of greatest significance for riparian and wetland vegetation would be the similarity of the released flow regime to the natural seasonality of vegetation communities. The stream reach immediately downstream of proposed Dam C does not typically support late dry season flows and conversion of this reach to permanent flow could bring about significant ecosystem changes to the vegetation units currently occurring there.

The mitigation measures described above would effectively minimise the potential impacts as outlined in **Section 7.10.2** associated with the construction and operation of the water supply dam and any subsequent alteration to the hydrological regime downstream of the water supply dam.

Altered hydrological regime downstream of the pumping point on the Ward River

Significant impacts on vegetation communities are not anticipated to occur as a result of the proposed pumping program and no specific mitigation measures are proposed; however, the environmental buffer system would serve to maintain natural groundwater discharge at the periphery of the Ward River system downstream of the pump location and help minimise changes to instream flows below the pump location, and maintain wet season inundation of peripheral alluvial/colluvial vegetation.

The mitigation measures described above would effectively minimise the potential impacts as outlined in **Section 7.10.3** associated with the operation of the pumping point on the Ward River and any subsequent alteration to the hydrological regime downstream of the pumping point.

Weed Management

With respect to potential weed impacts, a weed management program comprising monitoring and control components would be developed and implemented to prevent impacts on undisturbed vegetation. The main focus of the weed management program would be early detection and early control of any weed invasions. The weed management program would have the following attributes:

- The weed management program would be developed and implemented in the early stages of the Project.
- Prior to the establishment of the Mine Access Road, any vehicles travelling to the Project area would be required to be washed down for weeds.
- Washdown facilities would be provided at the Humbug barge terminal and all vehicles thoroughly washed before transfer to the Hey River barge/ferry terminal and site access road.
- Washdown facilities would be constructed, positioned and managed such that wash water and soil is contained and not released to the surrounding ecosystems.
- Annual weed surveys would be conducted post wet season, targeting:
    - all operational areas (mining and infrastructure) and immediately adjacent ecosystems; and
    - site access roads.
- Periodic weed surveys would be conducted at least every three years, targeting:
    - habitats where key weed species are most likely to become established; and
    - areas within the mining lease where there is high recreational visitation (especially riparian and wetland areas).
- Detailed mapping of the above areas would form the basis of the weed management program and guide annual weed surveys.
- Training courses would be conducted regularly for relevant mine personnel, highlighting significant weed species and basic identification features for weeds likely to be encountered on the site, to ensure staff have been provided with enough information to accurately identify weed species. Commonly this includes a combination of posters, a herbarium, newsletters and training packages.
- Protocols would be established for easy reporting of weed occurrence by any personnel working on site and be of a format that encourages reporting.

- Results of the weed survey and any weed reporting would be uploaded to the site GIS in a timely manner so that weed mapping is maintained as a live database.
- Any weed infestation areas would have controlled access until appropriate treatment and suppression is complete and there is no risk of propagules being translocated.

The mitigation measures described above would effectively manage the potential weed related impacts associated with the Project as outlined in **Section 7.10.4**.

Fire Management

A fire management program would be developed in cooperation with Traditional Owners and the relevant Western Cape Communities Coordinating Committee (WCCCC) sub-committee to address the adverse aspects of the current fire regime within the Project area. The fire management program would aim to conserve fire-sensitive flora and vegetation communities and promote overall vegetation diversity by reducing fire intensity and frequency and promoting a regime of early to mid dry season lower intensity burns with a lower frequency. This would be achieved by promoting a regime of planned early to mid dry season lower intensity burning, and suppression (where practicable) of inappropriate fires. These activities would be underpinned by establishment and maintenance of a network of fire breaks to facilitate effective control burns and provide opportunities for combating inappropriate fires.

Public access would be restricted to the Project area, which would help control the prevalence of unwanted fires, although unauthorised access to non-active sections of the Project area may see the persistence of unauthorised fires, for which strategic fire suppression may be required. While these fire management principles would be applied across undisturbed areas of the Project area, specific controlled burning at a greater frequency would be required to protect infrastructure and rehabilitated areas from fire damage, but would be restricted to the vicinity of such assets.

The mitigation measures described above would effectively manage the potential fire management related impacts associated with the Project as outlined in **Section 7.10.5**.

The mitigation of the risk of damage caused by bushfires is also discussed in **Section 19.3.3**.

Feral animal management

A feral animal management program would be developed with the following attributes:

- The program would focus on feral pigs, which are the main pest in the Project area.
- The feral animal management program would be developed and implemented in the early stages of the Project.
- The program would focus on reducing pig numbers in sensitive environmental areas where pig populations are concentrated.
- Control measures would be compatible with accepted animal welfare outcomes.
- The control program would include appropriate monitoring for measuring program performance and guiding subsequent control effort.

The mitigation measures described above would effectively manage the potential impacts related to feral animals as outlined in **Section 7.10.6**.

7.11 Potential Impacts and Mitigation Measures – Threatened Flora

7.11.1 Potential Impacts

Of the 15 threatened plant species either confirmed as present or assessed as possible or likely to occur in the Project area, three are known to occur in Darwin Stringybark woodland on the bauxite plateau, comprising:

- *Acacia ommatosperma*

- *Albizia retusa; and*
- *Heterachne baileyi.*

None of these species were confirmed as present during field surveys.

Heterachne baileyi is known to occur on the lower slopes of the Weipa bauxite plateau and adjoining alluvial plains and probably colluvial plains. This habitat generally lies within the environmental buffer areas and hence outside of the mining footprint; consequently, *Heterachne baileyi* is unlikely to be directly affected by mining activity. However, the proposed water supply dam on a freshwater tributary of Norman Creek (Dam C) occupies lower bauxite slopes and adjoining colluvial/alluvial flats with *Melaleuca viridflora* and the species may occur in these areas, although it was not observed during targeted surveys. The potential habitat area for this species, within the dam footprint, would comprise approximately 3% of this habitat type within the Project area, so the majority of potential preferred habitat would not be affected. It is unlikely that indirect effects on any potentially occurring populations would occur as a result of alterations to hydrology or edge effects. The proposed fire management plan is likely to favour this species.

Acacia ommatosperma was not observed during surveys of the Project area but is known to occur on ironstone ridges and the slope of the bauxite plateau, as well as colluvial/alluvial plains adjacent to the lower plateau. The species thus has a similar potential distribution to *Heterachne baileyi* and consequently most of the potential habitat for the species is likely to occur within environmental buffer areas. Furthermore, ironstone ridges are unlikely to be included in mining areas as they do not yield commercial bauxite. The proposed water supply dam and other infrastructure would disturb less than 5% of the potential habitat for the species within the Project area, and it is unlikely that indirect effects on any potentially occurring populations would occur as a result of alterations to hydrology or edge effects.

Albizia retusa is known to occur in Darwin Stringybark woodland, predominantly in the vicinity of vine forest. The proposed environmental buffer system would prevent mining in the vicinity of vine forest and avoid disturbance of this area. Furthermore, no infrastructure is proposed in close proximity to vine forests. *Albizia retusa* may occur within notophyll vine forests in the Project area, although targeted surveys of vine forests did not locate the species. Indirect effects due to altered hydrology and edge effects are unlikely to affect any potential populations, and the proposed fire management plan is likely to favour this species.

The remaining threatened species confirmed as present or assessed as possible or likely to occur in the Project area do not occur in Darwin Stringybark woodland and would not be affected by clearing for mining. Eight of the threatened species are associated with freshwater riparian or wetland habitats that may be affected by construction of infrastructure, especially the water supply dam (Dam C) on a freshwater tributary of Norman Creek. These species comprise:

- Acacia fleckeri;
- Calophyllum bicolor;
- Cooktown Orchid (Dendrobium bigibbum);
- Chocolate Tea Tree Orchid *(Dendrobium johannis);*
- Lindsaea walkerae;
- Ant Plant (Myrmecodia beccarii);
- Sarcolobus vittatus; and
- Spathoglottis plicata.

Of these species, Chocolate Tea Tree Orchid is confirmed as occurring within the infrastructure corridor where it crosses Norman Creek. Cooktown Orchid is confirmed in pockets of riparian rainforest within the footprint of Dam C, in the vicinity of the infrastructure corridor crossings on Norman Creek and vicinity of road crossings of Norman Creek and Winda Winda Creek.

Consequently, these two species would be impacted by construction of the dam and/or linear infrastructure. Both Chocolate Tea Tree Orchid and Cooktown Orchid are relatively widely distributed within the Project area in suitable habitat that would not be adversely affected by the Project. Specifically, Chocolate Tea Tree Orchid is ubiquitous within riparian gallery forest and Melaleuca wetlands throughout the Project area. Cooktown Orchid is commonly encountered within riparian rainforest, the edge of mangrove forests, and coastal vine forests. Disturbance associated with the water supply dam and infrastructure for these two species represents a minor proportion of their overall occurrence in the Project area.

Targeted surveys of the dam area and infrastructure crossings of riparian areas indicated with a relatively high reliability that the more detectable species listed above (*Acacia fleckeri, Calophyllum bicolor,* Ant Plant) are not present in these locations and would not be directly affected by the dam and linear infrastructure.

Although not recorded during targeted field surveys, the potential presence of the more diminutive species (*Lindsaea walkerae, Sarcolobus vittatus, Spathoglottis plicata*) within the dam footprint cannot be discounted; however, potential habitat for all of these species occurs extensively elsewhere in the Project area in areas that would not be directly disturbed by the Project. Consequently, the potential impact on these species, should they be present within the infrastructure areas, is not regarded as significant.

The 8 riparian species listed above may also be locally affected to some degree by changes to surface and groundwater hydrology as described in **Section 7.10.1.** Potential impacts from alterations to hydrology on habitats supporting these species would be localised and would not change the catchment-wide occurrence of different riparian, wetland and mangrove habitats, or the overall availability of potential habitat for most of these species. One species, *Calophyllum bicolor,* would be potentially more susceptible to alterations to groundwater discharge rates as it grows only in association with permanent groundwater seepage areas (which have not been identified within the Project area) within rainforest. However, this species was not detected at five semi-permanent spring heads with suitable habitat located close to proposed mining areas that were visited during targeted surveys. Nor was it present at six other seepage areas which lacked suitable habitat. The species may occur in other unsurveyed isolated patches of suitable habitat at wetland margins closer to the coast on the lower reaches of the main drainage systems. The proposed environmental buffer system would minimise hydrological impacts on groundwater seepage zones particularly in lower catchment areas where the species may occur.

All the threatened flora species occurring in riparian and wetland situations would be favoured by the proposed fire management program, which would provide a more suitable fire regime for fire-sensitive species.

The remaining four threatened species occur predominantly in vine forest, which would not be affected by clearing for mining or infrastructure. Cooktown Orchid also occurs in this habitat. The vine forest species comprise:

- Cooktown Orchid (Dendrobium bigibbum);
- Habenaria hymenophylla;
- Hoya (Hoya revoluta);
- Lepturus geminatus; and
- Beach Nightshade (Solanum dunalianum).

One of these species, Cooktown Orchid, has been confirmed in the Project area within coastal vine forest areas on sand, and Beach Nightshade, *Hoya revoluta* and *Lepturus geminatus* also potentially occur in this habitat. Vine forest patches on coastal dunes are unlikely to be affected by changes to groundwater as the coastal dune complexes are not influenced by shallow aquifers or groundwater discharge. Consequently, impacts on threatened flora occurring in coastal vine forest are not anticipated.

Cooktown Orchid*, Habenaria hymenophylla* and Hoya all potentially occur in vine forest on bauxite. Vine forest areas on bauxite may be susceptible to effects related to changes in

groundwater hydrology following mining; however, any effects would be minimised by the proposed environmental buffer system which would prevent mining in close proximity to vine forest areas. Observations over a number of years of similar vine forest areas within other mining areas near Weipa suggest deleterious effects on vine forest communities have not occurred where appropriate environmental buffers have been implemented. It is anticipated there would not be any adverse impacts on threatened flora occurring within vine forest patches from Project-related disturbance.

Cooktown Orchid also occurs in mangrove areas predominantly along the landward edge of mangrove forest. These mangrove areas would not be directly affected by clearing and are not anticipated to experience any indirect effects via changes to hydrology.

All the above vine forest species are likely to benefit from the proposed fire management plan, which would promote a fire regime more favourable for fire-sensitive species.

7.11.2 Mitigation Measures

Species of riparian and wetland habitats

The environmental buffer system would mitigate impacts on riparian threatened flora by avoiding direct disturbance (apart from the water supply dam site and infrastructure corridors) and minimising potential hydrological effects and edge effects on the vegetation communities supporting these species. The potential for groundwater changes and impacts are further discussed in **Section 5.4.1** and **Section 8.14**.

All the fire-sensitive species would be favoured by improvements to riparian habitat condition in undisturbed areas as a result of the fire management program. The target regime of less frequent and less intense fires (via early – mid dry season burns) would reduce suppression of the moister riparian and wetland vegetation and maximise the spatial extent of these communities. Ground cover and shrub species that potentially occur in the Project area such as *Lindsaea walkerae, Sarcolobus vittatus*, and *Spathoglottis plicata* would especially benefit, with the epiphytic *Dendrobium bigibbum* and *Dendrobium johannis* also benefiting from the lower scorch height which should accompany the new fire regime. The proposed fire regime, which would result in a habitat mosaic of mixed fire age, would also promote the establishment of fire refugia where robust populations of threatened flora may develop and provide source populations for recolonisation of adjoining areas following natural disturbance events.

The terrestrial rooted species would also benefit from the feral pig control program. The riparian gallery forest of freshwater streams and adjoining colluvial areas is currently heavily utilised and disturbed by feral pigs throughout the year causing extensive damage to native vegetation within these habitats. The proposed feral animal management program would reduce damage to vegetation in general and to any of the threatened flora species that may be present.

The mitigation measures described above would effectively minimise the potential impacts of the Project on threatened flora associated with riparian and wetland habitats as outlined in **Section 7.11.1**.

Species of vine forest habitats

The environmental buffer system provides the primary mitigation measure for vine forest threatened species by controlling potential hydrological induced effects and habitat edge effects on the vine forest community. In addition, the fire management plan would provide positive outcomes for these species by mitigating existing non mining related fire impacts.

The mitigation measures described above would effectively minimise the potential impacts of the Project on threatened flora associated with vine forest habitats as outlined in **Section 7.11.1**.

7.11.3 Impact on EPBC Act Threatened Flora

This assessment is based on the *Significant impact guidelines* (DEWHA 2009a) provided by the Commonwealth Government. Individual "significant impact" assessments are provided for each

of the EPBC listed flora species that were assessed as possible, likely or confirmed inhabitants of the Project area. Key definitions from the guidelines that apply to this assessment are as follows:

An "important population" is a population that is necessary for a species' long-term survival and recovery. This may include populations identified as such in recovery plans, and/or that are:

- key source populations either for breeding or dispersal;
- populations that are necessary for maintaining genetic diversity; and/or
- populations that are near the limit of the species range.

"Habitat critical to the survival of a species" refers to areas that are necessary:

- for activities such as foraging, breeding, roosting, or dispersal;
- for the long-term maintenance of the species (including the maintenance of species essential to the survival of the other species, such as pollinators);
- to maintain genetic diversity and long-term evolutionary development; or
- for the reintroduction of populations or recovery of the species.

Such habitat may be, but is not limited to: habitat identified in a recovery plan for the species or ecological community as habitat critical for that species or ecological community; and/or habitat listed on the Register of Critical Habitat maintained by the Minister under the EPBC Act.

An "invasive species" is an introduced species, including an introduced (translocated) native species, which out-competes native species for space and resources or which is a predator of native species. Introducing an invasive species into an area may result in that species becoming established. An invasive species may harm listed threatened species by direct competition, modification of habitat or predation.

The following EPBC Act listed species were confirmed to occur within the Project area:

- Cooktown Orchid (*Dendrobium bigibbum*); and
- Chocolate Tea Tree Orchid (*Dendrobium johannis*).
- The following EPBC Act listed species were not recorded during targeted surveys of the Project area, although suitable habitat was identified:
- Calophyllum bicolor;
- Spathoglottis plicata;
- Myrmecodia beccarii; and
- Beach Nightshade (*Solanum dunalianum*).

The EPBC Act listed species listed above have been assessed against the DEWHA (2009a) criteria for assessing significant impacts.

Calophyllum bicolor

Calophyllum bicolor was not recorded within the Project area. However, as the regional population size of this species is relatively small, if *Calophyllum bicolor* was to occur within the disturbance footprint of the Project area, this would be regarded as an important population. However, if a population was to be disturbed, this disturbance would be unlikely to lead to a long term decrease in the region of *Calophyllum bicolor*.

There are no threats specifically listed for *Calophyllum bicolor* (DSEWPaC 2010).

Will the proposed works ...	***Calophyllum bicolor*: Vulnerable**
... lead to a long-term decrease in the size of an important population of a species?	*Calophyllum bicolor* is currently known only from 17 populations on Cape York Peninsula (DERM 2010). It occurs on spring-fed areas that form a distinct habitat with evergreen rainforest and permanently wet substrates, but does not occur on stream banks away from the spring heads. There are four specimen records of the

Will the proposed works ...	***Calophyllum bicolor*: Vulnerable**
	species from the Weipa area, but the species has not been recorded from the Project area. *Calophyllum bicolor* was not recorded within the Project area despite the location and survey of five semi-permanent groundwater seepage zones that provided suitable habitat for the species. These sites were located in close proximity to proposed mining areas and no other potential habitat areas appear to occur close to mining or infrastructure areas. The species was absent from six other seepage zones surveyed where the habitat was unsuitable. However, unsurveyed isolated patches of suitable habitat may occur at the margin of wetlands in the lower freshwater sections of the main drainages (Norman Creek, Ward River, Winda Winda Creek) and may support the species. Any population of *Calophyllum bicolor* that may be present within the Project area would be regarded as an important population as the location would represent the southern distribution limit for the species. The groundwater seepage habitats on the lower sections of the main drainages where the species may occur are well removed from the proposed mining area and infrastructure and would not be directly disturbed. These habitats would be susceptible to impacts from altered groundwater hydrology; however, their location well away from mining areas and implementation of the proposed environmental buffer system and post-mining rehabilitation measures, which would seek to protect hydrological regimes, are anticipated to minimise impacts on groundwater discharge areas effectively. As such, it is unlikely that the species, if present, would be adversely affected. It is not anticipated that the Project would lead to a long-term decrease in any population of *Calophyllum bicolor* that may be present.
... reduce the area of occupancy of an important population?	As per the discussion above, if *Calophyllum bicolor* is present within the Project area its habitat would not be directly affected by mining and it is not anticipated there would be sufficient hydrological impacts on the groundwater dependent habitats it occupies to lead to a reduction of the area of occupancy of an important population.
... fragment an existing important population into two or more populations?	*Calophyllum bicolor* has a naturally patchy and restricted distribution associated with the isolated occurrence of permanent groundwater seepage zones. Populations of *Calophyllum bicolor* on Cape York are therefore naturally fragmented and not sensitive to disturbance of sub-optimal habitat between patches of preferred habitat. The Project would not lead to fragmentation of any potentially occurring *Calophyllum bicolor* populations.
... adversely affect habitat critical to the survival of a species?	The Project area does not include any critical habitat areas for *Calophyllum bicolor* that are listed under the EPBC Act or identified in Recovery Plans.
... disrupt the breeding cycle of an important population?	If *Calophyllum bicolor* is present within the Project area, it is not anticipated that its preferred habitat would be adversely affected by the Project and consequently the breeding cycle of the species would not be disrupted.
... modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	If *Calophyllum bicolor* is present within the Project area its habitat would not be directly affected by mining and it is not anticipated there would be sufficient hydrological impacts on the groundwater dependent habitats it occupies to lead to a decline in the species.
... result in invasive species that are harmful to a vulnerable species becoming established in the vulnerable species' habitat?	The Project area is currently predominantly free of serious weeds and invasive species; however, a number of significant environmental weeds occur in the surrounding region. The preferred habitat of *Calophyllum bicolor* is often favoured by invasive species due to the moist nature of the habitat. Should *Calophyllum bicolor* be present, the potential introduction of Rubber Vine (*Cryptostegia grandiflora*) would be of particular concern. Proposed mitigation measures for invasive species include a rigorous weed management program, which includes preventative measures and control measures for weeds within the Project area. Riparian areas including groundwater discharge areas would be one of the habitats targeted by the program. These mitigation measures would be effective in managing the impacts of weeds on *Calophyllum bicolor*. The Project is not anticipated to lead to the introduction or spread of invasive weeds within any potential habitat of *Calophyllum bicolor*.
... introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is not anticipated that the Project would represent a threat with respect to the introduction of disease.
... interfere substantially with the recovery of the species?	It is not anticipated that the Project would adversely affect *Calophyllum bicolor* (if present). The Project would not interfere with the recovery of *Calophyllum bicolor*.

Cooktown Orchid *Dendrobium bigibbum*

The population of Cooktown Orchid within the Project area is not considered an important population under the EPBC Act.

Known threats to the Cooktown Orchid include pressure from localised settlement and visitor pressures, changed fire regimes and illegal collection. It has also been suggested that the Cooktown Orchid may also be detrimentally affected by an increase in the incidence of severe cyclones (DEWHA, 2008a).

Will the proposed works ...	**Cooktown Orchid (*Dendrobium bigibbum*): Vulnerable**
... lead to a long-term decrease in the size of an important population of a species?	The Cooktown Orchid occurs on Cape York Peninsula north from Princess Charlotte Bay and Kowanyama to the tip and into southern Asia. It has been recorded from several locations in the Weipa region, particularly in notophyll vine forest on coastal dunes and on lateritic red earths. The habitat preference of this species in the Weipa region is well known: it is restricted to closed forest, typically as an epiphyte in rainforest or vine thicket habitats. The species is sensitive to fire and therefore is found only in situations where frequent fires do not occur. The Cooktown Orchid was recorded from a number of locations throughout the Project area in coastal and Weipa plateau vine forest, mangrove communities and in areas of riparian rainforest and riparian gallery forest and is expected to be widespread within the entire Project area and adjoining areas in suitable habitat. Cooktown Orchid was confirmed in two pockets of riparian rainforest within the footprint of Dam C. The population of Cooktown Orchid within the Project area is not considered an important population under the EPBC Act.
....reduce the area of occupancy of an important population?	As per the discussion above, the population within the Project area is not regarded as an important population.
....fragment an existing important population into two or more populations?	As per the discussion above, the population within the Project area is not regarded as an important population.
....adversely affect habitat critical to the survival of a species?	The Project area does not include any critical habitat areas for *Dendrobium bigibbum* that are listed under the EPBC Act or identified in Recovery Plans. The species is widespread through central and northern Cape York.
....disrupt the breeding cycle of an important population?	As per the discussion above, the population within the Project area is not regarded as an important population.
....modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	The two pockets of rainforest with Cooktown Orchids within the footprint of Dam C would be inundated. The orchid was found in the vicinity of the infrastructure corridor crossings on Norman Creek and vicinity of road crossings of Norman Creek and Winda Winda Creek. None of the vine forest or mangrove habitat types supporting Cooktown Orchid within the Project area would be directly affected by clearing for mining. No significant modifications of these habitats due to changes in hydrology are anticipated. Overall, the reduction of habitats supporting the species would be very minor. The proposed fire management program would favour the species by effectively reducing the impacts of the current fire regime on fire-sensitive habitats such as vine forest (refer **Section 7.10.2**)
....result in invasive species that are harmful to a vulnerable species becoming established in the vulnerable species' habitat?	The Project area is currently predominantly free of serious weeds and invasive species; however, a number of significant environmental weeds occur in the surrounding region. The vine forest habitat of Cooktown Orchid is not considered at risk of weed invasion as most of the significant weeds in the region do not colonise closed forest. The mangrove habitat of the species is threatened by the introduction of Rubber Vine (*Cryptostegia grandiflora*). Proposed mitigation measures include a rigorous weed management program, which includes preventative measures and control measures for weeds within the Project area. Riparian areas including mangroves would be one of the habitats targeted by the program. These mitigation measures would be effective in managing the impact of weeds on the Cooktown Orchid. The Project is not anticipated to lead to the establishment of invasive weeds within the habitat of the Cooktown Orchid.
.....introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is not anticipated that the Project would represent a threat with respect to the introduction of disease.
....interfere substantially with the recovery of the species?	The Project would lead to a minor reduction of the extent of habitats supporting the species due to the inundation of riparian habitat by the water supply dam and linear infrastructure, but given the extensive occurrence of the species elsewhere within the Project area and surrounding areas it is not anticipated that the Project would interfere substantially with the recovery of the species.

Chocolate Tea Tree Orchid *Dendrobium johannis*

As the Chocolate Tea Tree Orchid is widely distributed throughout the region, the population within the Project area is not regarded as an important population and any impact to the regional population as a result of disturbance associated with the Project would be negligible.

The key known potential threats to the Chocolate Tea Tree orchid include over-collection by orchid enthusiasts and habitat degradation from settlement and visitor pressures (DEWHA 2008b).

Will the proposed works ...	**Chocolate Tea Tree Orchid (*Dendrobium johannis*): Vulnerable**
....lead to a long-term decrease in the size of an important population of a species?	The Chocolate Tea Tree Orchid occurs from the Coen area north to the tip of Cape York and in Torres Strait and New Guinea, and has been recorded from several locations in the Weipa region, including the Andoom, Weipa and Ely mining lease areas. The habitat preferences of this species are well known: the Chocolate Tea Tree Orchid is restricted to mesic habitats, typically as an epiphyte on mature *Syzygium* spp. and *Melaleuca* spp. trees in riparian gallery forest and on the margins of swamp habitats and their associated ecotones. The Chocolate Tea Tree Orchid was recorded from a number of locations throughout the Project area in riparian gallery forest and *Melaleuca* dominated wetlands and is expected to be widespread within the entire Project area and adjoining areas in these habitats. The population of the Chocolate Tea Tree Orchid within the Project area is not considered an important population under the intent of the EPBC Act. The Chocolate Tea Tree Orchid occurs within riparian and wetland habitats throughout the Project area. The population within the Project area is not a discrete population, as the species occurs throughout the Weipa Plateau subregion and within the wider Cape York Bioregion.
....reduce the area of occupancy of an important population?	As per the discussion above, the population within the Project area is not regarded as an important population.
....fragment an existing important population into two or more populations?	As per the discussion above, the population within the Project area is not regarded as an important population.
....adversely affect habitat critical to the survival of a species?	The Project area does not include any critical habitat areas for the Chocolate Tea Tree Orchid that are listed under the EPBC Act or identified in Recovery Plans. The species is widespread through central and northern Cape York.
....disrupt the breeding cycle of an important population?	As per the discussion above, the population within the Project area is not regarded as an important population.
....modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	Areas of riparian gallery forest and fringing *Melaleuca* wetland supporting the Chocolate Tea Tree Orchid would be disturbed by the infrastructure corridor crossing of Norman Creek. While not found within the footprint of the water supply dam, there is suitable habitat present in this location. Elsewhere the habitats of the species would be avoided by the mine plan and buffered by the proposed environmental buffer system. Significant modification of these habitats due to changes to hydrology is not anticipated. Overall, there would be a minor reduction of the extent of habitats supporting the species but, given the extensive occurrence of the species outside of these impact areas, it is not anticipated that the species would be caused to decline. The proposed fire management program would favour the species by effectively reducing the impacts of the current fire regime on fire-sensitive habitats such as riparian gallery forest and melaleuca wetlands (refer **Section 7.10.2**).
....result in invasive species that are harmful to a vulnerable species becoming established in the vulnerable species' habitat?	The Project area is currently predominantly free of serious weeds and invasive species; however, a number of significant environmental weeds occur in the surrounding region. The habitats of the Chocolate Tea Tree Orchid are often favoured by weed invasion, as the moist nature of the habitats supports weed establishment. Of particular threat is the introduction of Rubber Vine (*Cryptostegia grandiflora*) which can thrive and displace native vegetation in riparian and wetland situations. Proposed mitigation measures include a weed management program, which involves preventative measures and control measures for weeds within the Project area. Riparian areas would be one of the habitats targeted by the program. These mitigation measures would be effective in managing the impacts of weeds on the Chocolate Tea Tree Orchid. The Project is not anticipated to lead to the establishment of invasive weeds within the habitat of the Chocolate Tea Tree Orchid.
.....introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is not anticipated that the Project would represent a threat with respect to the introduction of disease.
....interfere substantially with the recovery of the species?	The Project would lead to a minor reduction of the extent of habitats supporting the species due to the infrastructure corridor crossing of Norman Creek, but given the extensive occurrence of the species elsewhere within the Project area and surrounding areas it is not anticipated that the Project would interfere substantially with the recovery of the species.

Ant Plant *Myrmecodia beccarii*

Although the Ant Plant has not been identified within the Project area, a population of *Myrmecodia beccarii* within the Project area (if present) would be considered an important population under the intent of the EPBC Act since the species is little known with no specimen records from western Cape York. It is not anticipated that any important population of *Myrmecodia beccarii* that may be present would be adversely effected by the Project

Known threats the Ant Plant include clearing of lowland paperbark woodlands, localised settlement pressures and the removal or destruction of plants by plant and butterfly collectors (DEWHA 2008c).

Will the proposed works ...	***Myrmecodia beccarii*: Vulnerable**
....lead to a long-term decrease in the size of an important population of a species?	*Myrmecodia beccarii* is known from coastal woodlands between Cooktown and Ingham and northern Cape York Peninsula between Weipa and the tip of Cape York. *Myrmecodia beccarii* was not located within the Project area and distribution within adjoining areas is not well known, although the species was recently located in a permanent groundwater seepage area near Weipa (pers. obs.). *Myrmecodia beccarii* is known from a variety of habitats on Cape York including *Melaleuca* wetlands, coastal closed forest, mangroves and swamp forest on permanent groundwater seepages. A potential population of *Myrmecodia beccarii* within the Project area (if found) would be considered an important population under the intent of the EPBC Act since the species is little known with no specimen records from western Cape York. The closest record for the species is from Weipa, with apparently no records of the species south of the Project area. The Project area would represent a distributional limit for the species. Any isolated population in this area would be regarded as an important population as it would represent: • key source populations either for breeding or dispersal; • population that is necessary for maintaining genetic diversity; and/or • population that is near the limit of the species range. (i.e. there are no other records of the species on the west coast of Cape York south of Weipa). Significant areas of potential wetland, mangrove and coastal vine forest habitat occur within the Project area. Targeted threatened surveys were undertaken in a number of *Melaleuca* wetland, coastal vine forest, and groundwater seepage forest habitats within the Project area but the species was not located and it is not anticipated that the species occurs in these habitats within the Project area. Mangrove areas were less intensively surveyed and may be a host to the species. Mangrove habitats within the Project area would not be directly affected by clearing and it is also highly unlikely that these areas would be significantly affected by changes to surface and groundwater hydrology. It is not anticipated that a long-term decrease in the size of any important population of *Myrmecodia beccarii* present within the Project area would occur.
....reduce the area of occupancy of an important population?	It is not anticipated that the area of any important population of *Myrmecodia beccarii* that may be present within the Project area would be reduced.
....fragment an existing important population into two or more populations?	*Myrmecodia beccarii* has a naturally patchy and restricted distribution associated with the restricted habitats it occupies. Populations of *Myrmecodia beccarii* on Cape York are therefore naturally fragmented and not sensitive to disturbance of sub-optimal habitat between patches of preferred habitat. The Project would not lead to fragmentation of important populations of *Myrmecodia beccarii*.
....adversely affect habitat critical to the survival of a species?	The Project area does not include any critical habitat areas for *Myrmecodia beccarii* that are listed under the EPBC Act or identified in Recovery Plans. The species is known from a number of other locations on Cape York.
....disrupt the breeding cycle of an important population?	It is not anticipated that any important population of *Myrmecodia beccarii* that may be present would be adversely effected by the Project; consequently, disruption of any important populations of *Myrmecodia beccarii* present is not expected to occur.
....modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	Potential mangrove habitat for *Myrmecodia beccarii* within the Project area would not be adversely affected by the Project. The Project would not affect numerous other populations of the species reported from elsewhere on Cape York. A decline in the species as a result of the Project is not expected.
....result in invasive species that are harmful to a vulnerable species becoming established in the vulnerable species' habitat?	The Project area is currently predominantly free of serious weeds and invasive species; however, a number of significant environmental weeds occur in the surrounding region. The preferred habitat of *Myrmecodia beccarii* is susceptible to weed invasion due to the moist nature which is often favoured by invasive species. Of particular concern is the potential introduction of Rubber Vine (*Cryptostegia grandiflora*). Proposed mitigation measures include a weed management program, which includes preventative measures and control measures for weeds within the Project area. Riparian areas including groundwater discharge areas would be one of

Will the proposed works ...	***Myrmecodia beccarii*: Vulnerable**
	the habitats targeted by the program. These mitigation measures would be effective in managing the impacts of weeds on *Myrmecodia beccarii* (if present). The Project is not anticipated to lead to the spread of invasive weeds within the habitat of *Myrmecodia beccarii*.
.....introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is not anticipated that the Project would represent a threat with respect to the introduction of disease.
....interfere substantially with the recovery of the species?	Potential mangrove habitat for *Myrmecodia beccarii* within the Project area would not be adversely affected by the Project. The Project would not affect numerous other populations of the species reported from elsewhere on Cape York. It is not anticipated that the Project would interfere with the recovery of the species.

Beach Nightshade *Solanum dunalianum*

Although there are limited records of Beach Nightshade in the Weipa area and the species has not been identified within the Project area, it is expected to be widespread on Cape York (Landsberg and Clarkson 2004) and is therefore likely to occur in the Project area. If this species was disturbed as a result of the Project, the disturbance would have a minor impact on the regional population of the species.

DEWHA (2008d) identify the key known threats to some populations of Beach Nightshade as localised settlement pressures including land clearing, exotic animals such as feral pigs, weeds and altered fire regimes. DEWHA (2008d) also noted that a potential threat to the Beach Nightshade may be habitat destruction associated with mining activities.

Will the proposed works ...	**Beach Nightshade (*Solanum dunalianum*): Vulnerable**
....lead to a long-term decrease in the size of an important population of a species?	The Beach Nightshade is known from two Torres Strait islands and between Weipa and Mapoon on western Cape York Peninsula, however it is expected to be more widespread on Cape York (Landsberg and Clarkson 2004). The species was not found in the Project area during targeted surveys, however for the purposes of the impact assessment it is assumed that it is likely to occur in the Project area in the vicinity of coastal vine forest and possibly vine forest on bauxite. Any occurrence of the species is considered an important population under the intent of the EPBC Act since the species is little known with few existing records for the mainland, and any known occurrence of the species is regarded as: • key source populations either for breeding or dispersal; • populations that are necessary for maintaining genetic diversity; and/or • populations that are near the limit of the species range. The Beach Nightshade is expected to be restricted to the margins of vine forest – these habitats would not be disturbed by mining or development of infrastructure. Furthermore, indirect effects on these communities from changes to surface and sub-surface hydrology are not expected to lead to significant impacts as effective mitigation would occur via the proposed environmental buffer system and measures to emulate pre-disturbance drainage characteristics in the post-mining landscape. The Project would not lead to a long-term decrease in the size of the Beach Nightshade population.
....reduce the area of occupancy of an important population?	As discussed above, habitats supporting the Beach Nightshade would not be adversely affected by the Project; consequently, the area of occupancy of the Beach Nightshade within the Project area would not be reduced.
....fragment an existing important population into two or more populations?	Reduction in the area of the Beach Nightshade would not occur as a result of the Project and the population of this species would not be fragmented.
....adversely affect habitat critical to the survival of a species?	The Project area does not include any critical habitat areas for the Beach Nightshade that are listed under the EPBC Act or identified in Recovery Plans. The species is probably widespread on Cape York.
....disrupt the breeding cycle of an important population?	Vine forest habitat would not be affected by the Project and there would be no effect on the breeding cycle of the species.
....modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	The vine forest habitat that supports the species would not be adversely affected by the Project, thus a decline in the species is not anticipated. The proposed fire management plan would favour the species by effectively reducing the impacts of the current fire regime on the fire-sensitive vine forest habitats.
....result in invasive species that are harmful to a vulnerable species becoming established in the vulnerable species'	The Project area is currently predominantly free of serious weeds and invasive species; however, a number of significant environmental weeds occur in the surrounding region. The peripheral vine forest habitats of the Beach Nightshade are

Will the proposed works ...	**Beach Nightshade (*Solanum dunalianum*): Vulnerable**
habitat?	favoured by weed invasion as the moist nature of the vine forest edge supports weed establishment. A number of smothering and ground cover weed species pose a threat, including Rubber Vine (*Cryptostegia grandiflora*) Hyptis (*Hyptis suaveolens*) and Stylo (*Stylosanthes* spp.). Proposed mitigation measures include a weed management program which includes preventative measures and control measures for weeds within the Project area. These mitigation measures would be effective in managing the impacts of weeds on the Beach Nightshade. The Project is not anticipated to lead to the establishment of invasive weeds within the habitat of the Beach Nightshade.
.....introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is not anticipated that the Project would represent a threat with respect to the introduction of disease.
....interfere substantially with the recovery of the species?	The Project would not lead to impacts on the Beach Nightshade and would consequently not interfere with the recovery of the species.

Spathoglottis plicata

As the regional population size of *Spathoglottis plicata* is relatively small, if this species was to occur within the disturbance footprint of the Project area, this would be regarded as an important population. However, if a population was present, it is unlikely the Project would interfere substantially with recovery of the species.

The key known potential threats to *Spathoglottis plicata* include over-collection and illegal collection by orchid enthusiasts, disturbance and foraging by feral pigs and altered hydrology (DEWHA 2008e).

Will the proposed works ...	***Spathoglottis plicata*: Vulnerable**
....lead to a long-term decrease in the size of an important population of a species?	*Spathoglottis plicata* is known from Cape York peninsula between Cooktown and the Jardine River and in the Asia Pacific region. *Spathoglottis plicata* has not been recorded from surveys within the Project area but suitable habitat occurs in the Project area, including riparian gallery forest, Melaleuca wetlands, and seasonally inundated grassy areas. A potential population of *Spathoglottis plicata* within the Project area (if found) would be considered an important population under the intent of the EPBC Act since the species is little known with only one record from western Cape York (near Weipa). Any additional known occurrence of the species would be regarded as significant because it would represent: • key source populations either for breeding or dispersal; • populations that are necessary for maintaining genetic diversity; and/or • populations that are near the limit of the species' range. *Spathoglottis plicata* may occur within the footprint of the proposed water supply dam (Dam C), although targeted surveys within the dam footprint did not locate the species. Suitable habitat for the species also occurs elsewhere in the Project area in areas to be undisturbed by mining and infrastructure. Habitat areas adjacent to mining areas may experience isolated localised minor effects due to changes in hydrology associated with removal of bauxite. However, these effects would be limited by effective mitigation measures including spatial buffering of riparian and wetland areas and use of reconstructed surface drainage and detention areas in mine pits to recharge shallow groundwater aquifers. Significant indirect impacts on the species due to hydrological change are not anticipated. Should *Spathoglottis plicata* occur within the footprint of the water supply dam, a long-term decrease in the size of the population may occur; however, there is no current evidence to suggest the species is present in this area.
....reduce the area of occupancy of an important population?	Should *Spathoglottis plicata* occur within the footprint of the water supply dam then the area of occupancy of the species within the Project area would be reduced; however, there is no current evidence to suggest the species is present in this area.
....fragment an existing important population into two or more populations?	It is not anticipated that *Spathoglottis plicata* would occur as discrete populations within the Project area. Disturbance of *Spathoglottis plicata* within the footprint of the water supply dam is not expected to fragment any population that may be present within the Project area.
....adversely affect habitat critical to the survival of a species?	The Project area does not include any critical habitat areas for *Spathoglottis plicata* that are listed under the EPBC Act or identified in Recovery Plans.
....disrupt the breeding cycle of an important population?	Should *Spathogolottis plicata* occur within the footprint of the water supply dam then the breeding cycle of the species would be disrupted within that area; however, there is no current evidence to suggest the species is present in this area.
....modify, destroy, remove, isolate or	The Project would disturb potential habitat for this species within the water supply dam

Will the proposed works ...	***Spathoglottis plicata*: Vulnerable**
decrease the availability or quality of habitat to the extent that the species is likely to decline?	footprint; however, more extensive areas of similar suitable habitat occur elsewhere throughout the Project area. The proposed feral animal control program would effectively reduce pig numbers in the Project area and would most likely reduce damage levels to potentially occurring populations of *Spathoglottis plicata* during the dry season. Furthermore, the fire management program would effectively reduce the impacts of fire to potential habitat areas. If the species occurrence is restricted to the Dam C footprint area then the species would experience a decline; however, if present within the Project area it is regarded as unlikely that the species would be restricted to the Dam C area given the availability of more extensive areas of similar suitable habitat associated with the main drainage systems of Norman Creek, Ward River and Winda Winda Creek.
....result in invasive species that are harmful to a vulnerable species becoming established in the vulnerable species' habitat?	The Project area is currently predominantly free of significant weeds and invasive species; however, a number of significant environmental weeds occur in the surrounding region. The moist nature of wetland and seasonally inundated habitats favoured by *Spathoglottis plicata* puts them at risk of invasion by weed species. Of particular concern is Rubber Vine (*Cryptostegia grandiflora*). Proposed mitigation measures include a rigorous weed management program, which includes preventative measures and control measures for weeds within the Project area. These mitigation measures would be effective in managing the impacts of weeds on *Spathoglottis plicata*. The Project is not anticipated to lead to the establishment of invasive weeds within any potential habitat of *Spathoglottis plicata*.
8.....introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is not anticipated that the Project would represent a threat with respect to the introduction of disease.
9....interfere substantially with the recovery of the species?	It is not anticipated that the species, if present in the Project area, would be restricted to the Dam C site only given the occurrence of more extensive areas of similar suitable habitat throughout the Project area, and consequently it is unlikely the Project would interfere substantially with recovery of the species.

7.12 Environmental Offsets

Under the Queensland offset matters specified in the Terms of Reference (ToR) (i.e. Queensland Government-specific issues environmental offsets policies and the *Policy for Vegetation Management Offsets* (NRW 2007) (refer to the *Regional Vegetation Management Code for Western Bioregions*)), no vegetation offsets are required under either of these Policies for clearing associated with the Project. The Project would not have a significant impact on the terrestrial MNES; therefore, offsets for terrestrial impacts are not required under the EPBC Act.

A condition of approval under the *Fisheries Act 1994* for removal of mangroves in the area of the Hey River barge/ferry terminal may include a requirement to provide a compensatory measure as an offset (refer **Section 6.9.3.2** for further discussion).

7.13 Overview of Terrestrial Fauna Survey Methods

Surveys were undertaken of the terrestrial fauna and habitats within the Project area. The main objectives of the fauna survey program were to characterise the fauna communities within the terrestrial habitats present and to provide substantial coverage of threatened and migratory species listed under the EPBC Act as these are the primary matters of national environmental significance relevant for the Project area (i.e. in the absence of threatened communities or populations). Survey techniques were used that were specifically suited to the species and habitats likely to be present as well as providing an optimal balance of intensive site based data and more extensive data on threatened and migratory species. A detailed description of the survey methodology used for threatened and migratory terrestrial fauna species is provided in **Appendix 7E**.Preliminary surveys were undertaken in July 2006 and May 2007 with dedicated surveys for the EIS undertaken in December 2007, May 2008, December 2008 and May 2009. The spread of survey events provided survey effort over key seasons for detecting fauna variability within the Project area, namely late dry season (December) and late wet season (May). Extensive survey during the wet season was not possible due to the difficulty of access to and within the Project area with the presence of seasonal inundation. Nevertheless, the main late wet season survey in May 2008 and subsequent targeted surveys in May 2009 were

conducted as soon as vehicle access to the Project area was possible, ensuring there was still a significant level of fauna activity.

The two preliminary fauna surveys in 2006 and May 2007 focussed on Darwin Stringybark (*Eucalyptus tetrodonta*) dominated communities on the bauxite plateau. These are the communities that occur within the mining path. Prior to the dedicated EIS surveys, a gap analysis was undertaken to identify fauna habitats requiring further survey effort to adequately describe their fauna community and potential for supporting endangered, vulnerable or rare (threatened) fauna species. As a result, the December 2007, May 2008, December 2008 and May 2009 surveys concentrated survey effort within non *Eucalyptus tetrodonta* dominated habitats occurring predominantly in riparian, seasonally inundated, coastal vine forest, and vine forest habitats occurring on the bauxite plateau. Additional surveys were also undertaken in *Eucalyptus tetrodonta* dominated habitats during these survey periods to extend the distribution of survey sites and coverage in this habitat within the Project area.

The location of fauna survey sites surveyed within the Project area is indicated in **Figure 7-10**. **Table 7-12** summarises the survey effort employed during all surveys in the Project area. A detailed description of fauna survey methods and other aspects of the study is provided in **Appendix 7E**.

Table 7-12 Summary of Fauna Survey Effort

Survey Component	Survey Effort
Comprehensive Fauna Sites	**12 Sites (48 days/nights)**
Elliot traps	2400 trap nights
Cage traps	16 trap nights
Pitfall traps	120 pitfall nights
Funnel traps	1000 trap nights
Hair tubes	288 hair tube nights
Anabat sessions	12 Anabat nights
Harp trap	12 trap nights
Morning bird searches	24 searches
Reptile searches	12 searches
Spotlight searches	12 searches
Call broadcast sessions	8 broadcasts
Supplementary Fauna Sites	**15 Sites**
Targeted (threatened) Fauna Survey	**27 days comprising**: • extensive foot traverses; • coastal observations with spotting scope; • Anabat sessions; • harp trapping; • funnel traps (224 trap nights); • spotlight surveys; • call broadcast sessions; • nocturnal crocodile spotlight surveys in the Ward River; • boat-based observational transect in Norman Creek; and • all terrain vehicle (ATV) traverses of beach habitats.

7.14 Fauna Habitats and Landscape Ecology

7.14.1 Description of Main Fauna Habitats

Detailed description of the floristic and structural composition of fauna habitats can be found in **Section 7-5** and **Appendix 7B**.

Darwin Stringybark (Eucalyptus tetrodonta) Open Forest on laterite

This habitat corresponds with RE 3.5.2 and is the dominant habitat type over the Project area and indeed the wider area of lateritic red earth plateau of the western Cape (covering more than 80% of the Weipa mining leases – Welch *et al.* 2004), and is the habitat where bauxite mining occurs.

Overall terrestrial microhabitat values are relatively abundant, comprising fallen timber, leaf litter, bark exfoliates and vegetative cover. Variability exists within localities supporting a number of tree species, especially where Cooktown Ironwood (*Erythrophleum chlorostachys*) is present, providing suitable microhabitats for a range of reptile, frog and mammal species. The denser exfoliates typical of Cooktown Ironwood not only provide thermally stable refugia but appear more resilient to fire damage, increasing the longevity of microhabitat availability. Furthermore, the canopy of Cooktown Ironwood provides increased shade and shelter opportunity as well as promoting a more patchy grass understorey compared to very tall closed grasslands beneath the canopy where Cooktown Ironwood is absent. Many stands of this habitat support a notable density and diversity of microhabitat for hollow dependant fauna.

Riparian Gallery Forest and associated alluvial/colluvial Woodland

The core feature of this habitat is as a narrow band of tall riparian "gallery" forest bordering the watercourses which drain the bauxite plateau within the Project area. The width of the riparian gallery forests (including the stream) generally ranges from a few metres in upper stream reaches to 90m in downstream reaches, with an isolated occurrence of 150m wide on Norman Creek. The associated woodlands comprise bands of *Banksia dentata* dominated low open woodland with sedgy understorey which occur on seasonal groundwater seepage zones, grading into a Bloodwood tall open woodland.

The water supply dam (Dam C) proposed for a freshwater tributary of Norman Creek would be situated within this habitat type. This habitat consists of a mosaic of RE types, which are defined as:

- Swamp Mahogany (*Lophostemon suaveolens*) dominated gallery open forest of streamlines, swamps and alluvial terraces (RE 3.3.9);
- Gallery notophyll vine forest on major watercourses (RE 3.3.5), which includes a high diversity of closed forest plant species;
- Bloodwood / Banksia in upper parts of broad basins (RE 3.3.21); and
- Bloodwood / Red Gum (*C. polycarpa* / *E. brassiana*) Woodland on colluvial upper reaches of broad drainage basins (RE 3.5.22c).

Arboreal habitat values are limited to a certain extent by a paucity of tree hollows and cavities which, if present, usually occur within dead and senescent *Lophostemon suaveolens*. The canopy structure and density is variable, with denser foliage providing potential refugia for bird and arboreal mammal species. The greater floristic diversity of shrub, small tree and canopy tree species provides a variety of feeding resources not available in drier vegetation types on the bauxite plateau.

Terrestrial habitat values comprise a mosaic of fallen tree litter and vegetation, with the persistent soil moisture providing refugial shelter opportunities beneath litter and logs and within burrows during the dry season. Leaf litter densities are variable with respect to the tree species present, time of year, and fire history, although piles of debris occur as a result of high streamflows. Scouring around tree roots in the riparian gallery forest caused by wet season

streamflows also provide shelter microhabitat and foraging areas for amphibians and small terrestrial reptiles. Ground mammal densities appear highest in association with this habitat type.

Notophyll Vine Forest on lateritic red earths

These habitats comprise notophyll vine forest on lateritic red earths of the bauxite plateau, and occur as isolated patches within broad areas of Darwin Stringybark open forest. Within the Project area this habitat occurs only in the Hey Point area with occurrences ranging in size from 2 to 50ha. These vine forest areas would not be disturbed by mining or infrastructure. These habitats are floristically diverse and structurally complex, with canopy heights reaching 20 to 30m with taller emergents. These habitats are often referred to as interfluvial vine forest and correspond with RE 3.5.4.

Arboreal habitat structure comprises fissures, exfoliations and some hollows with the abundance of each dependant on the frequency of large emergent trees such as *Ficus* spp. These trees also provide significant seasonal feeding and refugia resources for frugivorous birds and mammals. Terrestrial habitat opportunities are sporadic and highly dependent upon the failing structure of large trees. Although leaf litter is prolific and provides some refugia for smaller species of reptiles and amphibians the rotting ground timber and buttress structure associated with large tree species appears to be the most usable habitat for terrestrial reptile and mammal species.

Paperbark Woodland and Wetland Swamps

Small areas of Paperbark woodland habitat occur in association with seasonally inundated depressions within the Bauxite Plateau, with more extensive occurrences on the lower reaches of the larger streams (Winda Winda Creek, Norman Creek and Ward River) and peripheral to the marine plains associated with these stream systems. The depressional wetlands are locally referred to as tree swamps given that they usually support tree cover throughout; although some patches of open water may occur.

Many wetlands and streams within the Project area are recognised to be at least partially supplied by groundwater discharge from shallow aquifers hosted in the near-surface lateritic strata of kaolinite overlain by bauxite (refer to **Section 5.3.2**). The shallow aquifers discharge water to surface water bodies and streams in addition to the annual wet season surface runoff (Herbert 1995).

Habitat values vary depending on the species of *Melaleuca* present with only the oldest of stands supporting potential arboreal refugia for hollow dependant fauna. The exfoliating bark of *Melaleuca* and swamp mahogany (*Lophostemon suaveloens)* provides microhabitat for small lizards and frogs as well as harbouring invertebrate prey for these species and also insectivorous bird species. Associated flowering events are highly favoured by nectivorous bird and mammal species and often occur during the dry season when feeding resources are typically limited.

Terrestrial habitat composition is variable depending on soil and vegetative structure but is generally typified by a low microhabitat yield and therefore low species diversity. Seasonal inundation of these habitats limits opportunities for subsequent long-term microhabitat formation and occupation by fauna.

No mining is proposed for paperbark woodlands and wetland swamps in the Project area, however some wetland (RE 3.3.9 dominated by *Melaleuca leucadendra*) occurs within the footprint of Dam C.

Foreshores, Tidal Flats and Beach Strand Habitats

These habitat types form a discontinuous band along the Gulf coast of the Project area, and include beaches, sand dunes, beach strand herb fields and Coastal She-oak (*Casuarina equisetifolia*) woodland. The latter two habitats generally occur on raised dunes of the coastal margin away from estuaries and creek systems, where mangrove communities do not occur. These communities are of limited extent within the Project area due the prevalence of bauxite

cliffs along the Gulf coast and the absence of extensive hind dune and strand areas. Similarly, extensive tidal flats that provide habitat for wader birds do not occur along the Gulf coast adjacent to the Project area, with limited areas in the Hey River area. The productivity of these areas is apparently not significant given an observed paucity of wader activity throughout the year.

Habitat values are varied depending on the presence of strand vegetation but scavenging/predatory species including feral pigs, goannas, wild dogs and a number of raptor species are frequently encountered in these areas. The seasonal presence of marine turtle eggs attracts feral pigs, feral dogs and potentially goannas to these habitats. The foreshore habitats provide key habitat for the Beach Thick-knee (*Esacus neglectus*) and seasonal habitat for nectivorous and frugivorous birds that take advantage of flowering shrubs within the strand vegetation. No mining would occur within the coastal environment, although a bauxite ship loading port would be constructed on the coastline area south of Boyd Point.

Semi-evergreen Coastal Vine Forest

Semi-evergreen Coastal Vine Forest habitat corresponds with RE 3.2.2 and occurs on the primary dune sequence behind coastal fore dune habitats. Structural development is limited to a single closed canopy layer to 10m, with a diversity of mesic plant species in this layer. Within the Project area Semi-evergreen coastal vine forest occurs as isolated patches along the Gulf coastline associated predominantly with dunal deposits adjacent to rocky points and headlands. No mining or infrastructure related disturbance would occur within this habitat type.

Arboreal microhabitats including fissures, exfoliations and occasional hollows are dependant on the frequency of large emergent trees such as *Ficus* spp. These trees provide significant seasonal feeding and refugia resources for frugivorous birds and mammals. Terrestrial habitat opportunities are variable and highly dependant upon the failing structure of large tree species. Although leaf litter is prolific and provides some refugia for smaller species of reptiles and amphibians, the ground timber and buttress structure associated with large tree species appears to be the most favourable habitat for terrestrial reptile and mammal species. Considerable damage to the ground surface and lower vegetation can occur in these habitats from activity by sheltering and foraging feral pigs.

Mangrove and Estuary

This habitat occurs extensively in association with Norman Creek within the Project area and along downstream reaches of the Ward River and Triluck Creek that are just outside the Project area. Mangroves and estuaries also occur along the northern coastline of the Project area within the Embley/Hey River estuaries. These habitats provide significant foraging habitat for a variety of bird species, especially predatory species such as raptors, herons, egrets and diving birds but also smaller passerines associated with the nectivorous and insectivorous feeding resources provided within the mangrove forests. These areas are also the main habitat for the Estuarine Crocodile (*Crocodylus porosus*) within the Project area, providing year round foraging and shelter habitat compared to seasonal wetland areas. The only Project related disturbance to this habitat type would be construction of the barge and ferry terminals on the Embley and Hey rivers. Construction would involve some dredging, reclamation and piling at the barge and ferry terminals. The main disturbance to mangroves would be at the Hey River barge / ferry terminal, where removal of a relatively thin band of mangroves (400m^2) would be required directly at the terminal site.

7.14.2 Habitat Landscape and Condition

Other than minor direct disturbance associated with exploration drilling tracks, no broadscale clearing of vegetation has occurred within the Project area and consequently the natural habitat cover persists within the area, although significant modification of habitat features has apparently occurred as a result of the current regime of frequent intense fires (refer **Section 7.15.2**). Fires in the Cape York region start through: maintenance of fire regimes by Traditional Owners; fire management for the purposes of biodiversity conservation and protection of the community by DERM in the National Parks; maintenance of native pastures by the pastoral industry; as well as through storms and accidental or deliberate means. Although

mature canopy trees would take a significant time to re-establish along drill lines, the ground cover and midstorey vegetation re-establishes rapidly on drilling tracks and quickly emulates the lower strata of undisturbed forest. This limits the potential disruption to habitat continuity across drill lines to a short temporal effect and consequently, the existing system of drill lines within the Project area is not anticipated to have significantly altered the prevailing landscape of continuous native habitats.

The Darwin Stringybark open forest community is by far the most extensive habitat type covering approximately 85% of the vegetation within the Project area. There is very little intra-habitat variation within the Darwin Stringybark community; however, significant variation occurs between habitats within the Project area by virtue of the freshwater and marine wetland and riparian habitats, and small areas of coastal and bauxite plateau vine forest. A feature of fauna communities in tropical climes is the highly variable nature of availability of feeding resources determined by the pronounced dry and wet seasons. Typically this results in a large proportion of the relatively mobile component of the fauna community undergoing either seasonal migratory movements or undertaking local sequential use of a mosaic of different habitat types throughout the year. Migratory movements may be local or more extensive including beyond the Australian continent. Local migratory movements are anticipated to focus on movement between riparian/wetland habitats and the adjacent Darwin Stringybark open forest habitat. Although the Darwin Stringybark open forest habitat becomes progressively drier as the dry season proceeds, Darwin Stringybark (*Eucalyptus tetrodonta*) usually flowers in the early dry season providing a productivity peak.

Flowering, fruiting and seeding of plants from all vegetation strata within all habitats in the mid-late wet season also provides a significant peak in feeding resources. Within the riparian, wetland and vine forest habitats similarly staggered productivity spikes attract mobile vertebrate fauna at different times of the year. Overall this implies that the aggregation of woodland, riparian and wetland habitat types that occurs in a typical topographically determined sequence from the drop off of the bauxite plateau into the drainage systems (refer **Figure 7-5**) represent a key landscape element for fauna, as a wide array of resources are available throughout the year within a relatively compact area. This drainage corridor habitat aggregation occurs throughout the Project area on drainage systems but is best developed on the mid to lower reaches of tributaries of the Norman Creek system.

The riparian corridors linking upper tributary and bottom end wetlands and estuary habitats are also likely to represent key natural fauna movement corridors providing seasonal access to a variety of habitat opportunities.

Within the Project area the bauxite plateau typically extends right to the beach and a dunal system with associated vine forest and dunal woodland occurs only as an intermittent feature in association with isolated dunal systems, close to stream mouths and rocky points. Consequently there is not a natural corridor of denser vegetation linking individual drainage systems such as can be observed to the north of Weipa where a continuous band of dunal vine forest and swale wetlands links the lower end of drainage systems. This implies that mobile fauna that need to move between riparian habitats hosted by different drainage systems to fulfil their annual foraging and possibly breeding requirements may need to traverse extensive areas of Darwin Stringybark open forest between these systems.

Relevant species include raptors, waterfowl, honeyeaters, parrots and cockatoos, fruit pigeons and flying fox. For instance, the Norman Creek and Ina Creek systems are separated by extensive Darwin Stringybark open forest with bauxite cliffs as is Norman Creek and Winda Winda Creek. It is anticipated that corridors of Darwin Stringybark open forest would be important in providing access between these riparian features and connectivity would be maintained by buffer vegetation and unmined remnant vegetation.

7.15 Fauna Communities

7.15.1 Overview

A combination of surveys and literature reviews were completed to develop an understanding of Project area fauna. A total of 269 native terrestrial vertebrate fauna species (including common species) was recorded from all habitat types within the Project area based on the results of EIS surveys and preliminary studies. This constitutes approximately 83% of the 324 native species of terrestrial vertebrate fauna collated in a recent review of fauna occurring in the Weipa region. About 98 species or approximately 36% of the total compliment of species from the Project area have been identified from Darwin Stringybark open woodland which is the habitat that occurs almost exclusively on the bauxite plateau. A detailed list of the fauna species recorded from the Project area indicating the relative abundance and habitats for each species and the results for each of the twelve comprehensive survey sites is provided in **Appendix 7F.**

Table 7-13 summarises the fauna diversity recorded in the Project area compared to the Regional fauna community and indicates that there is considerable fauna diversity within the Project area reflecting the diversity of habitats present including closed forest, woodland, and a range of stream, wetland and coastal habitats. Fauna diversity is concentrated within the non Darwin Stringybark open forest habitats which together comprise less than 20% of the total area of the Project area.

Five species were recorded only from Darwin Stringybark open forest: Black-headed Python (*Aspidites melanocephalus*), King Brown Snake (*Pseudechis australis*), Australian Bustard (*Ardeotis australis*), Red-tailed Black Cockatoo (*Calyptorhynchus banksii*), and *Pipistrellus westralis* (a microbat). However, this is regarded as an artefact of sampling probability as all of these species are known to utilise the other types of habitats present within the Project area, and no species are expected to be restricted to Darwin Stringybark open forest.

Table 7-13 Native Fauna Diversity within the Project and Weipa Areas

Area	Main Habitats	Birds	Mammals	Reptiles	Amphibians	Total
Project area	Darwin Stringybark open Forest habitat	62	10	23	3	98
	Riparian Gallery Forest/alluvial woodland	95	10	28	16	149
	Vine Forest on bauxite	20	2	5	2	29
	Paperbark Woodland and Wetland Swamps	78	5	14	15	112
	Foreshores, Tidal Flats, Beach	39	1	4	0	44
	Coastal Vine Forest	23	5	8	2	38
	Mangrove and Estuary	49	1	3	1	54
	All habitat types	184	23	45	17	269
Weipa region	All habitat types	201	41	61	21	324

Note: All data are numbers of species

The relatively low proportion of the regional native mammal diversity recorded within the Project area is notable. A total of 23 mammal species was recorded, including 10 microbat species, representing 56% of the regional mammal fauna. The Sugar Glider (*Petaurus breviceps*) was recorded at five locations and the Common Brushtail Possum (*Trichosurus vulpecula*) was recorded only once and within beach strand vegetation near False Pera Head. The absence of the Common Brushtail Possum from the extensive Darwin Stringybark open forest habitat and riparian habitats suggests the current land management regime is adversely affecting arboreal mammals (refer **Section 7.14.2**).

Similarly, only minimal numbers of small ground mammals from four species were recorded during the surveys, with a single individual Cape York Melomys (*Melomys capensis*) the only small mammal captured in Darwin Stringybark open forest. Small mammals were generally

restricted to moister refugial habitats comprising vine forest and riparian gallery forest but did not attain high densities in any of these habitats.

7.15.2 Habitat Condition and Effects on Fauna Diversity

Habitat condition within the Project area appears significantly affected by fire; however, little information is available for the Weipa region in particular that details the effect of fire and subsequent changes to fauna habitat quality and utilisation by various fauna species. General fire research in northern Australian savannah vegetation suggests that biodiversity would be maintained through administration of a diverse range of fire regimes that retain or enhance heterogeneity of habitat (Crowley 1995). The creation of a mosaic of vegetation patterns (with different fire age) increases the ability of fire-sensitive fauna species to move into refuge areas (swamps, vine forest, drainage lines) and areas of the more widespread open forest habitat types which have been less recently burnt. Extensive late dry season fires which are currently a feature of the fire regime within the Project area do not result in such mosaics, leading to extensive areas from which species can be eliminated and few refuge areas from which recolonisation can occur (Crowley 1995).

Habitat types that are infrequently burnt, including vine forest, riparian gallery forest and some Melaleuca wetlands, support species that are poorly adapted to fire, and also act as refuge areas for open forest/woodland species which breed or roost in these areas. Responses to fires vary considerably among fauna groups in northern Australia, ranging from seeking refuge in soil fissures or tree hollows to movements to unburnt areas or refuge habitats (Crowley 1995). Responses relate to the ability of individuals to survive fire events and, following this, survive predation/competition while continuing to locate necessary resources in the post-fire landscape (Crowley 1995).

Variable responses to fire lead to changes in assemblages of animals, depending on the fire history of an area. This is particularly relevant to the Project area as recent fire history appears to have favoured fire-tolerant species across large tracts of forest/woodland, and a decline in fire-sensitive species that formerly occurred in open forest/woodland is apparent. There is also evidence to suggest floristic changes and contraction in area of fire-sensitive habitat types is continuing to occur in response to the current fire management regime (Dames and Moore 1996), a factor which is likely to have implications for fauna species that rely on these areas as primary or secondary habitat.

The current occurrence of late dry season burning produces hot fires with high scorch height and extensive spatial extent that burn into moist riparian forest and wetland communities that would otherwise be too moist to burn in the early dry season. This has had the effect of further reducing the availability of refuge habitat from which animals can re-colonise open eucalypt forest/woodland communities after fire. A regime of patchy, early dry season fires when vine forest, riparian and swamp vegetation is less dry would help to maintain a greater diversity of habitats and would benefit species that require specific less fired vegetation types and fire-sensitive species that require vegetation to remain unburnt for many years. Significant fauna species identified for the Weipa region are included in both these groups.

RTA is involved in the Cape York Peninsula Sustainable Fire Management (CYPSFM) project, which aims to improve coordination and cooperation between land holders across all land tenures, and develop a sound basis for sustainable fire management strategies and practices (CYPDA 2009).

Significant changes to the fauna assemblage of most habitat types, including the more common and widespread Darwin Stringybark open forest habitat, were noted for a nearby area of similar habitat composition between 1985 and 1996, and attributed primarily to inappropriate fire management practices (Dames and Moore 1996). This fire regime is similar to that occurring within the Project area and was identified as responsible for degrading habitat values (Dames and Moore 1996), and resulted in the contraction and decline in abundance of terrestrial fauna species within these habitat types (Winter and Lethbridge 1994). An example of this is the contraction and decline in abundance of the Common Brushtail Possum (*Trichosurus vulpecula eburacensis*) in a large tract of Darwin Stringybark open forest and associated woodland to the

north of Weipa. Formerly dense populations of this species, described as being "particularly common" in the area and easy to locate if present in an area (Winter and Atherton 1985), appear to have become locally extinct due to changes in fire management (Winter and Lethbridge 1994). This decline was also confirmed across the broader northern Cape York area (Winter 2007) and is reflected in the survey data for the Project area where only one individual of Common Brushtail Possum was recorded from beach vegetation near False Pera Head.

Other groups of fauna have also recently become less common in the Weipa area, such as birds that feed on bark and foliage invertebrate communities. In particular, the decline of the Brown Treecreeper (*Climacteris picumnus*) on Cape York has been associated with recent burning practices (Winter and Lethbridge 1994), and this species was not recorded from the Project area.

Disturbance of ground habitat resulting from wallowing and foraging pigs is widespread within the Project area and impacts on the quality of habitat for fauna. Wetland and riparian areas are particularly targeted and the former can experience significant damage towards the end of the dry season. This may not have a significant effect on fauna activity which typically declines in these areas as the wetland dries out; however, there may be a long-term effect on the quality of this habitat – for instance, by consumption of sedge and rush tubers that would otherwise regenerate the following wet season.

7.15.3 Introduced Fauna

Six species of introduced fauna were detected during the survey, including three species listed under the *Land Protection Regulation 2002* (class 2 pest animals). **Table 7-14** lists these species. All these species are commonly encountered throughout the Weipa–Aurukun area.

Pest animals can have major impacts on native animals by preying on them, competing for food and damaging ecosystems.

The Feral Pig is by far the most abundant species within the Project area, occurring within all habitat types. The distribution and occurrence of feral pigs within the Project area follows seasonal patterns related to the inundation of wetland habitats and availability of potential food sources. Fresh pig diggings were consistently observed within the Darwin Stringybark woodland habitat of the bauxite plateau following the wet season, indicating widespread utilisation of this habitat during the wet season when substantial vegetative growth provides foraging opportunities. The inundation of wetland habitats during this time also tends to transfer pig activity from wetland areas as pigs tend to avoid substantially inundated areas presumably due to the risk of predation by Estuarine Crocodiles (*Crocodylus porosus*). As the dry season progresses, feral pig activity becomes more concentrated on wetland and riparian areas where sustained shallow inundation and elevated soil moisture continue to provide foraging opportunities. The seasonal 'Bulkuru' spike rush (*Eleocharus dulcis*) wetlands located in lower catchment areas are particularly targeted for foraging as water levels recede.

Foraging by feral pigs for fruit and seeds, leaves and stems, bulbs, tubers, fungi, soil invertebrates and insects causes disturbance which can damage soil structure resulting in erosion, affect plant succession or play a role in dispersing exotic plant seeds, and subsequently affect native fauna habitat. Predation of turtle nests by feral pigs is discussed in **Section 6.9.4.3**.

The Yellow Crazy Ant (*Anoplolepis gracilipes*) is a declared pest animal in Queensland. Crazy ants spray formic acid as a defence mechanism, which can kill some fauna (e.g. crabs) (DEWHA 2009b). They also protect scale insects which, when high in density, can cause forest trees to die back. There have been no crazy ants detected in the Weipa area to date. They are most commonly transported in sea cargo. The Australian Quarantine Inspection Service (AQIS) inspect and eradicate these types of pests in port areas. All vessels owned and contracted by Rio Tinto would comply with AQIS guidelines, where required.

Disease vectors and biting insects are discussed in **Section 18.5.3**.

Relatively high densities of feral cats were recorded during the July 2007 survey period, with numerous individuals recorded in a single night's spotlighting effort. High numbers of feral cats

were not subsequently recorded in later surveys but the species is regarded as ubiquitous and numerous throughout the Project area. Given the low densities of small mammals within the Project area, key prey items for feral cats are likely to be ground reptiles, amphibians and birds.

Table 7-14 Pest and Introduced Fauna in Project area

Species*	Common Name
Class 2 Pest Animals	
Feral Cat	*Felis catus*
Dingo/Dingo Hybrid	*Canis familiaris dingo / x C. Familiaris*
Feral Pig	*Sus scrofa*
Other Introduced Fauna	
Cane Toad	*Bufo marinus*
Feral Horse	*Equus caballus*
Feral Cattle	*Bos* spp.

* Declared under *Land Protection Regulation 2002*

Class 1 Not generally established in Queensland and has potential to cause an adverse economic, environmental or social impact.
Class 2 Established in Queensland and can cause significant adverse economic, environmental or social impact.
Class 3 Established in Queensland and has or could have adverse economic, environmental or social impact.

Feral Dogs/Dingoes were observed occasionally during survey events with signs of the species also observed from time to time. The species was most frequently observed at campsites utilised during surveys that were located close to the coast and wetland areas. It is anticipated that, although the species would be encountered in all habitat types, it is most prevalent close to the coast where scavenging opportunities exist along beaches and close to human campsites.

The Cane Toad was not observed in the very high densities that can be encountered on the east coast of Queensland, but was observed frequently in and around wetland and riparian areas. Similarly, no dense aggregations of Cane Toad tadpoles were observed in any of the wetland waterbodies within the Project area, although minimal observations were possible during the commencement and middle of the wet season when peak reproduction would be expected. Cane Toads were not observed within the Darwin Stringybark Woodland habitat but may utilise these habitats during the wet season, although extensive use of this habitat away from wetland and riparian areas is not anticipated.

Feral horses and cattle were observed infrequently during all surveys but most often encountered in the Hey Point area close to the coast. It is likely that both species make use of grassy areas associated with seasonal wetlands and marine plains but neither are anticipated to be widespread in the Project area.

7.15.4 Threatened and Migratory Fauna – EPBC Act

Threatened Fauna

The Commonwealth EPBC Act provides for the listing and protection of threatened fauna in Australia. The threatened status categories for fauna under the EPBC Act in order of increasing conservation significance are "vulnerable", "endangered", "critically endangered" or "conservation dependant". **Table 7-15** lists the threatened fauna species that:

- have been previously recorded from within or in close proximity to the Project area (DERM 2009c);
- have been found during surveys for the EIS;
- could potentially occur within the Project area based on EPBC database search; and
- could potentially occur within the Project area based on previous surveys in the Weipa area for RTA.

Table 7-15 Threatened fauna listed under the EPBC Act

Species **Common Name (Source of Record)**	**EPBC Status**	**Key Resources**	**Habitat**	**Likelihood of Occurrence within Project Area and Areas of Proposed Disturbance within the Project Area (Site)**
Birds				
Erythrotriorchis radiatus Red Goshawk (Wild, epbc)	V	Trees >20m high for nesting within 1km of a watercourse or wetland. Abundance of passerine prey	Favours coastal and sub-coastal areas. Prefers a mix of vegetation types including tall open forest, woodland, lightly treed savannah and the edge of rainforest and riparian forests. If present, the species could utilise all RE's within the Project area (Refer to **Figures 7-6** to **7-6d** for the locations of RE's within the Project area).	**Project Area** **Possible**: the open forest, woodland, riparian, and wetland habitats that occur throughout the Project area, in areas not to be disturbed by mining, present suitable nesting and feeding opportunities for the species. **Mining Area** **Possible:** the open forests of the mining area and adjacent habitats constitute likely foraging habitat for the Red Goshawk, although no sightings of the Red Goshawk were made during the surveys. Darwin Stringybark woodlands within 1km of permanent water could be used for nesting. It is possible that nests of the species could be within proposed mining areas. **Dam C on Norman Creek and infrastructure footprint** **Possible**: no nests were located within the proposed dam site. However, Dam C contains potential foraging and nesting habitat.
Erythrura gouldiae Gouldian Finch (Wild, epbc)	E	Annual and perennial grasses (especially Sorghum), a nearby source of surface water and unburnt hollow-bearing *Eucalyptus* trees for nesting	Inhabits open woodlands that are dominated by *Eucalyptus* trees and support a ground cover of Sorghum and other grasses, close to a reliable dry season water supply.	**Unlikely**: The species is recorded only rarely, and in small numbers, on the Cape York Peninsula. The Project area is located well outside the historical known range of the species although there are confirmed WildNet records from the Aurukun Council area. The current regime of frequent extensive fires is likely to affect the availability of favoured seed during the dry season over large areas of the Project area. In most years, fresh water does not persist across the vast majority of the Project area during the dry season, and it is likely that fresh surface water is totally absent following poor wet seasons. The species was not located during surveys in the most suitable habitat location within the Project area and consequently it is anticipated that the Project area does not support the species.
*Rostratula australis** Australian Painted Snipe (epbc)	V	Vegetated ephemeral wetlands	Inhabits shallow vegetated ephemeral wetlands in coastal and inland areas	**Unlikely:** Project area is well beyond the known range of the species, which is not known to occur on Cape York Peninsula.

Species **Common Name** **(Source of Record)**	**EPBC Status**	**Key Resources**	**Habitat**	**Likelihood of Occurrence within Project Area and Areas of Proposed Disturbance within the Project Area (Site)**
Tyto novaehollandiae kimberli Masked Owl (+)	V	Medium to large tree hollows for nesting, and availability of preferred small mammal prey	Prefers tall eucalypt forest and woodlands. Potential habitat comprises REs 3.2.2, 3.2.3, 3.3.5, 3.3.9, 3.3.14a and 3.5.4 (Refer to **Figures 7-6** to **7-6d** for the locations of RE's within the Project area).	**Project Area** **Possible**: the majority of key habitat resources for the species within the Project area are located in areas not to be disturbed, however, the prevalence of the species may be significantly limited by the apparent paucity of small mammal populations. **Mining Area** **Unlikely:** key potential habitat areas (riparian, wetland and vine forest habitats) and peripheral habitat (Darwin Stringybark open forest habitat adjacent to the key habitat areas), are not located within the proposed mining area. **Dam C on Norman Creek and infrastructure footprint** **Possible**: sections of tall closed forest on major drainages along Norman Creek and the Ward River provide potentially suitable habitat. The Dam C footprint contains some suitable habitat, however, this area is not regarded as especially significant for foraging or breeding. The prevalence of the species may be significantly limited by the apparent paucity of small mammal populations within the Project area.
Mammals				
Dasyurus hallucatus Northern Quoll (Wild, epbc)	E	Availability of tree hollows and rock crevices for den sites. Availability of land based prey	Rocky escarpments in eucalypt forests and woodlands within coastal regions (Oakwood 2008, Menkhorst and Knight 2001). Potential habitat comprises REs 3.2.2, 3.3.9, 3.3.14a, 3.3.21, 3.5.4 and 3.5.22c (Refer to **Figures 7-6** to **7-6d** for the locations of RE's within the Project area).	**Project Area** **Possible**: although the optimal habitat for the species, rocky outcrops and other rocky habitat, is not available within the Project area, the Northern Quoll may occur in vine forest and riparian gallery forest. All vine forest areas, and most riparian habitats within the Project area, are located in areas not to be disturbed. **Mining Area** **Unlikely:** this species has declined on Cape York following the spread of Cane Toads to the area. A paucity of favoured rocky habitat and continued exposure to modification and suppression by fire may see limited persistence of the species in suitable habitat within the Project area. Whilst the species may once have utilised Darwin Stringybark woodland it is most likely that patches of vine forest and riparian forest habitat currently provide the most likely habitat for the species within the Project area. Suitable habitat for the species includes the riparian communities of Norman Creek, and the vine forest patches in the Hey Point area, which are not within mining areas. **Dam C on Norman Creek and infrastructure footprint** **Possible**: minor areas of suitable riparian habitats are located within the footprint of the water supply dam, although targeted surveys did not locate the species in these areas. The habitat areas within the proposed dam footprint are not regarded as especially significant for foraging or breeding.
Notomys aquilo Northern Hopping Mouse (epbc)	V	Suitable sandy substrates for burrow excavation	In the Northern Territory part of its range, known to occur in Acacia scrub, heath and grasslands on sand dunes within coastal regions (Menkhorst and Knight 2004)	**Unlikely:** The type specimen of this species was recorded from Cape York Peninsula in 1867 but has since not been recorded in Queensland. Very little potential habitat within the Project area associated with isolated dunal systems.

Species **Common Name** **(Source of Record)**	**EPBC Status**	**Key Resources**	**Habitat**	**Likelihood of Occurrence within Project Area and Areas of Proposed Disturbance within the Project Area (Site)**
Saccolaimus saccolaimus nudicluniatus Bare-rumped Sheathtail Bat (Wild)	CE	Long deep tree hollows for roosting. Availability of flying insect prey.	Known habitats on Cape York include riparian forest and vine forest and adjacent woodland, including Darwin Stringybark dominated habitats. Potential habitat comprises REs, 3.2.10c, 3.3.5, 3.3.9, 3.3.21, 3.3.49b, 3.3.61, 3.5.2, 3.5.4, 3.5.11, 3.5.22c and 3.7.3 (Refer to **Figures 7-6** to **7-6d** for the locations of RE's within the Project area).	**Project Area** **Possible**: This species' habitat is poorly known. The species may favour riparian forest and vine forest and adjacent Darwin Stringybark dominated habitats and was found roosting in Darwin Stringybark at Iron Range. Vine forest areas and most riparian habitats within the Project area are located in areas not to be disturbed. Extensive areas of Darwin Stringybark woodland also occur outside of the disturbance footprint. **Mining area** **Possible**: Darwin Stringybark habitat within proposed mining areas may be suitable for the species, especially in the vicinity of riparian gallery forest and vine forest patches. **Dam C on Norman Creek and infrastructure footprint** **Possible**: Riparian forest within the Dam and infrastructure footprint may present suitable habitat.
Xeromys myoides Water Mouse (epbc)	V	Availability of prey especially crustaceans; availability of estuary and adjacent freshwater wetland habitat	Inhabits mangrove communities and associated saltmarsh, sedgelands, clay pans, heathlands and freshwater wetlands with intact hydrology	**Unlikely:** DSEWPC habitat mapping indicates the western Cape York area as potential habitat for the species but there are no known populations within approximately 750km of the Project area. Extensive traverses of wetland and mangrove habitat areas were undertaken within the Project area and no signs of the species, particularly nesting mounds, were located. It is not anticipated that the species occurs within or adjacent to the Project area.

* The schedules of the Queensland *Nature Conservation Act 1992* list this species as *Rostratula benghalensis* rather than the recently proposed species *R. australis*, formerly considered as a subspecies of *R. benghalensis*.

Key to Source of Record codes:

epbc	Potential species from the EPBC database
Wild	Records from the WildNet database
+	Additional potential threatened species added to assessment based on local knowledge

Key to Status:

CE	Critically Endangered
E	Endangered
V	Vulnerable

An assessment is provided of each species' potential occurrence in the Project area based on their habitat requirements and the condition and array of habitats available. The source of records for each species is indicated in **Table 7-15** along with the preferred habitat and known occurrence in the Weipa region. **Figure 7-7a**, **Figure 7-7b** and **Figure 7-11** detail the location of threatened fauna recorded during field surveys.

Of the 8 threatened species identified as potential inhabitants of the Project area, 1 is listed as critically endangered, 2 are listed as endangered and 5 are listed as vulnerable, and:

- 4 species possibly occur in the Project area; and
- 4 species are unlikely to occur in the Project area.

The REs that represent potential habitat for each threatened species is provided in **Table 7-15**. Refer to **Figure 7-6, Figure 7-6a, Figure 7-6b, Figure 7-6c** and **Figure 7-6d** for the location and distribution of these REs within the Project area. Refer to **Table 7-10** for data on the area of proposed disturbance of REs compared to the total area within the Project area, the Weipa Plateau subregion, and the Cape York Bioregion.

Profiles of each of the eight threatened species are provided below.

Red Goshawk *(Erythrotriorchis radiatus)*

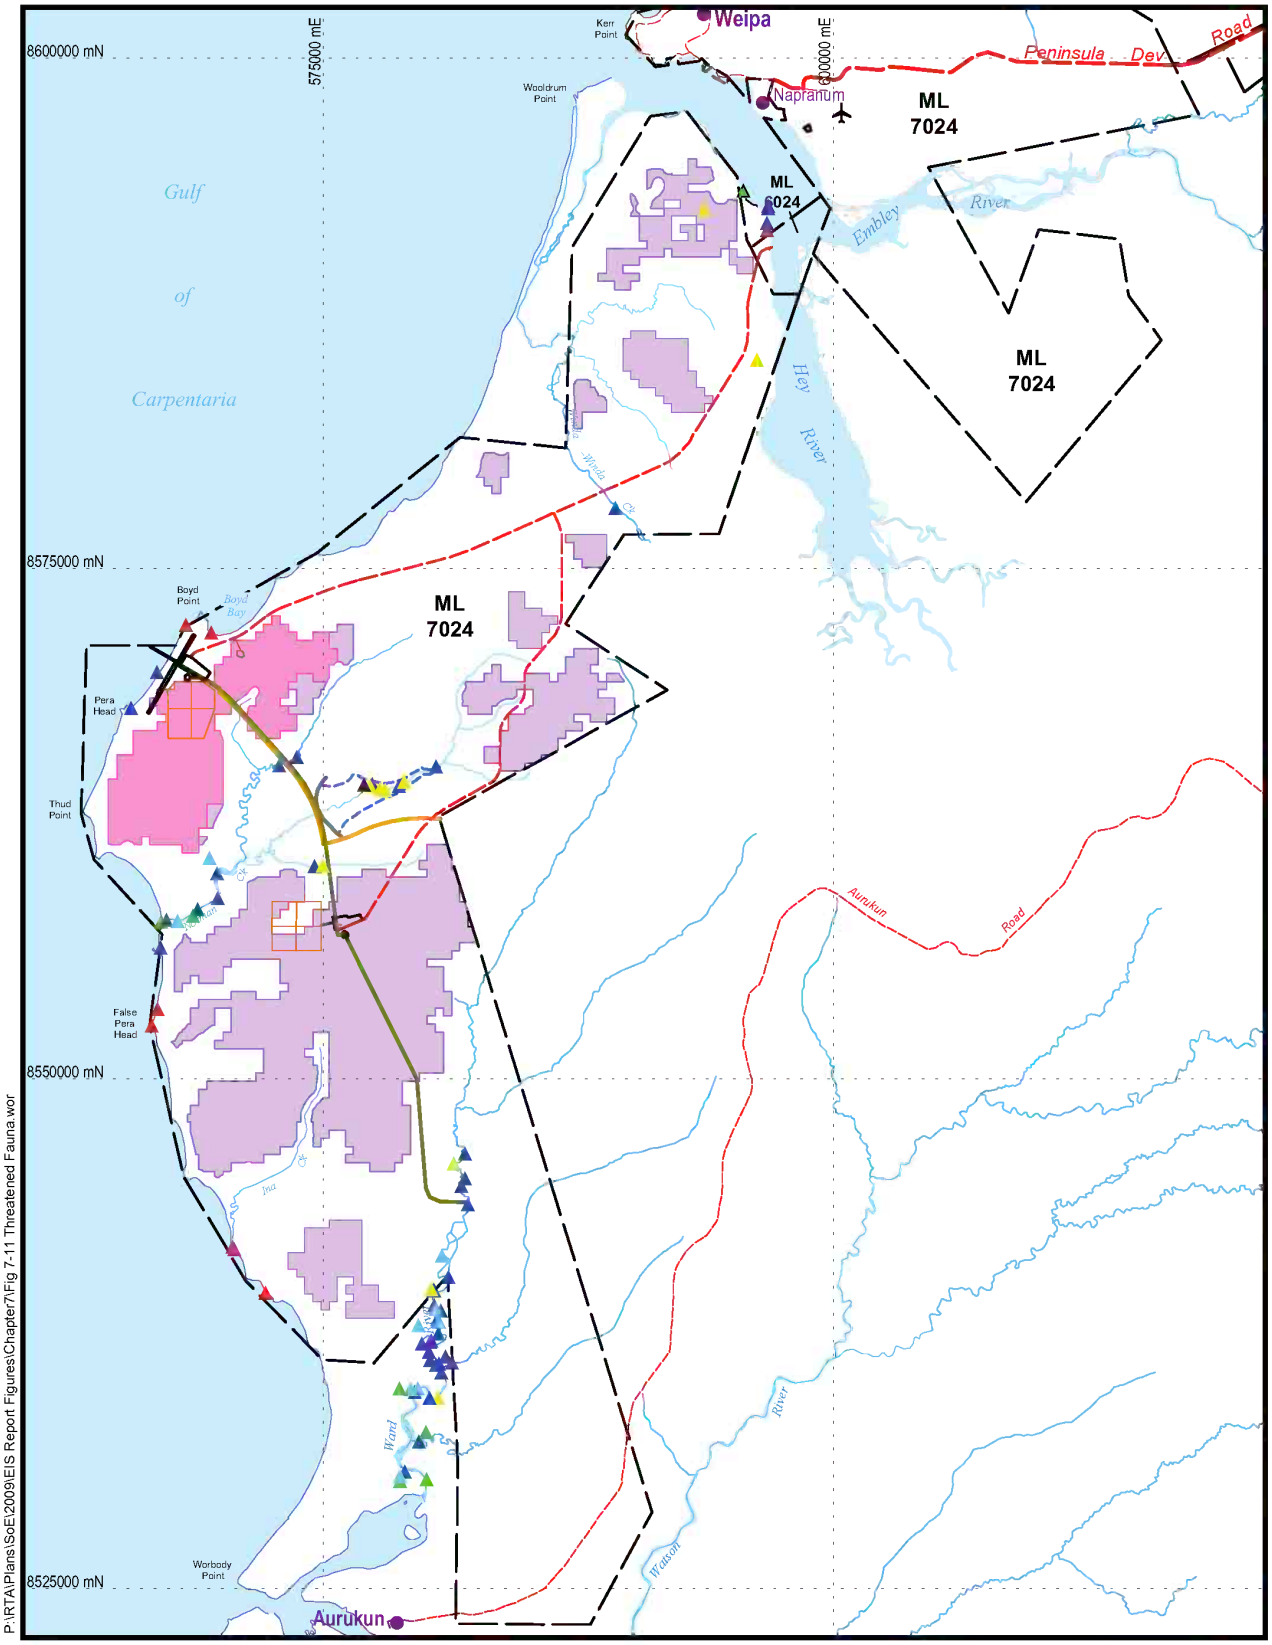
The Red Goshawk has a wide range from northern WA to northern NSW, although it occurs in low numbers. The species has been recorded in riparian gallery forest associated with the lower Wenlock River to the north of the Project area (Blandford and Associates 1994), and was also recorded in the open woodland of the Merluna Plain to the north-east of the Project area (Winter and Atherton 1985).

The Red Goshawk is known to inhabit large home ranges of between 50 and 220km^2 in Queensland, with foraging regularly taking birds up to 8km from established nesting sites (Marchant and Higgins 1993). Habitat utilised in north Australia is described as tall open forest and woodlands traversed by waterways supporting gallery forest (Garnett and Crowley 2000). The open forests of the Project area and adjacent habitats constitute likely habitat for the Red Goshawk, although no sightings of the Red Goshawk were made during the surveys. The species could possibly utilise the study area at least occasionally as part of its extensive home range.

The nest trees are restricted to trees taller than 20m located within 1km of, and often beside, permanent water (Aumann and Baker-Gabb 1991, DEWHA 2009c, NPWS 2002). On this basis it is possible that nests of the species could be located within Darwin Stringybark open forest adjacent to permanent water or coastal habitats, or adjacent to seasonally inundated wetlands or seasonal watercourses supporting riparian gallery forest.

The species hunts in open forests and gallery forests, taking mostly medium to large birds (Czechura and Hobson 2000). It is most likely that wetlands of the lower Ward River area (located immediately downstream of the Project area) provide the best dry season foraging for the species as they support a greater abundance of these wetland habitats compared to areas contained within the Project area.

Habitat clearing is the major known threat to the Red Goshawk (EPA 2006). Human disturbance at nest sites are also known to disturb breeding pairs and result in reduced reproductive success, because breeding pairs can use the same nest in successive years (EPA 2006). However, they have been reported to build new nests after nests have failed or been cleared, or to nest in different areas seasonally to be closer to target prey. Debus and Czechura (1988) reported that after clearing of habitat, one pair left their nest site and were presumed to have re-nested 5km away. Aumann and Baker-Gabb (1991) reported that following the failure of a nest the pair concerned constructed a replacement nest. In winter in eastern Australia, the birds appear to move from nest sites in the ranges to coastal plains, where they are associated with permanent wetlands and often feed on waterbirds (Czechura and Hobson 2000). It is likely that Red Goshawks also undertake this habitat shift on northern Cape York as large numbers of waterfowl become concentrated on fewer wetland areas as wet season inundation recedes.



P:\RTA\Plans\SoE\2009\EIS Report Figures\Chapter7\Fig 7-11 Threatened Fauna.wor

Rio Tinto Alcan

South of Embley Project

Fig. 7-11: Threatened and Migratory Fauna Records

Based on the EPBC Act species profile for the Red Goshawk (DSEWPaC 2010), other possible threats include the following:

- The theft of eggs for egg collections and the intentional killing of adults.
- The application of persistent pesticides such as DDT may have caused a historic reduction in the population. In 1989, Australia ceased widespread use of organochlorine pesticides and most affected species have now recovered;
- Overgrazing, or other changes in land management which could reduce prey availability, and therefore reduce productivity.
- Altered fire regimes have the potential to impact breeding sites and reduce prey availability, thus reducing productivity.
- The occurrence of a catastrophic event which may exaggerate the impact of existing threats.
- Possible genetic bottlenecks in the population.

Gouldian Finch (*Erythrura gouldiae*)

The Gouldian Finch is recorded reliably only at a small number of sites within six Northern Territory and Western Australia bioregions, while in Queensland the species is now rarely seen in the wild (O'Malley 2006). The Project area is located well outside the historical known range of the species. There are confirmed WildNet records from the Aurukun Council area, however, the habitat within which the species was recorded is unclear.. The species was not recorded during surveys within the Project area.

The critical components of suitable core habitat for the Gouldian Finch appear to be the presence of favoured annual and perennial grasses (especially *Sorghum*), the presence of reliable sources of dry season surface water in close proximity to nesting habitat (given their need to drink every day) and, in the breeding season, the presence of significant numbers of unburnt potential nesting hollows in *Eucalyptus* trees (O'Malley 2006a; Tidemann 1996).

The Gouldian Finch is largely sedentary although there may be some dispersal of young over a number of kilometres from nesting sites. Consequently, the critical components of core habitat would need to occur within, or in very close proximity to, the Project area for the species to be able to occupy the Project area.

The Project area supports grass species that are favoured by the Gouldian Finch, but the current regime of frequent extensive fires is likely to affect the availability of seed during the dry season over large areas of the Project area. In most years, fresh water does not persist across the vast majority of the Project area during the dry season, and it is likely that fresh surface water is totally absent following poor wet seasons. The Gouldian Finch requires access to unburnt eucalypts with hollows during the breeding season. It is unclear when the breeding season of the species would be on northern Cape York but elsewhere there is a peak in breeding activity in the late wet season. The species would have access to unburned eucalypts at this time, although many trees would be recovering from fire the previous season.

The characteristic vagaries of seed and fresh water availability within the Project area are anticipated to render the area unsuitable for the Gouldian Finch.

Vegetation change, through inappropriate fire regimes and grazing impacts of stock and feral herbivores, is the factor most likely to be contributing to ongoing declines, or absence of recovery, in Gouldian Finch populations. During the 1980s there was evidence of high rates of air sac mite (*Sternostoma tracheacolum*) in wild Gouldian Finch populations, however, the extent of impact from disease remains unclear (O'Malley 2006).

Australian Painted Snipe *(Rostratula australis)*

The Australian Painted Snipe generally inhabits shallow terrestrial freshwater (occasionally brackish) wetlands, including temporary and permanent lakes, swamps and claypans. They also use inundated or waterlogged grassland or saltmarsh, and dams.

The species has not been recorded on northern Cape York Peninsula (Garnett and Crowley 2000) and is regarded as unlikely to occur within the Project area.

Masked Owl *(Tyto novaehollandiae kimberli)*

The northern race of the Masked Owl occurs between Townsville and the Kimberley region with other races extending down the east coast to Tasmania. The Masked Owl has been recorded in the Aurukun area with a specimen record reported on the WildNet database although the habitat within which it was recorded is unclear. The species was not recorded during surveys within the Project area. General habitat preference of this species comprises riparian gallery forest, rainforest, mangroves and the periphery of Melaleuca swamp forest (Garnett and Crowley 2000). Clearly, all of these habitat types occur in the Project area with the sections of riparian forest on major drainages along Norman Creek and the Ward River providing likely habitat. However, the Masked Owl is a specialist predator of small–medium sized ground mammals and the apparent paucity of these mammal populations within the Project area is likely to limit the habitat values of the Project area for the species. On this basis the Masked Owl is regarded as a possible inhabitant of the Project area but would most likely be restricted to riparian gallery forest above the coastal/brackish wetland zone where reduced seasonal inundation allows persistence of small mammal populations.

Potentially suitable habitat occurs along Norman Creek and Coconut Creek/upper Ward River. Construction of the water supply dam would disturb some suitable habitat, although the majority of preferred habitat areas would not be disturbed by the Project.

There is some evidence to suggest that the main threat to the Masked Owl is the decline in populations of small and medium sized native mammals, which are the Masked Owl's primary food source (Woinarski, 2004). The broad scale application of the rodenticide Klerat (now banned) may also have lead directly to the mortality of Masked Owls.

Northern Quoll *(Dasyurus hallucatus)*

The Northern Quoll is distributed from south-east Queensland across northern Australia to the Pilbara but has declined in many parts of this range. The Northern Quoll historically occurred in Darwin Stringybark open forest and associated habitats within the Weipa area prior to the arrival of the Cane Toad in the 1980s. Although numerous records exist for Northern Quoll in the region surrounding Weipa, the majority of these are historical, and no other confirmed sightings are available for the area around Weipa after 1990. The decline of Northern Quoll around Kakadu National Park in the Northern Territory as a direct consequence of Cane Toad invasion is now well documented, and has resulted in listing this species as endangered in a national context (EPBC Act 1999).

Consultation with Traditional Owners during a targeted survey for Northern Quoll north of Weipa revealed an anecdotal record from around 2001 in vine forest on bauxite (Possum Scrub). Subsequent consultation with Traditional Owners from the Project area did not indicate any recent sightings of the species. Consequently it is anticipated that the Northern Quoll is now very rare in the Weipa area. With respect to the Project area, whilst the species may once have utilised Darwin Stringybark woodland, patches of vine forest and riparian forest habitat currently provide the most likely habitat for the species. Optimal habitat for the species, rocky outcrops and other rocky habitat, is not available within the Project Area. Nevertheless it is possible that the species could be present in certain locations, most likely the riparian communities and coastal vine forest associated with Norman Creek, and the vine forest patches in the Hey Point area.

Vine forest areas would not be disturbed by the Project. Minor areas of riparian habitats would be disturbed within the footprint of the water supply dam, although targeted surveys did not locate the species in these areas.

A number of factors are considered to be threatening the survival of the Northern Quoll (DSEWPaC 2010). These include:

- inappropriate fire regimes;

- predation following fire; and
- lethal toxic ingestion of Cane Toad toxin.

Northern Hopping Mouse *(Notomys aquilo)*

The type specimen of this species was recorded from Cape York Peninsula in 1867 but has since not been recorded in Queensland. Known threats to the Northern Hopping Mouse include (DSEWPaC 2010):

- predation of whole communities by feral cats;
- grazing by feral cattle, pigs and buffalo causing changes in the vegetation composition of the Northern Hopping Mouse's habitat and food resources;
- changes in habitat vegetation due to altered fire regimes; and
- mining activities adjacent to habitat.

Very little potential habitat associated with sandy dune systems occurs within the Project area and given the lack of recent records it is regarded as unlikely that the species would be present in the Project area. The preferred coastal dune habitat of the species would not be affected by mining or infrastructure.

Bare-rumped Sheathtail Bat (*Saccolaimus saccolaimus nudicluniatus*)

The Bare-rumped Sheathtail Bat has been recorded in the Aurukun area (DERM 2009c) although the habitat within which it was recorded is unclear. The species was not recorded during surveys within the Project area.

The Bare-rumped Sheathtail Bat is a poorly known species that is difficult to detect. The species is not readily captured using existing bat trapping techniques, and cannot be reliably identified from Anabat recordings.

Records of the species from Iron Range and Coen indicate that the species may favour riparian forest and vine forest and adjacent woodland including Darwin Stringybark dominated habitats. The species was found roosting in Darwin Stringybark at Iron Range. Based on this information, large areas of the Project area may be suitable for the species, especially in the vicinity of riparian gallery forest and vine forest patches but potentially also deeper into the Darwin Stringybark woodland that occurs across the majority of the Project area.

Known and likely threats are described by Schulz and Thomson (2007). The current known threat to the Bare-rumped Sheathtail Bat is habitat loss due to land clearing. Likely threats include:

- vegetation change due to clearing of understorey vegetation for agriculture and livestock grazing, altered fire regimes, saltwater intrusion and invasion by exotic weed species;
- timber collection and the targeted removal of hollow-bearing and dead trees resulting in destruction of roosts;
- competition for hollows;
- disease; and
- loss of climatic habitat such as tropical forests caused by anthropogenic emissions of greenhouse gases (identified as a key threatening process under the EPBC Act).

Water Mouse *(Xeromys myoides)*

The Water Mouse is a specialist rodent of tidal areas and adjoining wetland or heath areas. It is currently known from only three populations located in southeast Queensland; central Queensland between Agnes Waters and Cannonvale; and the Top End in eastern Arnhem Land and the Daly River. Water Mouse forage in wetland habitats, especially within the tidal zone amongst mangroves and saltmarsh and may construct a mud nest near the tidal limit. Habitat mapping for the species produced by DEWHA (2009d) indicates the western Cape York region,

including the Project area, as possible habitat for the species; however, this is well beyond the limits of known populations.

Extensive traverses of potential habitat for the species including mangrove fringes, saltmarsh and seasonally inundated freshwater wetlands were undertaken during post wet and dry seasons but no signs of the species were located. Given the survey results and the lack of records of the species for North Queensland it is not anticipated that the Water Mouse occurs within the Project area. Potential habitat for the species would not be directly disturbed by the Project.

7.15.5 Migratory Species

Migratory Bird Species

A large group of bird species recorded in the Weipa region are listed in international agreements and conventions such as the Japan–Australia Migratory Bird Agreement (JAMBA), the China–Australia Migratory Bird Agreement (CAMBA) and the Convention on the Conservation of Migratory Species of Wild Animals (Bonn Convention), and are covered by the EPBC Act. According to DEWHA (2009e), the known threats to migratory shorebird species include the following.

- Clearing, inundation, infilling or draining of habitat.
- Changes in hydrology, water quality or structural changes near roosting site causing an indirect loss or degradation of habitat.
- Habitat degradation due to loss of marine or estuarine vegetation, weed invasion of intertidal mudflats, water pollution and changes to the water regime, changes to hydrological regimes and the exposure of acid sulphate soils.
- Disturbance of migratory birds during foraging as a result of residential and recreational activities.
- Direct mortality as a result of interferences in the flyways or degradation of important sites across flyways. These may include but are not limited to the development of wind farms in migration pathways, bird strike by aeroplanes and oil and chemical spills.

The above threats are occurring mainly as a result of population growth and economic development, especially in east and south-east Asia.

Table 7-16 lists the EPBC listed migratory bird species potentially occurring in the Project area and indicates the likelihood of each occurring in the Project area. The list in **Table 7-16** comprises:

- species identified in the EPBC search for the Project area (and identified in the Project EPBC referral);
- additional species recorded during field surveys; and
- additional species assessed as potential inhabitants of the area based on the array of available habitats observed during field surveys.

The REs associated with each potential habitat for each migratory bird species is also provided in **Table 7-16**. Refer to **Figure 7-6, Figure 7-6a, Figure 7-6b, Figure 7-6c** and **Figure 7-6d** for the location and distribution of these REs within the Project area. Refer to **Table 7-10** for data on the area of proposed disturbance of REs compared to the total area within the Project area, the Weipa Plateau subregion, and the Cape York Bioregion. A description of each habitat is summarised in **Section 7.14.1**.

A discussion of the occurrence and habitat of other migratory species is summarised at the end of this section.

Of the 44 migratory bird species identified as potential inhabitants of the Project area:

- 19 species have been confirmed as present in the Project area;

- 3 species are likely to occur in the Project area;
- 17 species possibly occur in the Project area; and
- 5 species are unlikely to occur in the Project area.

Twenty of these migratory species are trans-equatorial migratory waders, which arrive in Australia each spring and disperse throughout the continent to feeding grounds amongst coastal and wetland habitats. The western Cape York coastline is known as a major entry corridor for many individuals of these species travelling to eastern Australia.

Given the location of the Project area within the East Asian-Australasian Flyway, these waders were identified in preliminary reviews as a key fauna group for field surveys. A detailed description of the survey methodology used for migratory shorebird species is provided in **Appendix 7E**. Initial observations of likely shorebird habitats including the Gulf shoreline, the lower and upper estuary of Norman Creek, Hey Point estuary, and coastal wetlands associated with Norman Creek and the Ward River revealed a notable paucity of migratory shorebirds both in terms of species diversity and density of individuals. It was also noted that despite the large rise and fall of tides that can occur in the Gulf, the Project area did not support any extensive inter-tidal flats. The shoreline of the Gulf coast in particular was predominantly sandy and of sufficient gradient to expose only minimal tidal flats at the mouth of Norman Creek. Furthermore, seasonal coastal wetlands formed by freshwater inundation of marine plains during the wet season were invariably dry during December survey events and frequently heavily impacted by feral pig activity.

During the field surveys only 5 species of migratory shorebird were recorded within the Project area (refer **Table 7-16**). The largest group of migratory shorebirds observed at any one time was six Whimbrels (*Numenius phaeopus*) flying up the Norman creek estuary. No high tide roosts of any migratory shorebird were observed during surveys nor any foraging aggregations during lower tides. Isolated roosting shorebirds were occasionally observed in larger roosts of terns.

The paucity of migratory shorebirds within the Project area is attributed to the lack of inter-tidal flat habitat, the dry nature of coastal wetlands during the late dry season until wet season rains occur, and a possible low productivity of inter-tidal benthic habitats potentially related to the very low sediment loads emanating from contributing spring fed drainages and the extraordinarily low mineral status of these waters. The survey results establish clearly that there are no internationally or nationally important sites or locations for migratory shorebirds located within or immediately adjacent to the Project area, and furthermore the Project area does not support an ecologically significant proportion of any migratory shorebird population.

The remaining species are known to undertake seasonal migratory movements within mainland Australia or to the mainland from areas to the north including Papua New Guinea and eastern Pacific islands.

A number of migratory wetland species occur within the Project area and predominantly utilise the more extensive wetland areas associated with the estuarine reaches of the main drainage systems, with the largest aggregations of species observed on the lower Ward system downstream of the Project area. No large-scale roosts of these species were observed within the Project area; however, it is possible that roosts and/or breeding of some of the species may occur within these habitats. These wetland habitats would not be directly affected for mining or infrastructure.

Table 7-16 Migratory Bird Species

Species	Likelihood of occurrence within Project area	Habitats						
		Darwin Stringybark Open Forest (RE 3.2.10c, 3.5.2, 3.5.11, 3.5.22c)	Riparian Gallery Forest/Alluvial Woodland (RE 3.3.5, RE 3.3.9 (excluding variant dominated by *Melaleuca leucadendra*), RE 3.3.21, 3.3.49b, 3.3.61)	Vine Forest on bauxite (RE3.5.4)	Paperbark Woodland and Wetland Swamps (RE 3.3.9 variant dominated by *Melaleuca leucadendra*, , 3.3.14a, 3.3.50a, 3.3.63, 3.3.64, 3.3.65, 3.7.3)	Foreshores, Tidal Flats, Beach (RE 3.2.3, 3.2.5a, 3.2.6a, 3.2.25)	Coastal Vine Forest (RE 3.2.2)	Mangrove and Estuary (RE 3.1.1a, 3.1.1c, 3.1.3, 3.1.5, 3.1.6, 3.3.60a)

Tringa stagnatilis Marsh Sandpiper	Confirmed during EIS surveys	-	-	-	✓	✓	-	✓
Xenus cinereus Terek Sandpiper	Possible	-	-	-	✓	✓	-	✓

The Great Frigatebird (*Fregata minor*) and Lesser Frigatebird (*Fregata ariel*) were observed to be common along the western coastline of the Project area during the December 2007, May 2008 and December 2008 survey events but were notably not observed during the May 2009 survey. Survey effort for the Great Frigatebird and Lesser Frigatebird included the extensive foot traverses and coastal survey tasks undertaken during targeted surveys for threatened species, as well as the comprehensive fauna survey undertaken over 48 nights which involved traversing hundreds of kilometres of the Project area, as detailed in **Table 7-12**. No roosts were observed within the Project area. The only known mainland roosts for these species occur in Weipa and individuals observed within the Project area are anticipated to come from these roosts. The coastal and beach habitats utilised by these species would not be directly affected by the Project other than construction of the proposed port. However, observations of these species in Weipa, and the location of the two roost sites in close proximity to the Weipa Port (north of Humbug Wharf), Weipa Airport, and active mining areas, indicates they are unlikely to be affected by operations.

Migratory Bird Species - Migration Paths

The Project area is situated within the East Asian-Australasian Flyway for trans-equatorial migratory waders. The Gulf of Carpentaria is regarded as one of the main access pathways for these species into Australia. The East Asian-Australasian Flyway is a general migratory route used by waders entering Australia from the northern hemisphere. Within the Gulf of Carpentaria, the south-east Gulf is recognised as a key site for waders with extensive wet season wetland habitats and tidal flats providing productive feeding grounds (Driscoll 2001). Tidal and wetland habitats within the Project area and along the Gulf coastline adjacent to the Project area do not provide extensive or productive feeding grounds for the species and although waders are present in these habitats they occur at relatively very low densities.

It is anticipated that the majority of waders that utilise the south east Gulf areas access these areas directly rather than work their way down the west coast of Cape York Peninsula (including the area covered by the Project). Consequently the Project area is not regarded as a significant component of the migratory pathway for migratory waders entering the Gulf of Carpentaria even though the Gulf waters in general form part of the East Asian-Australasian Flyway. A conceptual representation of the migratory pathway for waders is provided in **Figure 7-12**.

***Estuarine Crocodile* (*Crocodylus porosus*)**

The Estuarine Crocodile occurs in coastal and sub-coastal areas in northern Australia between Maryborough in Queensland and Broome in Western Australia. The Estuarine Crocodile is commonly encountered in the Weipa area, including the freshwater swamps and creek systems within the Weipa mining leases (Winter and Atherton 1985; Herbert 1995; Dames and Moore 1996). The tributaries that collectively form the Port Musgrave (Wenlock River – Tent Pole Creek) system and the Albatross Bay system surrounding Weipa (including the Embley–Hey estuary adjacent to the Project area) have been identified as the two most significant Estuarine Crocodile habitats in Queensland (Taplin *et al.* 1988).

The Estuarine Crocodile was recorded in all freshwater and marine habitats in the Project area, including freshwater swamps and streams well inland. Overall the species is widespread and numerous within the study area. Habitat utilisation appears to change seasonally with more use made of inland freshwater habitats during the wet season including the middle and upper reaches of groundwater-fed tributaries of Norman Creek and Coconut Creek. It appears that feral pigs represent a key feeding resource for the species within the freshwater habitats of the study area, especially groundwater-fed stream reaches along Norman Creek, Waterfall Creek and the Ward River – Coconut Creek systems.

Several nests and hatchling aggregations were located within the Project area on the middle reaches of Norman Creek and the lower reaches of the Ward River. An unused nest was located on the middle reaches of Winda Winda Creek. All these locations comprised a nest constructed of Blady Grass (*Imperata cylindrica*) within eucalypt fringing woodland and adjacent to an incised stream channel at least 2m deep. Each of these stream reaches would be fully fresh during the breeding season with the nests located above the high flow level. It appears that these locations may be favoured for nesting over downstream paperbark wetlands due to the inundation of these latter areas by freshwater flows during the wet season. Preferential use of riparian areas upstream of the paperbark wetland zone for nesting was also identified by Traditional Owners (Henry Kelinda pers. comm.). However, these nests may be more vulnerable to predation by feral pigs and wild dogs due to the exposed nature of the nesting areas.

Foraging and nesting habitat for the Estuarine Crocodile occurs within the footprint of Dam C. While some local effects on breeding habitat would be associated with the construction of Dam C, extensive nesting and feeding habitat would remain unaffected elsewhere in the Project area. Given the widespread nature of the species within the Project area, impact to the overall reproductive rates and population of the species within the Project area would minimal. Consequently, it is also not anticipated that the regional population of Estuarine Crocodile would also be minimal.

The REs associated with the habitats that the Estuarine Crocodile occurs in within the Project area are REs 3.1.1a, 3.1.1c, 3.1.3, 3.1.5, 3.1.6, 3.3.9, 3.3.14a, 3.3.50a, 3.3.60a, 3.3.63, 3.3.64, 3.3.65, 3.5.22c. Refer to **Figure 7-6, Figure 7-6a, Figure 7-6b, Figure 7-6c** and **Figure 7-6d** for the location and distribution of these REs within the Project area. Refer to **Table 7-10** for data on the area of proposed disturbance of REs compared to the total area within the Project area, the Weipa Plateau subregion, and the Cape York Bioregion.

Known threats to the Estuarine Crocodile (DSEWPaC 2010) include incidental mortality from fishing nets and habitat destruction. The incidence of feral animals within the Estuarine Crocodile's habitat may also lead to increasing drainage and destroying vegetation within the habitat.

Estuarine Crocodile - Migration Paths

Adult individuals of the Estuarine Crocodile are capable of extensive movements throughout the landscape and are known to move over several hundred kilometres in some cases although it does not appear that large scale migratory movements are a regular occurrence. Localised migration associated with dispersal of individuals from breeding areas and accessing nesting and feeding habitats however is common (Qld EPA, 2007). Within the Project area, seasonal movements of individuals into freshwater habitats created by wet season rains and movement between proximal drainage systems have been observed and are likely to represent the predominant movements undertaken by the species in the area.

In contrast to the Wenlock Basin, the area between Weipa and Aurukun within which the Project area occurs is not regarded as key breeding habitat for the species (Magnusson *et al.* 1980), although observations of nests and juvenile individuals confirm that the species does breed within the Project area at least at low densities. Some of the smaller seasonal stream systems within the Project area appear unlikely to support successful nesting and hatching of young, but support adult individuals, implying that seasonal movement of individuals between stream systems occurs within the Project area. **Figure 7-13** illustrates the likely movement pattern of individuals of the Estuarine Crocodile between stream systems within the Project area.

In addition to movement between drainage systems, regular wet season movement of sub-adult and adult individuals from estuary to freshwater stream reaches and wetlands occurs. Numerous observations have been made of individuals and slides well upstream on seasonal systems including Ward River/Coconut Creek, Norman Creek, and Triluck/Winda Winda Creek. These movements seem to be undertaken to take advantage of the nesting and feeding habitats that become available within these freshwater habitats during the wet season as the estuarine reaches of streams within the Project area are not well suited to nesting due to the

occurrence of dense fringing mangroves or flooding of Melaleuca swamps, whereas the grassy woodland habitat along the banks of the incised freshwater stream reaches provide flood-free nesting locations and access to deep water habitat for mothers. Seasonally available feeding resources that are exploited by Estuarine Crocodiles in wet season freshwater habitats are underpinned by seasonal fish breeding activity in seasonal wetlands and most likely the availability of feral pigs and macropods adjacent to freshwater streams. **Figure 7-13** illustrates notional wet season movement paths within the Project area.

Migratory Species Summary

Overall, the migratory species confirmed as present, likely or possible to occur within the Project area predominantly utilise habitats that would be located within environmental buffers and not directly affected by mining. Small areas of riparian gallery forest and associated alluvial/colluvial woodland that provide potential habitat for species would be disturbed within the footprint of the water supply dam but less than 10% of this habitat type within the Project area would be affected.

7.15.6 Threatened Fauna – NC Act

The Queensland NCA provides for the listing and protection of threatened fauna in Queensland. The main threatened status categories for fauna under the NCA in order of increasing conservation significance are: "near threatened", "vulnerable" and "endangered". **Table 7-17** lists the threatened fauna species that:

- have been previously recorded from within or in close proximity to the Project area (DERM 2009c, Queensland Herbarium 2009);
- have been found during surveys for the EIS;
- could potentially occur within the Project area based on EPBC database search; and
- could potentially occur with the Project area based on previous surveys in the Weipa area for RTA.

An assessment is provided of each species' potential occurrence in the Project area based on their habitat requirements and the condition and array of habitats available. The source of records for each species is indicated in **Table 7-17** along with the preferred habitat and known occurrence in the Weipa region.

Of the 20 NCA listed species identified as potential inhabitants of the Project area:

- 8 species have been confirmed as present in the Project area;
- 3 species are likely to occur in the Project area;
- 6 species possibly occur in the Project area; and
- 3 species are unlikely to occur in the Project area.

Profiles for these species are set out below but also refer to profiles in **Section 7.15.4** for species also listed under the EPBC Act.

Table 7-17 Threatened Fauna Listed Under the NC Act

Species **Common Name** **(Source of Record)**	**NCA Status**	**Key Resources**	**Habitat**	**Likelihood of Occurrence within Study Area**
Birds				
Accipiter novaehollandiae Grey Goshawk (Wild)	NT	Large tall trees for nest sites. Availability of birds, small mammals, reptiles and insects	Occurs in a variety of more mesic forest types, particularly closed forests situated along coastal regions. Known from vine forest in the Weipa area	**Possible:** May occur in association with vine forest, riparian gallery forest and mangrove areas within the Project area, but not anticipated to be numerous.
Ephippiorhynchus asiaticus Black Necked Stork (Wild)	NT	Availability of prey items including fish, frogs, reptiles, crustaceans	Wetland areas including rivers, swamps and tidal areas with shallow pools and areas of deep permanent bodies of water	**Confirmed:** Frequently encountered in wetland, estuary and beach habitats throughout the Project area.
Erythrotriorchis radiatus Red Goshawk (Wild, epbc)	E	Trees >20m high for nesting within 1km of a watercourse or wetland. Abundance of passerine prey	Favours coastal and sub-coastal areas. Prefers a mix of vegetation types including tall open forest, woodland, lightly treed savannah and the edge of rainforest and riparian forests	**Possible:** The open forest, woodland and wetland habitats that occur throughout the Project area present nesting and feeding opportunities required by the species.
Erythrura gouldiae Gouldian Finch (Wild, epbc)	E	Annual and perennial grasses (especially Sorghum), a nearby source of surface water and unburnt hollow-bearing *Eucalyptus* trees for nesting	Inhabits open woodlands that are dominated by *Eucalyptus* trees and support a ground cover of Sorghum and other grasses, close to a reliable dry season water supply.	**Unlikely**: The species is recorded only rarely, and in small numbers, on the Cape York Peninsula. The Project area is located well outside the historical known range of the species although there are confirmed WildNet records from the Aurukun Council area. The current regime of frequent extensive fires is likely to affect the availability of favoured seed during the dry season over large areas of the Project area. In most years, fresh water does not persist across the vast majority of the Project area during the dry season, and it is likely that fresh surface water is totally absent following poor wet seasons. The species was not located during surveys in the most suitable habitat location within the Project area and consequently it is anticipated that the Project area does not support the species.
Esacus magnirostris Beach Stone Curlew (Wild)	V	Availability of vegetation near foraging areas for shelter. Availability of hind dune areas for breeding	Inhabits beaches, tidal flats, estuaries, reefs and rocky points	**Confirmed:** A number of pairs identified along the Project area Gulf coast and Hey–Embley estuary and expected to occur along beaches within the Project area wherever there are rocky points or hind dunes in close proximity.
Lophoictinia isura Square-tailed Kite (+)	NT	Availability of small passerine prey, including eggs and nestlings. Presence of large wooded areas in close proximity to breeding sites	Structurally diverse landscape of Eucalypt open forests and woodlands, scrubs, riparian gallery forest, estuaries; not generally encountered in more open habitats	**Likely:** Suitable open forest and woodland habitats occur throughout the Project area and present the nesting and feeding opportunities required by the species.
Ninox rufa meesi Rufous Owl (+)	NT	Availability of medium sized mammal or bird prey species including flying fox, parrots, cockatoos.	Inhabits rainforests, monsoon forest, wet forested gullies, and adjoining woodland	**Confirmed:** One individual recorded in riparian rainforest on Norman Creek. Otherwise not detected during extensive survey effort but anticipated to be present at least occasionally along all major drainages in the Project area including riparian gallery forest, Melaleuca swamp forest and mangrove forest on Norman Creek and Coconut Creek – Ward River system. Also

Species **Common Name** **(Source of Record)**	**NCA Status**	**Key Resources**	**Habitat**	**Likelihood of Occurrence within Study Area**
		Availability of large tree hollows for breeding		possibly in minor drainage systems such as Ina Creek as well as larger vine forest patches near the coast in proximity to mangrove areas such as Ina Creek dunal vine forest, and vine forest patches at Hey Point.
Numenius madagascariensis Eastern Curlew (Wild)	NT	Availability of invertebrate prey in moist substrate. No nesting behaviour recorded in Australia	Inhabits estuaries, tidal flats, mangroves, sand spits, saltmarsh and occasionally freshwater wetlands	**Confirmed:** Suitable estuarine, mud flat and sandy beach habitat is found within the Project area. The western Cape York region is a main entry point to Australia for trans-equatorial migratory waders.
Probosciger aterrimus Palm Cockatoo (Wild)	NT	Mature trees with suitably sized nesting hollows. Available fruits and nuts for feeding	Rainforest/mesic environs often associated with riparian localities	**Confirmed:** Recorded on the major drainages of Norman Creek and Ward River in association with riparian rainforest and wetland areas; also recorded from vine forest on bauxite, and Darwin Stringybark open forest. Breeding pairs located within a relatively substantial riparian rainforest patch located in Norman Creek within the footprint of Dam C.
*Rostratula australis** Australian Painted Snipe (epbc)	V	Vegetated ephemeral wetlands	Inhabits shallow vegetated ephemeral wetlands in coastal and inland areas	**Unlikely:** Project area is well beyond the known range of the species, which is not known to occur on Cape York Peninsula.
Sternula albifrons Little Tern (Wild)	E	Sandy foreshore nesting localities	Coastal environments, including beaches, sheltered inlets, estuaries, lakes, bays and harbours, especially where exposed sandbanks or sand spits occur	**Confirmed:** Observed on a sandbank roost near the mouth of Waterfall Creek. Likely to forage in coastal and estuary areas throughout the Project area. Limited potential breeding habitat present due to the prevalence of coastal bauxite cliffs, but the scattered dunal areas that are present could accommodate breeding colonies.
Tadornah radjah Radjah Shelduck (Wild)	NT	Availability of tree hollows for nesting. Availability of wetland invertebrate prey	Aquatic habitat types including coastal wetlands, rivers, flooded plains, marsh and swamp regions	**Confirmed:** Regularly observed in pairs or small groups in or near coastal wetlands and estuaries including Norman Creek, Ward River and Winda Winda catchments. Most numerous within the Ward River system on brackish wetlands and channels during the late dry season.
Tyto novaehollandiae kimberli Masked Owl (+)	V	Medium to large tree hollows for nesting, and availability of preferred small mammal prey	Prefers tall eucalypt forest and woodlands	**Possible:** Sections of tall closed forest on major drainages along Norman Creek and the Ward River provide potentially suitable habitat; however, the prevalence of the species may be limited by the apparent paucity of small mammal populations.
Mammals				
Notomys aquilo Northern Hopping Mouse (epbc)	V	Suitable sandy substrates for burrow excavation	In the Northern Territory part of its range, known to occur in Acacia scrub, heath and grasslands on sand dunes within coastal regions (Menkhorst and Knight 2004)	**Unlikely:** The type specimen of this species was recorded from Cape York Peninsula in 1867 but has since not been recorded in Queensland. Very little potential habitat within the Project area associated with isolated dunal systems.
Saccolaimus mixtus Papuan Sheath-tail Bat (Wild)	NT	Tall trees adjacent to open forests with suitable hollows for roosting	Tall open forests and woodlands (Churchill 1998)	**Likely:** Commonly recorded in Darwin Stringybark open forest north of Weipa by Dames and Moore (1996) and extensive potential habitat within the Project area. Cannot be definitively identified from Anabat analysis but some call sequences from a variety of habitats, recorded during field surveys, were tentatively credited to the species.

Species **Common Name** **(Source of Record)**	**NCA Status**	**Key Resources**	**Habitat**	**Likelihood of Occurrence within Study Area**
Bare-rumped Sheathtail Bat *Saccolaimus saccolaimus nudicluniatus* (Wild)	E	Long deep tree hollows for roosting. Availability of flying insect prey.	Known habitats on Cape York include riparian forest and vine forest and adjacent woodland, including Darwin Stringybark dominated habitats. Potential habitat comprises REs, 3.2.10c, 3.3.5, 3.3.9, 3.3.21, 3.3.49b, 3.3.61, 3.5.2, 3.5.4, 3.5.11, 3.5.22c and 3.7.3 (Refer to **Figures 7-6** to **7-6d** for the locations of RE's within the Project area).	**Possible**: This species' habitat is poorly known. Records of the species from Iron Range and Coen indicate that it may favour riparian forest and vine forest and adjacent woodland including Darwin Stringybark dominated habitats. The species was found roosting in Darwin Stringybark at Iron Range. Based on this information, large areas of the Project area may be suitable for the species, especially in the vicinity of riparian gallery forest and vine forest patches, and potentially also deeper into the Darwin Stringybark woodland.
Sminthopsis archeri Chestnut Dunnart (+)	NT	Limited information available regarding the life history specifics of the species	Tall eucalypt woodlands and heathlands on red earth soils (Kutt 2008)	**Possible:** Records in synonymous eucalypt habitats to the north and south of the Project area indicate the possible presence of the species in Darwin Stringybark open forest, or ecotonal areas adjacent to streams, although small mammal densities are low within the Project area.
Spilocuscus maculatus Common Spotted Cuscus (+)	NT	Tall dense canopy structure situated near fruiting tree species	Lowland rainforests, mangrove margins, eucalypt and paper-bark open forests adjacent riparian strips (Winter and Leung 2008)	**Possible:** Riparian gallery and vine forest communities found on the Norman Creek and Ward River drainages represent potential habitat for the species. Vine forest on bauxite in the Hey Point area also provide potential habitat similar to that where the species has been recorded in the Weipa area. Apparently no recent knowledge of the species by Traditional Owners.
Reptiles				
Antaioserpens warro (a burrowing snake) (Wild)	NT	Availability of scincid lizards and suitably friable soil composition for burrowing activity	Sclerophyll forests and woodlands with a grassy understorey on sandy soils(Cameron and Cogger 1992)	**Likely:** Recorded in very close proximity (a few kilometres) to the Project area with a single specimen recorded from Beagle North Camp in the collection of the Queensland Museum (Cameron and Cogger 1992).
Crocodylus porosus Estuarine Crocodile (Wild)	V		A ubiquitous inhabitant of tropical watercourses including swamps, rivers and creeks. Will utilise monsoonal inundation to take advantage of prey opportunities in ephemeral localities	**Confirmed:** Presence in all freshwater and marine habitats in the study area including freshwater swamps and streams well inland. Overall, the species is widespread and numerous within the study area. Habitat utilisation likely to change seasonally with more use made of inland freshwater habitats during the wet season. Potential breeding habitat exists on the lower reaches of Norman Creek, Ward River and Winda Winda Creek, though more abundant in the Ward River system. Nests and hatchlings located on the lower Ward River and Norman Creek including within the footprint of Dam C.

Key to Source of Record codes:

epbc	Potential species from the EPBC database
Wild	Records from the WildNet database
+	Additional potential threatened species added to assessment based on local knowledge

Key to Status:

E	Endangered
V	Vulnerable
NT	Near Threatened

Grey Goshawk *(Accipiter novaehollandiae)*

The Grey Goshawk occurs in coastal and sub-coastal areas from southern Australia around the east coast to the Kimberley. The Grey Goshawk has been recorded in the Weipa area from riparian gallery forest, interfluvial vine forest patches, and nearby eucalypt woodland (Winter and Lethbridge 1995). In the Weipa area, this species is apparently dependent on interfluvial vine forest and other mesic vegetation, together with adjoining areas of ecotonal Darwin Stringybark open forest, to complete their overall habitat suite.

This species has not been recorded within the Project area but is likely to occur there given the abundance of similar habitat to known occupied areas immediately to the north. It is likely that, if present, the species would occupy predominantly vine forest, riparian gallery and mangrove areas. The Grey Goshawk has an affinity with mesic habitats and it is possible the large stream systems such as the Wenlock River and Archer River that link the western Cape area with the east coast forests provide dispersal corridors from east coast populations. The proximity of the Project area to the Archer River system increases the likelihood of the species being present. Potential riparian habitat occurs within the footprint of Dam C; however, the majority of potential riparian habitat and all vine forest areas would not be disturbed by mining or infrastructure, and the species were not located during surveys.

Black-necked Stork *(Ephippiorhynchus asiaticus)*

The Black-necked Stork occurs from southern NSW around the east coast to the Pilbara region. The Black-necked Stork is frequently encountered in the Weipa area in estuary and freshwater wetlands. Up to six individuals have been observed simultaneously on large freshwater wetlands in the Weipa area (Jason Searle pers. comm.).

The species was commonly encountered in the Project area in freshwater wetlands and estuary habitats with locality records from the Ward River, Norman Creek, Pera Head Wetland and Hey Point areas. The species is anticipated to be widespread in preferred estuarine and wetland habitats throughout the Project area. As Project related disturbances would not detrimentally affect preferred habitat types, no impacts are expected to the distribution and abundance of the Black-necked Stork in the Project area.

Beach Stone Curlew *(Esacus magnirostris)*

The Beach Stone Curlew occurs from Ballina on the east coast around the northern coastline to Exmouth in WA. The Beach Stone Curlew is well known from coastal habitats on Cape York Peninsula (Abrahams *et al.* 1995) and the species utilises a range of habitats including beaches, tidal flats, estuaries, reefs and rocky points. The species is usually absent from beaches adjacent to cliffs (Marchant and Higgins 1993) where the high tide floods the entire beach area. Similarly, the species nests in a shallow scrape in the sand at the back of the beach so requires areas of beach for breeding where the back of the beach is not inundated by tides.

Within the Project area the Beach Stone Curlew was recorded from numerous beach locations and is anticipated to occur on beaches within the Project area in the vicinity of stream mouths and rocky reefs where dune systems occur. Such suitable habitats are scattered along the western coastline of the Project area and occur within the intermittent stretches of coastal habitat included within the Project area along the Embley and Hey estuaries. The beach area to be traversed by the port loading facility is not regarded as potential habitat for the species. The area where the ferry terminal would be located on the Hey River supports the species but habitat would not be substantially affected in this area.

Square-tailed Kite *(Lophoictinia isura)*

The Square-tailed Kite has been recorded from throughout Australia apart from the arid centre and Nullarbor region. The Square-tailed Kite has previously been recorded for the open forests and woodlands of the Weipa region, including in Darwin Stringybark open forest on the bauxite plateau (Winter and Atherton 1985; Thomas 2004). This species has also been recorded in post-mining regeneration, although is expected to be reliant on adjoining areas of mature woodland habitat for suitable nesting habitat.

This species has not been recorded within the Project area but is likely to occur given the availability of suitable Darwin Stringybark, riparian, wetland and coastal habitats. The species was not located in proposed infrastructure areas during targeted surveys.

Rufous Owl *(Ninox rufa meesi)*

The Cape York race of the Rufous Owl occurs along the east coast of Cape York Peninsula and in the Weipa region. The eastern race of the species extends down the east coast to Rockhampton. The Rufous Owl has been recorded in the Weipa area from riparian gallery forest, interfluvial vine forest patches, and nearby eucalypt woodland (Winter and Atherton 1985, Dames and Moore 1996, Winter and Lethbridge 1995). The Rufous Owl was recorded within the Project area in a patch of riparian rainforest on Norman Creek. This patch is the largest riparian rainforest area (7.2ha) identified within the Project area and occurs within a mosaic of habitats including paperbark wetland, riparian gallery forest and alluvial/colluvial woodlands.

The species requires large tree hollows within its preferred habitats for nesting and these are available, though not abundant, within large Melaleucas and Swamp Mahogany (*Lophostemon suaveolens*) in riparian and wetland habitats, and large canopy trees in rainforest and vine forest. Given the relatively significant size of the rainforest area where the species was recorded and the presence of tree hollows of suitable size, it is possible the species utilises the area for breeding. This same rainforest area was used by Palm Cockatoos (a similar sized hollow utilising species) for breeding in 2008–09 indicating the suitability of the area for large hollow nesting species.

Otherwise, the Rufous Owl was not detected during extensive survey effort throughout the Project area but is anticipated to be present at least occasionally along all major drainages in the Project area including riparian gallery forest, Melaleuca swamp forest and mangrove forest on Norman Creek and the Coconut Creek – Ward River system. The species possibly also utilises minor drainage systems such as Ina Creek as well as larger vine forest patches near the coast in proximity to mangrove areas such as Ina Creek dunal vine forest, and vine forest patches in the Hey Point area.

The riparian gallery forest area where the species was recorded occurs within the footprint of Dam C; however, the majority of potential wetland and riparian gallery forest habitat for the species would not be disturbed for mining or infrastructure, and none of the potential vine forest habitat for the species would be disturbed by mining or infrastructure.

Eastern Curlew *(Numenius madagascariensis)*

The Eastern Curlew is known from all coastal areas of continental Australia. The Eastern Curlew has previously been recorded in coastal estuary and foreshore habitats adjoining the Weipa mining lease areas (Dames and Moore 1996). Abrahams *et al.* (1995) suggest there are no major feeding sites for this species on the Cape, yet these areas may be important resting areas for migrating shorebirds.

The eastern Curlew was observed within the Project area in the Boyd Bay area during the 2006 preliminary survey. The coastline areas of the Project area probably do not provide extensive foraging areas for the species but may provide important stop-over locations for migrating individuals (Abrahams *et al.* 1995). It is anticipated the species would utilise beach habitats along the Gulf coast of the Project area, and estuary habitats associated with the Embley–Hey, Norman Creek, Ina Creek and Ward River systems. The preferred intertidal habitat of this species would not be affected by mining or infrastructure development apart from minimal disturbance associated with the proposed port and the Hey River barge/ferry terminal.

Palm Cockatoo *(Probosciger aterrimus)*

The range of the Palm Cockatoo comprises northern Cape York Peninsula north of Pompuraaw and Princes Charlotte Bay. The Palm Cockatoo is frequently encountered in the Weipa area, including within the town limits of Weipa township, but is most often encountered in riparian gallery forest, interfluvial vine forest patches, and nearby eucalypt woodland. The Palm Cockatoo was recorded from several locations in the Project area comprising vine forest on

bauxite near Hey Point, riparian gallery forest along Norman Creek and Ward River, and Melaleuca swamp on the Ward River. The records from Norman Creek include at least two breeding pairs attending hollows in a relatively large area (7.2ha) of riparian gallery rainforest within the footprint of the proposed Dam C impoundment.

It is likely the species utilises most areas of vine forest (including coastal vine forest), riparian gallery forest and Melaleuca wetland within the Project area and adjacent Darwin Stringybark open forest. The species would traverse extensive areas of Darwin Stringybark open forest to access these preferred habitat areas. The Project-related disturbance would disturb known nesting sites of the Palm Cockatoo in the Dam C footprint, although the majority of preferred habitats areas would not be disturbed by the Project.

Little Tern *(Sternula albifrons)*

The Little Tern is recorded from coastal areas from Adelaide along the south-east, east and north coasts of Australia to Exmouth in Western Australia. The Little Tern is regularly recorded in low numbers at foreshores, estuaries and coastal margins around Weipa. An important breeding colony for Little Tern is located north of the Pennefather River mouth (approximately 50km north of the Project area), indicating that the coastline north of the Project area is important for this species (Abrahams *et al.* 1995).

Within the Project area several Little Terns were observed with other shorebirds on a sandbank roost near the mouth of Waterfall Creek. The species is likely to forage in coastal and estuary areas throughout the Project area.

The species breeds in back beach environments between the high tide mark and dune vegetation (Garnett and Crowley 2000) with a naturally high rate of breeding failure rate due to natural stochastic events such as high tides, storm surge and expansion of dune vegetation, and predation from a range of feral and native animals. Limited potential breeding habitat is present within the Project area due to the prevalence of coastal bauxite cliffs, but the scattered dunal areas that are present could accommodate breeding colonies. The only coastline and estuarine developments are associated with the proposed port and the barge/ferry terminals, which are outside of preferred breeding environments for the Little Tern.

Radjah Shelduck *(Tadorna radjah)*

The Radjah Shelduck occurs between Maryborough in Queensland to the Kimberley in Western Australia, although it is now uncommon south of Cape York Peninsula. The Radjah Shelduck has previously been recorded from freshwater wetland habitats in the Weipa area (Winter and Atherton 1985), and is also known to utilise estuary and brackish wetlands. Radjah Shelduck were regularly observed in pairs or small groups in near coastal wetlands and estuaries within the Norman Creek, Ward River and Winda Winda catchments. The species was observed to be most numerous within downstream reaches of the Ward River on brackish wetlands and channels during the late dry season. The species is anticipated to occur extensively in preferred habitat situations throughout the Project area. The preferred habitat of this species would not be affected by mining or infrastructure development.

Papuan Sheath-tailed Bat *(Saccolaimus mixtus)*

The Papuan Sheath-tailed Bat is known from northern Cape York Peninsula in the Weipa and Iron Range areas and on Torres Strait islands and New Guinea. The Papuan Sheath-tailed Bat has been recorded in low numbers in the Weipa area within Darwin Stringybark open forest habitat (Winter and Atherton 1985, Richards and Thompson 1995).

Extensive areas of suitable Darwin Stringybark open forest habitat occur within the Project area. This species has been tentatively recorded within the Project area; however, it is not possible to positively identify the species from Anabat recordings as there are no reliable reference calls available for the species (Greg Ford pers. comm.). The tentative record of the species was made on the basis of Anabat recordings that matched the anticipated ultrasonic call characteristics of the species and exhibited slight differences to the calls of *Saccolaimnus flaviventris* with which the species is most likely confused. No individuals were trapped in Harp Traps during targeted surveys.

It is likely the species is present within the Project area, especially in Darwin Stringybark open forest throughout the Project area. Areas of Darwin Stringybark open forest would be affected by mining and to a lesser extent infrastructure development.

Chestnut Dunnart *(Sminthopsis archeri)*

The Chestnut Dunnart is known only from a few specimens from the lower Archer River, Iron Range and Mapoon areas on northern Cape York Peninsula and in New Guinea. The Chestnut Dunnart was recorded in low numbers in earlier surveys of the Weipa area (Winter and Atherton 1985), but has not been recorded in several subsequent surveys. The Chestnut Dunnart appears to be sparsely and patchily distributed, potentially over a wide area of open forest and woodland throughout the bioregion. The known distribution of the species is restricted to a few, isolated records (Winter and Alford 1999) including the lower Archer River near Aurukun. Although little qualitative data exists, it is plausible that changes in fire frequency and intensity over the past few decades may be responsible for the decline in the Chestnut Dunnart.

Records of the species in synonymous eucalypt habitats to the north and south of the Project area indicate the possible presence of the species within the Project area in Darwin Stringybark open forest, or ecotonal areas adjacent to streams, although small mammal densities are low within the Project area and any occurrence of the species is likely to be patchy. Darwin Stringybark open forest would be disturbed by mining, and smaller areas of stream habitats occur within the footprint of Dam C although the species was not located in these areas during field surveys.

Common Spotted Cuscus *(Spilocuscus maculatus)*

The Common Spotted Cuscus occurs on northern Cape York Peninsula north of the Coen and Archer River areas. The Common Spotted Cuscus was recorded in low numbers in earlier surveys of the Weipa area (Winter and Atherton 1985), but has not been recorded in several subsequent surveys. The Spotted Cuscus is considered a relictual species and is largely restricted to riparian gallery forest and interfluvial vine forest (Abrahams *et al.* 1995; Winter and Lethbridge 1994), with the known distribution of the species restricted to a few isolated records (Winter and Alford 1999). Although little qualitative data exists, it is plausible that changes in fire frequency and intensity over the past few decades may be responsible for the apparent decline in the species.

Ample suitable habitat for the species occurs in the Project area; however, substantial survey effort in these areas comprising extensive spotlight traverses did not locate any individuals. Riparian gallery forest and vine forest along the Norman Creek and Ward River drainages represent potential habitat for the species, with vine forest on bauxite in the Hey Point area also providing potential habitat similar to that where the species has been recorded in the Weipa area. There does not appear to be any recent knowledge of the species in the Project area by Traditional Owners.

The Common Spotted Cuscus possibly occurs in the Project area but at very low densities and in restricted localities. Minor areas of riparian gallery forest habitat occur within the footprint of Dam C, although the species was not located in this area during targeted surveys.

***Antairoserpens warro* (a burrowing snake)**

Antairoserpens warro occurs between Townsville and the Jardine River on northern Cape York Peninsula. *Antairoserpens warro* is a nocturnal burrowing snake known from three records in the Weipa region. These include two museum specimens for eucalypt open forest and woodland habitat (Cameron and Cogger 1992) near Mapoon and just outside the Project area near Beagle Camp, and a third record from previously mined and regenerating woodland habitat at Weipa.

Despite trapping survey and active searches for the species it was not located within the Project area; however, it is anticipated that it has a patchy distribution within Darwin Stringybark open forest and upper tributary riparian areas within the Project area.

Areas of Darwin Stringybark open forest would be disturbed for mining, although targeted surveys in mining and infrastructure areas did not locate the species.

Estuarine Crocodile *(Crocodylus porosus)*

Breeding habitat for the Estuarine Crocodile (*Crocodylus porosus*) occurs within the footprint of the water supply dam. This is discussed in more detail in **Section 7.15.5** above.

7.15.7 Other Species of Conservation Significance

There are a number of other fauna species known to occur in the Weipa region that are not formally listed under state or federal nature conservation legislation but are considered to be of conservation significance for the following reasons:

- fauna with "Near threatened", poorly conserved, declining or insufficiently known populations and/or distributions, as acknowledged in relevant assessments or action plans (IUCN 2008);
- "intrusive" fauna with limited distribution on Cape York but also occurring in New Guinea, and subsequently considered recent arrivals to the Australian continent (Abrahams *et al.* 1995); and
- fauna species with populations endemic to the Cape York Bioregion.

A summary explanation of the significance of each of these fauna species is provided in **Table 7-18**.

Of these species, the detection of the Spotted Whistling Duck (*Dendrocygna guttata*) in the Ward River Estuary downstream of the Project area is particularly significant. This species has only been recorded within Australia from a handful of locations on Cape York, including settling ponds at the Weipa Sewage Treatment Plant. The species is currently listed internationally (IUCN 2008) as "Least concern" and has no significant conservation status under Australian legislation.

However, the occurrence of the species in the Ward River Estuary downstream of the Project area represents the largest recorded aggregation of the species on continental Australia and is of significance. It is possible the species also occurs within other estuary areas both within and adjacent to the Project area. None of the fauna habitats in estuary areas likely to be utilised by the species would be adversely affected by the Project.

Of the remaining species, all apart from the Brown Treecreeper (*Climacteris picumnus melanotis*) utilise habitats that would not be adversely affected by mining or infrastructure. The Brown Treecreeper is a species that typically occupies eucalypt woodland communities, such as the Darwin Stringybark open forest present in the Project area. This species has declined to less than 50% of its former distribution and was not detected within the Project area, although it may be present in low densities and restricted areas. Potential habitat for the species occurs within the mining area, although it was not recorded during field surveys.

7.15.8 Culturally Important Fauna

A number of species favoured for hunting occur within the Project area. Wallabies/kangaroo are present in moderate numbers, comprising Agile Wallaby (*Macropus agilis*), Antilopine Wallaroo (*Macropus antilopinus*) and the Eastern Grey Kangaroo (*Macropus giganteus*) which is rarely encountered within the Project area. The Agile Wallaby tends to be more abundant in association with coastal, stream, wetland and vine forest habitats throughout the Project area but can also be observed in Darwin Stringybark woodland on the bauxite plateau. The Antilopine Wallaroo favours the extensive Darwin Stringybark woodland that occurs across most of the Project area on the bauxite plateau with solitary individuals or groups of up to six individuals commonly observed.

The Emu is not common in the Project area but was observed in a variety of habitats including Darwin Stringybark woodland. The Emu (*Dromaius novaehollandiae*) probably favours the more open woodland habitats occurring to the east of the Project area. The Magpie Goose (*Anseranas semipalmata*) is a key hunting species whose presence and location within the Project area varies according to seasonal conditions. The Magpie Goose was not observed in the very large numbers that are known from extensive wetland aggregations occurring to the south of Aurukun and north of Weipa, but does occur on seasonally inundated marine plains where stands of 'Bulkuru' spike rush (*Eleocharis dulcis*) establish following wet season rains (veg. unit 12f). It does not appear that the Project area is particularly significant in terms of providing dry season habitat for the species, with most records of Magpie Geese after the wet season and into the dry season comprising flocks flying at night over the Project area.

Freshwater turtles are apparently very scarce within the Project area, with no individuals recorded during terrestrial or aquatic fauna surveys. It appears that the low nutrient and mineral status within the groundwater-fed aquatic ecosystems that dominate the Project area do not provide adequate conditions for turtles, although individuals may be present within dune swamps or tree swamps.

Whilst the freshwater reaches of streams in the Project area support a limited diversity of fish, favoured eating species such as Baramundi and Mangrove Jack and a variety of other large species are abundant in the estuaries of the three main stream catchments within the Project area (Triluck/Winda Winda Creek, Norman Creek, Ward River). Individuals of these species were frequently observed from the bank, swimming in schools in the clear post wet season waters of the Ward River.

Further discussion of impacts to and mitigation measures for culturally important fauna is provided in **Section 11.1.4**.

7.16 Overview of Potential Impacts on Terrestrial Fauna

Direct impacts on fauna habitats are linked to removal of vegetation to accommodate mining and Project infrastructure and these impacts have been described in **Section 7.17**. Construction and operational phases of the Project may potentially impact some fauna within certain habitats. Clearing for mining would affect only Darwin Stringybark open forest habitat, whilst disturbance of vegetation for certain infrastructure (e.g. the water supply dam) would affect a selection of habitat types including Darwin Stringybark open forest, riparian gallery forest, and a small area of paperbark wetland. The areas of different REs to be directly disturbed by the Project, based on interaction with the 40-year mine plan, proposed Dam C, and the location of Project infrastructure, are summarised in **Table 7-10**.

Secondary impacts on fauna habitats may occur during the operational phase of the Project, linked primarily to potential effects from altered hydrological regime due to mining activity and construction and operation of the water supply dam (refer **Section 7.10.1**). The introduction of exotic and weed flora, feral pig activity, and frequent fire regimes also pose a potential mechanism for impacts on fauna habitat within the Project area.

Alterations to the habitat landscape may affect the movement patterns of mobile fauna that need to move through the landscape to facilitate access to seasonal food resources,

reproductive activity, dispersal of young individuals, seasonal migratory movements, or access to refugial habitat patches following fire or other natural disasters.

The overall fauna community would be affected by the reduction in carrying capacity of the Project area due to removal of vegetation for mining activities. This effect would be mitigated to some extent by regeneration of mined areas, although regenerated habitats would take some time to develop and the rehabilitated landscape would differ from the original communities and provide altered habitat opportunities. Reduction in the carrying capacity of the area would result in concomitant reductions in the abundance of fauna within the Project area.

Impacts on threatened and migratory species would occur where lost habitat areas correspond with home ranges and/or habitats used by these individuals. The extent of this impact would depend on the potential for threatened fauna individuals to relocate or transfer activity to other suitable habitat areas. However, for sedentary individuals relocation away from lost habitat areas is unlikely. Of particular concern for threatened and migratory species is the potential for loss of nesting and breeding locations or key feeding areas, which may impact on reproductive success and the overall population of these species.

7.17 Potential Impacts and Mitigation Measures – Direct and Indirect Impacts on Fauna Communities

7.17.1 Potential Impacts

Habitat removal for Project development would result in some direct impacts on certain fauna communities. Impacts would comprise direct mortality of fauna through land clearing activities, and displacement of surviving fauna into surrounding areas. The displacement of individuals into surrounding habitat areas would also eventually result in additional mortality of fauna as surrounding areas are unlikely to accommodate extra individuals in the long term due to the limited availability of resources and the capacity for those resources to support a finite density of individuals. Eventually, fauna populations in surrounding undisturbed areas would re-equilibrate at the carrying capacity of the habitats present.

Table 7-19 summarises the approximate areas of major fauna habitats to be directly affected by the Project. All data in **Table 7-19** are based on predicted RE clearing extents detailed in **Table 7-10**. The Darwin Stringybark open forest habitat, which is present in the area to be developed for mining, would be most affected, with smaller losses of riparian and wetland areas due to establishment of the water supply dam and associated infrastructure. RE 3.3.9 is split over two major fauna habitats, with the variant dominated by *Melaleuca leucadendra* occurring in 'Paperbark Woodland and Wetland Swamps', and the remainder occurring in 'Riparian Gallery Forest/Alluvial Woodland'. The Project area data have been adjusted to reflect the presence of the variant, however information on the variant is not available for the Cape York Bioregion. A small area of foreshore habitat comprising dune and beach would be affected for construction of the port infrastructure but would be allowed to regenerate following construction. Several major habitat types would not be directly affected by the Project's activities.

Analysis of fauna survey data indicates that the riparian, wetland and vine forest habitats within the Project area together support a greater proportion of terrestrial vertebrate fauna diversity than the far more extensive Darwin Stringybark open forest habitat. These non Darwin Stringybark habitats are consequently regarded as more significant for fauna diversity. Protection of these non Darwin Stringybark habitats would be important to limiting the effects of the Project on fauna biodiversity and would be preserved by development of an environmental buffer system.

Secondary impacts on fauna habitats may occur from hydrological change resulting from mining, operation of the water supply dam on Norman Creek, and water extraction from the Ward River (refer **Section 7.10.1**). These hydrological changes may have localised effects on riparian, wetland and estuary habitats.

Table 7-19 Area of Fauna Habitats to be Directly Impacted

Major Fauna Habitat	Approximate area to be affected (ha)	Total habitat area in Project area (ha)	Proportion of habitat area in Project area to be disturbed	Total area in Cape York Bioregion[1] (ha)	Proportion of area in bioregion to be disturbed[1]
Darwin Stringybark (*Eucalyptus tetrodonta*) Open Forest on Laterite (RE 3.5.2, 3.5.11, 3.5.22c)	29,150	91,187	32%	1,261,386	2.3%
Riparian Gallery Forest/Alluvial Woodland (RE 3.3.5, 3.3.9 (excluding variant dominated by *Melaleuca leucadendra*), 3.3.21)	150[2]	1,747[2]	8.6%[2]	139,446[3]	0.1%[3]
Paperbark Woodland and Wetland Swamps (RE 3.3.9 variant dominated by *Melaleuca leucadendra*, 3.3.14a, 3.3.49b, and 3.3.50a)	38.6[3]	3,242[3]	1.8%[3]	935,535[2]	<0.1%[2]
Foredune Habitat (RE 3.2.6a)	0.3	149	0.2%	1,731	<0.1%
Mangrove and Estuary (RE 3.1.1a, 3.1.1c, 3.1.3, 3.1.5, 3.1.6, 3.3.60a)	0.04	481	<0.01%	68,381	<0.01%

1. Adjusted with RTA ground survey data
2. Data excludes RE 3.3.9 variant dominated by *Melaleuca leucadendra*
3. Data includes RE 3.3.9 variant dominated by *Melaleuca leucadendra*

Impacts on the condition and extent of fauna habitats may also occur as a result of the potential introduction of weed flora, increased pig activity, and altered fire regimes within the Project area. These impacts are discussed in **Section 7.10.1** (for vegetation impacts) which identifies the need for appropriate management programs for fire, weeds and feral animals to minimise impacts on habitat.

Clearing of habitats for mining and infrastructure would also have some impacts on the way in which fauna can access feeding and shelter resources, and undertake feeding, reproductive, dispersal or migratory movements through the landscape. The proposed access road crossings of Winda Winda Creek and the southern branch of Norman Creek would produce a narrow gap (up to 40m wide) across groundwater-fed stream reaches with riparian gallery forest. These crossings may affect the ability of non-flying riparian fauna to move up and down the riparian corridor and would expose fauna to mortality through collision with vehicles.

7.17.2 Mitigation Measures

The primary mitigation measures for reducing the loss of fauna habitat are the same as proposed in **Section 7.9.2** for limiting the area of vegetation cleared for the Project. In summary these comprise:

- restrict clearing of vegetation for mining and infrastructure to the minimum required for the safe operation of mining equipment and infrastructure;
- avoid clearing vegetation outside of the mine plan/infrastructure footprint for infrastructure or purposes that could be accommodated within areas already disturbed by mining or to be disturbed by mining (e.g. borrow pits, laydown areas, access tracks);
- wherever possible, locate linear infrastructure – such as roads, tracks, pipelines, and power lines – in a single consolidated infrastructure corridor rather than several smaller corridors; and

- plan for clearing of vegetation and stripping of topsoil to occur as soon as practicable before mining to avoid redundant clearing of vegetation due to changes in the mine plan.

The direct impacts on fauna communities from habitat removal would be mitigated to a large extent by post-mining rehabilitation that seeks to establish a self-sustaining native vegetation community using appropriate local native tree, shrub and grass species from the pre-mining vegetation communities. However, post-mining rehabilitated areas are unlikely to support an equivalent diversity of fauna species as found in pre-mining habitats unless the full range of pre-mine microhabitats develops in the long term.

Monitoring of fauna communities in rehabilitated bauxite mine areas near Weipa indicates that a majority of pre-disturbance fauna would re-occupy the rehabilitated areas but a number of species are either absent or under-represented in rehabilitated areas (Winter and Alford 1999, Reeders and Morton 1983). In addition, the exact extent to which the areas are utilised by fauna is not well understood and there is evidence (Winter and Alford 1999, Reeders and Morton 1983) that rehabilitated areas may be used by many species as a component of an overall habitat suite that must also include undisturbed habitat areas, or that rehabilitated areas are annually recolonised by individuals (particularly frogs) from nearby undisturbed areas. Winter and Alford (1999) found that under-represented or absent fauna were predominantly those associated with mature trees and the microhabitats they provide including hollows and spouts for nesting and shelter, flaking bark and large canopies for foraging. **Table 7-20** summarises the colonisation success of different fauna groups within regenerated mine sites near Weipa.

The SoE rehabilitation program would incorporate aspects to maximise habitat diversity which in turn would maximise native fauna diversity in the post-mining landscape. It is anticipated that the proposed rehabilitation program for the Project would at least achieve a similar re-creation of fauna habitats and re-colonisation by native fauna to the ranges indicated in **Table 7-20**.

Table 7-20 Faunal Colonisation of Rehabilitated Mine Areas Near Weipa

	Species Recorded in Rehabilitated Areas as a percentage of total Species Occurring in Area					
Monitoring Study	**Mammals**	**Birds**	**Reptiles**		**Frogs**	**Overall**
			Lizards	Snakes		
Reeders and Morton 1983	55%	73%	86%	94%	94%	73%
Winter and Alford 1999	83%	80%	78%		94%	N/A

Manual trapping and relocation of fauna from mine development areas would not be undertaken as a mitigation measure for fauna mortality as the relocation of fauna into adjoining habitat areas would result in elevating fauna densities above the carrying capacity of the area which would be is unsustainable. Mortality of the relocated fauna or the resident fauna in the receiving habitat area would eventually occur as the population recedes to the carrying capacity of the area. To ensure the welfare of any injured animals found during mine activities, RTA would ensure that appropriate staff are trained or have access to trained professionals to handle injured animals or humanely destroy them.

Minimising disturbance to vine forests, riparian gallery forest and wetland habitats would be achieved via the environmental buffer system as proposed in **Section 7.9.2** for mitigation of impacts on sensitive vegetation types. The environmental buffer system is discussed in detail in **Section 7.9.2**, but in summary comprises a system of spatial buffers from sensitive vegetation types in which mining is excluded. The retained tract of undisturbed land within the buffer between mined bauxite areas and nearby riparian and wetland ecosystems would minimise changes to the groundwater hydrology and limit effects on nearby vegetation. The environmental buffer system would be a primary mitigation measure for edge effects and

hydrological effects on sensitive vegetation types, and would ensure hydrological changes would not significantly alter the overall availability or utilisation of habitats by fauna communities.

Impacts of habitat removal on the overall habitat landscape for fauna and in particular faunal movement patterns would be mitigated by retention of the coastal margin vegetation buffer and remnant vegetation not disturbed by the mine plan. Importantly, the main habitat corridors and conduit for fauna movement in the Project area are the natural drainage systems, and these would not be affected by clearing for mining. Development of the water supply dam on the southern tributary of Norman Creek would fragment this corridor, although adjacent remnant habitats would provide some opportunity for faunal movements. Furthermore, it has been observed at Ely Dam (north of Weipa) that establishment of a new water supply level would promote the establishment of a riparian gallery forest along the margins of the full supply level. While the extent to which this new gallery forest would emulate natural riparian gallery forest habitat is dependent on the operation of the impoundment and the periodicity of full supply water levels, it is likely that this newly established riparian gallery forest would provide some habitat continuity between riparian habitats upstream and downstream of the impoundment. The proposed environmental buffer system would protect habitats within the riparian corridors and maintain their faunal movement function.

Constructed access road crossings of Winda Winda Creek and the southern branch of Norman Creek would incorporate "dry culvert" cells to maintain habitat continuity along the riparian corridor apart from during periodic high flow events. These comprise culverts on either end of the crossing structure positioned above perennial streamflow levels so as to provide a passage opportunity for non-aquatic fauna beneath the crossing.

Rehabilitated mined areas would provide certain habitat values for native fauna and support faunal movement, but many species may require undisturbed habitats to provide full movement functionality.

The network of habitat preserved within environmental buffers and located outside of the proposed mining area provides a substantial system of habitat corridors between all minor and major drainage tributaries and isolated habitat types within the Project area. Of particular functionality is the band of habitat within the proposed environmental buffer that extends along the western coastline of the Project area, providing a linkage between the lower sections of the Gulf drainage systems and coastal habitats. This network of retained habitat would to a large extent maintain habitat functionality and the pre-disturbance faunal movement regime.

The proposed fire and feral animal management programs (refer **Section 7.10.2**) would provide positive outcomes for fauna in undisturbed habitats throughout the Project area by delivering enhanced habitat quality.

Periodic monitoring of targeted fauna communities shall be undertaken to monitor the condition and any trends in communities likely to be subject to indirect impacts such as hydrological changes, fire regime change, weeds and feral animals. Monitoring sites would be representative of the major habitats present and provide an appropriate seasonal and spatial coverage of the Project area. Monitoring sites would be established progressively as mining proceeds.

The mitigation measures described above would effectively minimise the potential impacts of the Project on the fauna community as outlined in **Section 7.17.1**.

7.18 Potential Impacts and Mitigation Measures – Impacts on Threatened Fauna

7.18.1 Potential Impacts

Mining Area

Of the 17 threatened fauna species either confirmed as present or assessed as possible or likely to occur in the Project area, Darwin Stringybark woodland on bauxite is considered suitable habitat for nine of these species, comprising:

- Red Goshawk;
- Square Tailed Kite;
- Palm Cockatoo;
- Rufous Owl;
- Masked Owl;
- Northern Quoll;
- Chestnut Dunnart;
- Bare-rumped Sheathtail Bat;
- Papuan Sheathtail Bat; and
- *Antairoserpens warro* (a burrowing snake).

The Red Goshawk has not been recorded from the Project area during numerous surveys but ample suitable habitat exists for the species. The Red Goshawk is anticipated to utilise Darwin Stringybark open forest as part of its extensive home range. If present, it is likely the species would establish a home range centred on a riparian, wetland or coastal locality but include extensive areas of Darwin Stringybark open forest. It is unlikely that progressive removal of Darwin Stringybark open forest for mining would significantly adversely affect any potentially occurring populations with respect to the availability of foraging areas as it is a highly mobile species that could access other habitat areas. Re-establishment of prey fauna within rehabilitated mine areas would reinstate potential foraging habitat in these areas, although the productivity in these areas is unlikely to be as high as for undisturbed habitat.

The species has a preference for nesting in tall trees within 1km of permanent water (Aumann and Baker-Gabb 1991, DEWHA 2009c, NPWS 2002), which suggests Darwin Stringybark woodlands within 1km of permanent water could be used for nesting. Consequently, it is possible that nests of the species could be within proposed mining areas. The Red Goshawk is listed as endangered under State legislation and vulnerable under Commonwealth legislation and therefore any adverse effect on the reproductive effort of the species could be regarded as a significant impact under the EPBC Act. Red Goshawk breeding pairs can use the same nest site in successive years (EPA 2006), therefore, clearing of an unoccupied nest could lead to reproductive disruption in subsequent breeding seasons (Mr. Greg Czechura pers. comm.) as the adult birds would have to select a site for and build another nest. More significantly, if a nest with eggs or chicks was disturbed during clearing, mortality of those individuals would occur plus potential disruption to the adults' subsequent breeding season.

Re-nesting by Red Goshawk after nests have failed or been cleared, or nesting in different areas seasonally to be closer to target prey is known to occur (refer **Section 7.15.4**). Aumann and Baker-Gabb (1991) reported that nests were placed at the top of trees in exposed areas, in dead trees, and in dead sections of living trees. Given these nesting habits and the frequency of cyclones in northern Australia, it is likely there would be some natural loss of nests or nest trees due to cyclones within the Project area, and intentional removal of nests during clearing would be analogous to natural nest attrition.

With respect to the likelihood of a nest of the species intersecting with mining area, consideration of the proposed mine plan for the Project indicates that for the large majority of the mid to lower reaches of the main drainage systems (Winda Winda Creek, Norman Creek and Ward River) the mining area is located more than 1km from permanent water or seasonally inundated wetlands or watercourses supporting riparian gallery forest.

This is also the case for the northern part of the Project area where the proposed mining area is almost exclusively located greater than 1km from permanent water or seasonally inundated wetlands or watercourses supporting riparian gallery forest. Consequently the probability of a nest intersecting with proposed mining areas is low. However, additional mitigation measures to avoid nest disturbance are proposed.

The Square Tailed Kite has not been recorded in the Project area, but is considered likely to occur. This species is a specialised predator of the tree canopy preying on small birds, nestlings and insects; if present, the Square Tailed Kite would utilise a habitat focussing on riparian and wetland areas where these prey resources are most abundant, although Darwin Stringybark open forest habitat is also likely to be utilised to a lesser extent. With respect to foraging habitat, the Square Tailed Kite is a highly mobile species that would be able to access un-mined areas to compensate for any lost Darwin Stringybark open forest foraging habitat within the mine area, and rehabilitation areas would also reinstate foraging habitat to some extent.

The species may also nest in Darwin Stringybark open forest. However, nesting is anticipated to occur within proximity to a diversity of habitats for foraging; thus, nesting deep within Darwin Stringybark open forest habitat is unlikely. As discussed for the Red Goshawk, very little of the proposed mining area occurs in close proximity to the riparian and wetland complexes occurring on the mid to lower reaches of the main drainage systems. Therefore, it is unlikely that the Square Tailed Kite would be adversely affected by mining area development.

For the Palm Cockatoo, Rufous Owl and Masked Owl, Darwin Stringybark open forest habitat represents only peripheral habitat to the main habitat areas for these species, which comprise riparian, wetland and vine forest habitats. The environmental buffer system would retain peripheral areas of Darwin Stringybark open forest habitat adjacent to the key habitat areas. None of the key habitats would be affected by mining; consequently, impacts on the species related to development of the mining area are not anticipated.

The Northern Quoll, Chestnut Dunnart, Bare-rumped Sheathtail Bat, Papuan Sheath-tail Bat and *Antairoserpens warro* were not confirmed to be present within the Project area during surveys but, if present, are likely to utilise Darwin Stringybark open forest as part of their overall habitat suite. However, these species are known to utilise other habitats such as riparian gallery forest and alluvial/colluvial woodland, and vine forest and consequently would not be confined to habitat within the mining area. While approximately 32% of Darwin Stringybark open forest within the Project area would be disturbed by mining (refer **Table 7-19**) other habitats used by the species occur outside of the mining area and would be largely unaffected by the Project. Consequently, it is unlikely that development of the mining area would have a substantial adverse effect on the species.

Infrastructure Development

Disturbance of fauna habitats from infrastructure development would be minimal given the location of significant portions of infrastructure (e.g. tailings storage facilities) in mined areas. **Table 7-19** details the overall disturbance to habitats from the Project. Disturbance of habitat due to infrastructure development would comprise the following:

- Approximately 1,769ha of Darwin Stringybark open forest (RE 3.5.2) would be disturbed in the vicinity of the proposed water supply dam, tailings storage facilities, beneficiation plants, stockpiles, and roads (refer **Table 7-10**).
- Approximately 35ha of Melaleuca wetland habitat (part of RE 3.3.9) would be affected by dam and infrastructure corridor development for the water supply dam (Dam C). Of this, a small area (7.5ha) is adjacent to the wall, while the remainder lies within the impoundment area. These wetlands comprise seasonal shallow freshwater swamps with a closed canopy and consequently no open water or macrophyte beds.
- Approximately 150ha of riparian gallery forest and associated alluvial/colluvial woodland would be disturbed within the footprint of Dam C and at access road crossings of upper tributaries of Norman Creek and Winda Winda Creek. This comprises approximately 8.6% of the overall extent of these habitats within the Project area.
- A very small area (0.3ha) of foreshore and beach strand habitat would be affected beneath the conveyor deck for the proposed port facility. However, the deck would span the area, with disturbance confined to the footings of support piers.

Of the 17 threatened fauna species either confirmed as present or assessed as possible or likely to occur in the Project area, construction of infrastructure may impact suitable habitat for 13 of these species.

These species comprise:

- Grey Goshawk;
- Red Goshawk;
- Square Tailed Kite;
- Rufous Owl;
- Palm Cockatoo;
- Masked Owl;
- Northern Quoll;
- Bare-rumped Sheathtail Bat;
- Papuan Sheath-tail Bat;
- Common Spotted Cuscus;
- Chestnut Dunnart;
- *Antairoserpens warro* (a burrowing snake); and
- Estuarine Crocodile.

Potential impacts on fauna associated with Darwin Stringybark open forest within the proposed mining area are discussed in the previous section, and impacts would be similar for areas disturbed by infrastructure although over a much smaller extent. With respect to potential disturbance of nesting by the Red Goshawk, the water supply dam (Dam C) would disturb potential nesting habitat along Norman Creek. The proposed dam site was surveyed for presence of threatened fauna and no nests were located. However, additional confirmation of the presence or absence of nests at the time of construction would be required to avoid potential impacts on breeding by the species.

Of the 13 species, the Rufous Owl, Palm Cockatoo, and Estuarine Crocodile have been confirmed as present within the footprint of Dam C, including confirmed breeding sites for the Palm Cockatoo and Estuarine Crocodile. Breeding sites for the Estuarine Crocodile also occur on the Ward River downstream of the proposed pump location. The remaining species potentially occur within the Dam C footprint.

For the Grey Goshawk, Red Goshawk, Square Tailed Kite, Masked Owl, Northern Quoll, Papuan Sheath-tail Bat, Chestnut Dunnart, and the burrowing snake, the habitat areas within the proposed dam footprint are not regarded as especially significant for foraging or breeding (although pre-construction confirmation of the breeding status of Red Goshawk is required). Given that the habitat loss would comprise a minor proportion (less than 10%) of the overall extent of these habitats within the Project area, and that most of these species would also utilise other undisturbed habitat types, the overall impact of the loss of habitat within the dam footprint is unlikely to be significant for these species.

For the Bare-rumped Sheathtail Bat the Dam C footprint supports a habitat mosaic similar to that where the species has previously been recorded on Cape York; i.e. riparian gallery forest and alluvial/colluvial woodland with adjacent Darwin Stringybark woodland. Given the critically endangered status of this species (EPBC Act) disturbance of breeding efforts by the species could lead to significant impacts under the EPBC Act. Given the proposed mitigation measures and that the majority of the habitat mosaic where the species is most likely to occur would be protected within the environmental buffer system, the overall impact of the loss of potential habitat within the dam footprint is unlikely to be significant for these species.

The Palm Cockatoo is known to breed within a small patch of riparian rainforest within the footprint of Dam C, apparently by virtue of the availability of large trees with suitable sized nesting hollows that occur in this area. While potential nesting trees do not occur in all riparian areas due to smaller tree sizes, potentially suitable nesting trees are likely to occur within vine forest on bauxite, coastal Melaleuca wetlands containing mature *Melaleuca leucadendra* and *Lophostemon suaveolens,* and other riparian rainforest patches located on spring heads (particularly on Norman Creek tributaries).

The species is also known to nest in eucalypts within woodland habitats. However, it is not anticipated that Palm Cockatoos nest in Darwin Stringybark trees within the Project area as these trees typically do not develop the types of hollows required by the species given the current fire regime where trees tend to get culled by fire before reaching full maturity, when larger hollows form.

Given the loss of the known breeding location within Dam C there is likely be a short-term impact on the breeding success of some pairs of Palm Cockatoos when this area is disturbed for dam construction. However, given the availability of other habitats likely to support suitable nesting trees, and the occurrence of foraging habitat elsewhere throughout the Project area, a long-term impact on the species is unlikely.

The Rufous Owl is not known to breed in the Dam C area but the species has a similar tree hollow size requirement to the Palm Cockatoo and thus the area provides potential breeding habitat for the species. As discussed for the Palm Cockatoo, other suitable breeding trees are likely to be located in wetland, vine forest and riparian gallery rainforest habitats which are all known to be used by the Rufous Owl and thus alternative breeding locations are available within the Project area. With respect to foraging habitat, the habitat complex within the Dam C footprint includes the largest (7.2ha) patch of riparian gallery rainforest within the Project area and is regarded as prime habitat for the species. The loss of this area is not insignificant in terms of habitat availability for the Rufous Owl; however, other areas of suitable habitat occur throughout the Project area in association with wetland, mangrove, riparian and vine forest habitats and overall it is not anticipated that there would be a significant impact on this species.

The Dam C area provides suitable habitat for the Common Spotted Cuscus, although intensive survey of this area failed to locate the species. Other suitable habitat for this species occurs within areas that would not be disturbed by the Project, including similar riparian gallery forest habitat on the other main arms of Norman Creek and along Winda Winda Creek, riparian gallery forest along the Ward River (Coconut Creek), and mangrove and Melaleuca wetland complexes occurring along the estuarine reaches of Norman Creek and the Ward River. The impoundment of Dam C may represent a partial barrier to movement by the Common Spotted Cuscus as the riparian gallery forest corridor would be removed for a distance of approximately 6.7km. This would certainly curtail day-to-day feeding movements. However, given that the species is known to occupy eucalypt woodland adjacent to its prime habitats, long-term genetic connectivity between individuals that may be present upstream and downstream of the impoundment is unlikely to be substantially affected. Furthermore, observation of the Ely Dam situated in similar habitats near Weipa indicate that at least a rudimentary gallery forest comprised of Melaleuca and Swamp Mahogany (*Lophostemon suaveolens*) is likely to re-establish at the periphery of the full supply level and provide some level of densely vegetated corridor.

Estuarine Crocodiles occupy and feed within freshwater reaches of Norman Creek, Winda Winda Creek and the Ward River during the wet season, with nests also located in these reaches on all three systems including within the footprint of Dam C. It appears that these reaches, where a deep channel is available in close proximity to grassy nesting areas above flood level, are used for nesting rather than the extensive shallow Melaleuca and estuarine wetland complexes on the lower reaches of these systems. However, where deep channels abut these wetlands with narrow levees, these areas may also be suitable for nesting.

Area suitable for Estuarine Crocodile habitat in and around the Project area is shown in **Figure 7-13**, including the approximate extent of potential freshwater nesting habitat within the Project area. The potential freshwater nesting habitat totals 71.3km of stream reach on Winda

Winda Creek, Norman Creek and tributaries, and Ward River and tributaries. The length of potential nesting habitat reach to be disturbed by the proposed Dam C footprint comprises 6.7km, representing approximately 9% of the total extent of the freshwater nesting habitat within the Project area. Additional nesting habitat could occur on stream levees in estuary areas, and therefore the total occurrence of nesting habitat is likely to be greater.

It is unclear whether the impoundment would affect access of breeding females to potential habitat upstream and whether juveniles potentially hatched upstream of the impoundment would be exposed to increased mortality rates in traversing to lower reaches as streamflows recede in the dry season. There is a possibility that the impoundment may provide a permanent aquatic habitat area that assists juvenile recruitment.

Changes to hydrology downstream of the dam may result in a localised reduction of water levels and flow rate during the breeding season. This may further alienate small reaches of breeding habitat for Estuarine Crocodiles immediately downstream of the dam due to less favourable (lower) water levels within the channel which may not provide sufficiently deep water to accommodate breeding females. Overall, the availability of potential freshwater nesting habitat for the Estuarine Crocodile would be reduced as a result of dam development. While this may have a local effect on reproductive rates of the species, it is not anticipated that total breeding effort within the Project area would be significantly affected.

Minor changes to streamflow would occur within the Ward River downstream of the pump location between July and the following wet season. Pumping would only occur if streamflow is above 1000L/s and the extraction rate would not exceed 20% of flow at any time; therefore flows would be within the natural inter-annual variation, with natural streamflow re-established prior to Estuarine Crocodile laying and hatching. Consequently, breeding effort of the Estuarine Crocodile within the area downstream of the pump location is not anticipated to be significantly affected.

Disturbance to foreshore and beach strand habitats at the location of the proposed port facility would be minor and is not expected to have any adverse effect on the usage of the area by threatened fauna. The area is not anticipated to be used for roosting or breeding by Beach Stone Curlew or Little Tern and therefore only minimal repulsion effects from the noise and lights associated with the facility can be expected for species that may be feeding in the area such as Black Necked Stork, Eastern Curlew and Little Tern.

The preferred habitat of the Radjah Shelduck would not be affected by infrastructure development (refer **Section 7.15.6**).

Hydrological Change

The potential effect on vegetation communities and habitat of hydrological change resulting from mining, operation of the water supply dam on Norman Creek, and water extraction from the Ward River is regarded as being minor (refer **Section 7.10.1**), apart from localised effects (particularly immediately downstream of the dam). The environmental buffer system as described in **Section 7.9.2** would ensure hydrological changes would not significantly alter the overall availability or utilisation of habitats by threatened fauna. Consequently, significant impacts on threatened fauna are unlikely to occur.

7.18.2 Mitigation Measures

The proposed fire management plan and feral animal control program (refer **Section 7.10.2**) would deliver positive benefits for threatened fauna in undisturbed areas by enhancing the current habitat values in these areas. A number of more specific mitigation measures are proposed below.

Mining Area

Surveys for Red Goshawk nests would be undertaken in sections of the mining plan located within 1km of permanent water supporting riparian gallery forest or paperbark wetland, seasonally inundated paperbark wetlands, seasonal watercourses supporting riparian gallery forest, or an estuary. Surveys would be completed as soon as practicable prior to vegetation

clearing for mining. If any active Red Goshawk nests are found within mining areas, a 200m buffer around the nesting tree would be excised from the mining plan until the end of the breeding season. Any active Red Goshawk nesting site identified within the mining path would be monitored until the nesting cycle has been completed, after which clearing activities would resume. If a nest is found in an area to be cleared it is considered likely that a breeding pair would find another location for nesting in the subsequent breeding season (refer **Section 7.15.4**).

Aumann and Baker-Gabb (1991) made several management recommendations to manage threats to the Red Goshawk. One recommendation was that when egg collection from a nest is strongly suspected, in an area where nest sites are not limiting, that the branch supporting the nest be removed during the non-breeding period to encourage the pair to re-nest at a new location. The proposed mitigation strategy for this Project to clear nest trees at the end of the breeding season and encourage the birds to re-nest in another location is consistent with this recommendation.

The mitigation measures described above would effectively minimise the potential impacts on Red Goshawk nesting as a result of vegetation clearing for mining as outlined in **Section 7.18.1**.

Infrastructure Development

Similar to surveys proposed for mining areas, targeted surveys for Red Goshawk nests would be conducted within the footprint of the water supply dam up to 1km from riparian gallery forest as soon as practicable prior to vegetation clearing. If any active Red Goshawk nests are found within the survey areas, a 200m buffer around the nesting tree would be established and the nest monitored until completion of the breeding season, after which vegetation clearing would resume.

The mitigation measures described above would effectively minimise the potential impacts on Red Goshawk nesting as a result of vegetation clearing for the construction of the water supply dam as outlined in **Section 7.18.1**.

The Bare-rumped Sheathtail Bat is reported to breed during the wet season with a colony containing juveniles reported as late as April in the Northern Territory (Schulz & Thompson 2007). Targeted pre-clearing surveys would be undertaken to determine the presence of the species within the Dam C disturbance area, and if present, disturbance of habitat trees would be avoided until after the breeding season (i.e. clearing to commence no earlier than May and be completed by end of November). If the species is present, all potential roost trees would also be identified within the Dam C disturbance area and pushed over in a manner that would allow any bats present to leave the roosts unharmed.

7.19 Potential Impacts and Mitigation Measures – Impacts on Migratory Fauna

7.19.1 Potential Impacts

Overall, the migratory species possible, likely or confirmed as occurring within the Project area predominantly utilise habitats that would be located within environmental buffers and not directly affected by mining. Small areas of riparian habitat that provide potential habitat for species such as Grey Goshawk (*Accipiter novaehollandiae*) and Red Goshawk (*Erythrotriorchis radiatus*) would be disturbed within the footprint of the water supply dam. However, less than 10% of the area of this habitat type within the Project area would be affected.

The migratory birds that are likely to or confirmed as occurring in the Project area comprise a range of species including mainly trans-equatorial migratory waders, and wetland and woodland species that undergo more local migratory movements. Whilst the waders fly from the northern hemisphere in large flocks, and the Gulf of Carpentaria is a main flight path for their entry to Australia, the birds themselves make only limited use of the Project area as it does not provide the extensive productive mudflats required by the species for feeding. It is not anticipated that

large flocks of these species would fly at low levels across the Project area, preferring instead to travel along the shoreline and out to sea. There is very little chance of these species colliding with infrastructure, including powerlines and port facilities. The remaining migratory species do not move through the Project area in mass movements but may utilise natural movement corridors such as riparian corridors and the coastline. Once again, the chance of large numbers of birds colliding with infrastructure is minimal given the high visibility of most project infrastructure and minimal suspended infrastructure across riparian corridors, wetlands and the shoreline (refer to **Section 2.7.5** for description of powerlines).

Disturbance to foreshore and beach strand habitats at the location of the proposed port facility would be very minor and is not expected to have any direct adverse affect on the usage of the area by migratory fauna. Most of the shorebirds confirmed as present, likely to occur or possibly occurring in the Project area utilise foreshore, tidal flat and beach habitats and/or mangrove and estuary habitats. Only 0.3 ha of foreshore habitats and only 400 square metres of mangrove habitat (0.008% of that mangrove community within the Project area) would be directly disturbed by the Project, which is a minor proportion of these habitats in the area. Indirect impacts on migratory shorebirds during the operational phase from lighting, noise or movement associated with the port facility and Hey Point ferry terminal are also unlikely to lead to significant impacts on migratory shorebirds given the very low incidence of these species within the Project area, and the capacity of most shorebirds to adapt to such disturbance.

Apart from potential impacts outlined for the Estuarine Crocodile, there are not anticipated to be any significant impacts on migratory fauna resulting from the Project.

7.19.2 Mitigation Measures

No specific mitigation measures are required for migratory fauna, as no significant impacts on migratory fauna are anticipated. However, the fauna impact mitigation strategies described in **Section 7.17.2** would minimise impacts on migratory fauna and areas of potential habitat.

7.20 EPBC Act Significant Impact Assessments for Threatened and Migratory Fauna

The "significant impact" assessments in this section are based on the *Significant impact guidelines* (DEWHA 2009a) provided by the Commonwealth Government.

7.20.1 Threatened Fauna

Individual "significant impact" assessments are provided below for each of the EPBC Act listed threatened fauna species assessed as possible, likely or confirmed inhabitants of the Project area comprising:

- Red Goshawk (*Erythrotriorchis radiatus*);
- Masked Owl (*Tyto novaehollandiae kimberli*);
- Bare-rumped Sheathtail Bat (*Saccolaimus saccolaimus nudicluniatus*); and
- Northern Quoll (*Dasyurus hallucatus*).

Key definitions from the DSEWPaC guidelines that apply to this assessment are as follows:

An "important population" is a population that is necessary for a species' long-term survival and recovery. This may include populations identified as such in recovery plans, and/or that are:

- key source populations either for breeding or dispersal;
- populations that are necessary for maintaining genetic diversity; and/or
- populations that are near the limit of the species range.

"Habitat critical to the survival of a species or ecological community" refers to areas that are necessary:

- for activities such as foraging, breeding, roosting, or dispersal;

- for the long-term maintenance of the species or ecological community (including the maintenance of species essential to the survival of the species or ecological community, such as pollinators);
- to maintain genetic diversity and long-term evolutionary development; or
- for the reintroduction of populations or recovery of the species or ecological community.

Such habitat may be, but is not limited to:

- habitat identified in a recovery plan for the species or ecological community as habitat critical for that species or ecological community; and/or,
- habitat listed on the Register of Critical Habitat maintained by the Minister under the EPBC Act.

An "invasive species" is an introduced species, including an introduced (translocated) native species, which out-competes native species for space and resources or which is a predator of native species. Introducing an invasive species into an area may result in that species becoming established. An invasive species may harm listed threatened species or ecological communities by direct competition, modification of habitat or predation.

Red Goshawk (*Erythrotriorchis radiatus*)

The Red Goshawk was not located in the Project area during general and targeted surveys. However, as the regional population size of this species is relatively small, if the Red Goshawk was to occur within the disturbance footprint of the Project area, it would be regarded as an important population. However, if the species is present within the Project area sufficient foraging habitat would remain undisturbed to support the species and proposed mitigation measures would avoid disturbance of active nests.

Habitat clearing is the major known threat to the Red Goshawk (EPA 2006). Human disturbance at nest sites are also known to disturb breeding pairs and result in reduced reproductive success. Based on the DSEWPaC (2010) SPRAT database, other possible threats to this species include:

- The theft of eggs for egg collections and the intentional killing of adults.
- The application of persistent pesticides such as DDT may have caused a historic reduction in the population. In 1989, Australia ceased widespread use of organochlorine pesticides and most affected species have now recovered;
- Overgrazing, or other changes in land management which could reduce prey availability, and therefore reduce productivity.
- Altered fire regimes have the potential to impact breeding sites and reduce prey availability, thus reducing productivity.
- The occurrence of a catastrophic event which may exaggerate the impact of existing threats.
- Possible genetic bottlenecks in the population.

The proposed Project is not expected to interfere with the recovery of the species.

Will the proposed works ...	**Red Goshawk (*Erythrotriorchis radiatus*): Vulnerable**
....lead to a long-term decrease in the size of an important population?	The Red Goshawk occurs in coastal and sub-coastal habitats from northern NSW to the Kimberley, although it has declined significantly in the southern part of its range. The species was not located in the Project area during general and targeted surveys. As the regional population size of this species is relatively small, if the Red Goshawk was to occur within the disturbance footprint of the Project area, it would be regarded as an important population. However, if the species is present within the Project area, sufficient foraging habitat would remain undisturbed to support the species and proposed mitigation measures would effectively avoid disturbance of active nests. A long-term decrease in any population of the species present is unlikely to occur.
....reduce the area of occupancy of an important population?	The key habitats for the species would be largely unaffected by the Project and the area of occupancy of any population of the species, if present, would not be reduced.
....fragment an existing important population into two or more populations?	Key habitats for the species would not be affected and, given the high mobility of the species, any population present would not be fragmented.
....adversely affect habitat critical to the survival of a species?	The Project area does not include any critical habitat areas for the Red Goshawk that are listed under the EPBC Act or identified in Recovery Plans, nor is the Project area regarded as critical habitat for the species given its similarity to other potential habitat areas on northern Cape York Peninsula.
....disrupt the breeding cycle of an important population?	Proposed mitigation measures would avoid disturbance of active nests and consequently the breeding cycle of the species would not be disrupted.
....modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	The key habitats for the species would be largely unaffected by the Project; consequently, the species is unlikely to decline as a result of the Project.
....result in invasive species that are harmful to a vulnerable species becoming established in the vulnerable species' habitat?	The Project is unlikely to lead to the introduction of any invasive fauna that could affect the species. Proposed control measures for weeds would effectively avoid the spread of invasive weeds within the habitat of the Red Goshawk.
.....introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is not anticipated that the Project would represent a threat with respect to the introduction of disease.
....interfere substantially with the recovery of the species?	The Project is not expected to interfere with the recovery of the Red Goshawk.

Masked Owl *(Tyto Novaehollandiae)*

The Masked Owl was not recorded within the Project area. However, a population of Masked Owl, if present in the Project area, could be regarded as an important population as the species is now rare on Cape York Peninsula with limited recent records. It is not expected that the Project would lead to a long term decrease in the population as the key potential habitats for the species would be largely unaffected by the Project.

There is some evidence to suggest that the main threat to the Masked Owl is the decline in populations of small and medium sized native mammals, which are the Masked Owl's primary food source (Woinarski 2004). The broad scale application of the rodenticide Klerat (now banned) may also have lead directly to the mortality of Masked Owls. The proposed Project is not expected to interfere with the recovery of the species.

Will the proposed works ...	**Masked Owl (*Tyto Novaehollandiae*): Vulnerable**
....lead to a long-term decrease in the size of an important population of a species?	The northern race of the Masked Owl occurs between Townsville and the Kimberley region with other races extending down the east coast to Tasmania. The Masked Owl has been recorded in the Weipa area, although the habitat within which it was recorded is unclear. The species was not recorded during surveys within the Project area. A population of Masked Owl, if present, in the Project area could be regarded as an important population as the species is now rare on Cape York Peninsula with limited recent records. It is not expected that the Project would lead to a long-term decrease in the population as the key potential habitats for the species would be largely unaffected by the Project.
....reduce the area of occupancy of an	The key potential habitats for the species would be largely unaffected by the Project and therefore the area of occupancy of the species, if present, is unlikely to

Will the proposed works ...	Masked Owl (*Tyto Novaehollandiae*): Vulnerable
important population?	be reduced.
....fragment an existing important population into two or more populations?	Key habitats for the species would not be significantly affected by the Project and, given the high mobility of the species, any population present would not be fragmented.
....adversely affect habitat critical to the survival of a species?	The Project area does not include any critical habitat areas for the Masked Owl that are listed under the EPBC Act or identified in Recovery Plans. If the species is present, the area could be regarded as including critical habitat given the recent decline of the species within Queensland; however, key habitats for the species would not be significantly affected by the Project and habitat critical to the survival of the species is unlikely to be adversely affected.
....disrupt the breeding cycle of an important population?	Key habitats for the species would not be significantly affected by the Project and disruption to the breeding cycle of any population present is unlikely.
....modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	The key habitats for the species would be largely unaffected by the Project and consequently the species, if present, is unlikely to decline as a result of the Project.
....result in invasive species that are harmful to a vulnerable species becoming established in the vulnerable species' habitat?	The Project is unlikely to lead to the introduction of any invasive fauna that could affect the species. Proposed control measures for weeds would effectively avoid the spread of invasive weeds within the habitat of the Masked Owl.
.....introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is not anticipated that the Project would represent a threat with respect to the introduction of disease.
....interfere substantially with the recovery of the species?	The Project is not expected to interfere with the recovery of the Masked Owl.

Northern Quoll *(Dasyurus hallucatus)*

The Northern Quoll was not recorded within the Project area. However, as the regional population size of this species is thought to be relatively small, if the Northern Quoll was to occur within the disturbance footprint of the Project area, it would be regarded as an important population. Vine forest areas would not be disturbed by the Project. Minor areas of riparian habitats would be disturbed within the footprint of the water supply dam, although targeted surveys did not locate the species in these areas.

A number of factors are considered to be threatening the survival of the Northern Quoll (DSEWPaC 2010). These include:

- inappropriate fire regimes;
- predation following fire; and
- lethal toxic ingestion of Cane Toad toxin.

The proposed Project is not expected to interfere with the recovery of the species.

Will the proposed works ...	Northern Quoll (*Dasyurus hallucatus*): Endangered
....lead to a long-term decrease in the size of a population?	The Northern Quoll is distributed from south-east Queensland across northern Australia to the Pilbara but has declined in many parts of this range. The Northern Quoll historically occurred in Darwin Stringybark open forest and associated habitats within the Weipa area prior to the arrival of the Cane Toad in the 1980s. Although numerous records exist for Northern Quoll in the region surrounding Weipa, the majority of these are historical, and no other confirmed sightings are available for the area around Weipa after 1990. The species has not been recorded from the Project area. If the species is present within the Project area, sufficient foraging habitat would remain undisturbed to support the species. A long-term decrease in any population of the species present is unlikely to occur.
....reduce the area of occupancy of the species?	Although a substantial area of Darwin Stringybark open forest would be disturbed by the Project, the majority of this habitat would remain undisturbed and other habitats utilised by the species would be largely unaffected. Sufficient habitat would remain to support the species, if present, and the area of occupancy of any population of the species present would not be reduced.

....fragment an existing population into two or more populations?	The main riparian habitat corridors and cross catchment habitat connections would be retained within the Project area and, given the high mobility of the species, any population present would not be fragmented.
....adversely affect habitat critical to the survival of a species?	The Project area does not include any critical habitat areas for the Northern Quoll that are listed under the EPBC Act or identified in Recovery Plans, nor is the Project area regarded as critical habitat for the species given its similarity to other potential habitat areas on northern Cape York Peninsula.
....disrupt the breeding cycle of a population?	The breeding cycle of the species (if present) would not be disrupted.
....modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	Although a substantial area of Darwin Stringybark open forest would be disturbed by the Project the majority of this habitat would remain undisturbed and other habitats utilised by the species would be largely unaffected; consequently, the species is unlikely to decline as a result of the Project.
....result in invasive species that are harmful to an endangered species becoming established in the endangered species' habitat?	The Project is unlikely to lead to the introduction of any invasive fauna that could affect the species. Proposed control measures for weeds would effectively avoid the spread of invasive weeds within the habitat of the Northern Quoll.
.....introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is not anticipated that the Project would represent a threat with respect to the introduction of disease.
....interfere with the recovery of the species?	The Project is not expected to interfere with the recovery of the Northern Quoll.

Bare-rumped Sheathtail Bat (*Saccolaimus saccolaimus nudicluniatus*)

The Bare-rumped Sheathtail Bat was not recorded during surveys within the Project area. Habitat for this species is poorly known and the habitats within the Project area that may be favoured by the species are uncertain. Records from elsewhere on Cape York Peninsula indicate that riparian gallery forest, vine forest and adjacent woodland, including Darwin Stringybark woodland, may be favoured. Much of this habitat suite would fall within proposed environmental buffer areas in the Project area; however, the species could also utilise Darwin Stringybark woodland within proposed disturbance areas.

If the species is present within the Project area it is highly likely that it would also be present in the extensive areas of similar bauxite plateau ecosystem that dominate the western half of northern Cape York Peninsula.

The Dam C footprint represents potential habitat for the species. The proposed mitigation measures would avoid disturbance of breeding activity and avoid impacts on individuals that may be present within the Dam C footprint.

The majority of habitat where the species is most likely to occur within the Project area would be protected within environmental buffers, therefore it is unlikely that a significant impact on the species would occur as a result of the Project.

Will the proposed works ...	**Bare-rumped Sheathtail Bat (*Saccolaimus saccolaimus nudicluniatus*): Critically Endangered**
....lead to a long-term decrease in the size of a population?	The current occurrence of this species within the Project area and disturbance areas is not known. Based on the nearest records of the species from Cape York Peninsula it is likely that the species would focus habitat utilisation on riparian or vine forest areas and adjacent woodland including Darwin Stringybark. These habitat mosaics would be largely protected within the environmental buffer system and not subject to disturbance, apart from at the proposed Dam C. Proposed mitigation measures would avoid impacts on breeding activity and impacts on individuals in this area, and would allow individuals to relocate to adjoining similar habitat. If the species is present within the Project area, targeted mitigation measures would avoid impacts on individuals, and the environmental buffer system would protect the majority of the habitat mosaic where the species is most likely to occur, and a long-term decrease in any population of the species present is unlikely to occur.
....reduce the area of occupancy of the species?	The key habitats for the species would be largely unaffected by the Project and the area of occupancy of any population of the species, if present, would not be reduced.
....fragment an existing population into two or more populations?	Key habitats for the species would not be significantly affected by the Project and, given the high mobility of the species, any population present would not be fragmented.

….adversely affect habitat critical to the survival of a species?	The Project area does not include any critical habitat areas for the Bare-rumped Sheathtail Bat that are listed under the EPBC Act or identified in Recovery Plans, nor is the Project area regarded as critical habitat for the species given its similarity to other potential habitat areas on northern Cape York Peninsula.
….disrupt the breeding cycle of a population?	Mitigation measures would ensure that breeding activity is not affected within the habitat areas where the species is most likely to occur and disruption to the breeding cycle of any population present is unlikely.
….modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	Although a substantial area of Darwin Stringybark open forest would be disturbed by the Project the majority of this habitat within the Project area would remain undisturbed and other habitats more likely to be utilised by the species would be largely unaffected; consequently, the species is unlikely to decline as a result of the Project.
….result in invasive species that are harmful to an endangered species becoming established in the endangered species' habitat?	The Project is unlikely to lead to the introduction of any invasive fauna that could affect the species. Proposed control measures for weeds would effectively avoid the spread of invasive weeds within the habitat of the Bare-rumped Sheathtail Bat.
…..introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is not anticipated that the Project would represent a threat with respect to the introduction of disease.
….interfere with the recovery of the species?	The Project is not expected to interfere with the recovery of the Bare-rumped Sheathtail Bat.

7.20.2 Migratory Species

Significant impact assessments are provided below for the EPBC Act listed migratory fauna species assessed as possible, likely or confirmed inhabitants of the Project area.

Key definitions from the DSEWPC guidelines that apply to this assessment are as follows:

An area of "important habitat" for a migratory species is:

- habitat utilised by a migratory species occasionally or periodically within a region that supports an ecologically significant proportion of the population of the species; and/or
- habitat that is of critical importance to the species at particular life-cycle stages; and/or
- habitat utilised by a migratory species which is at the limit of the species range; and/or
- habitat within an area where the species is declining.

Listed migratory species cover a broad range of species with different life cycles and population sizes. Therefore, what is an "ecologically significant proportion" of the population varies with the species (each circumstance would need to be evaluated). Some factors that should be considered include the species' population status, genetic distinctiveness and species-specific behavioural patterns (for example, site fidelity and dispersal rates).

"Population", in relation to migratory species, means the entire population or any geographically separate part of the population of any species or lower taxon of wild animals, a significant proportion of whose members cyclically and predictably cross one or more national jurisdictional boundaries including Australia.

Estuarine Crocodile *(Crocodylus porosus)*

An individual significant impact assessment is provided below for the Estuarine Crocodile (*Crocodylus porosus*).

Will the proposed works …	**Estuarine Crocodile *(Crocodylus porosus)***
… substantially modify (including by fragmenting, altering fire regimes, altering nutrient cycles or altering hydrological cycles), destroy or isolate an area of important habitat for a migratory species?.	The migratory species confirmed as present within the Project area predominantly utilise habitats that would be located within riparian areas (environmental buffers) and not directly affected by mining and only minimally affected by infrastructure development. The vast majority of habitats utilised by this species would be unaffected by the Project and substantial modification of any important habitats present is not expected to occur.

… result in an invasive species that is harmful to the migratory species becoming established in an area of important habitat for the migratory species?.	The Project is unlikely to lead to the introduction of any invasive fauna that could affect the Estuarine Crocodile.
… seriously disrupt the lifecycle (breeding, feeding, migration or resting behavior) of an ecologically significant proportion of the population of a migratory species?	Habitat is predominantly riparian areas with the exception of migration to new areas. Serious disruption to the life cycle of this migratory species is not anticipated as primary habitat is located within environmental buffers with minimal infrastructure development.

Significant impact assessments for the EPBC Act listed marine migratory fauna species are provided in **Section 6.9.5**.

Avian Migratory Species

The remaining EPBC Act listed migratory species assessed as possible, likely or confirmed inhabitants of the Project area are all avian species. These species have similar habitat requirements and have been grouped for the purpose of the assessment.

Will the proposed works …	**Refer to Table 7-16 for a list of the migratory fauna species covered by this assessment.**
… substantially modify (including by fragmenting, altering fire regimes, altering nutrient cycles or altering hydrological cycles), destroy or isolate an area of important habitat for a migratory species?	The migratory species confirmed as present, likely or possible to occur within the Project area predominantly utilise habitats that would be located within areas to be protected by environmental buffers and not directly or indirectly affected by mining, and only minimally affected by infrastructure development. The vast majority of habitats utilised by these species would be unaffected by the Project and substantial modification of any important habitats present is not expected to occur.
… result in an invasive species that is harmful to the migratory species becoming established in an area of important habitat for the migratory species?	The Project is unlikely to lead to the introduction of any invasive fauna that could affect migratory species. Proposed control measures for weeds would effectively avoid the spread of invasive weeds within habitats of the migratory species.
… seriously disrupt the lifecycle (breeding, feeding, migration or resting behavior) of an ecologically significant proportion of the population of a migratory species?	Serious disruption to the life cycle of any migratory species confirmed as present, likely or possible to occur within the Project area is not anticipated.

7.20.3 Summary of EPBC Impact Assessments

None of the EPBC Act listed threatened fauna or migratory fauna species known to occur or potentially occurring within the Project area are expected to experience significant impacts as a result of the Project. The proposed mitigation measures would be effective in minimising any potential impacts from the Project on the abovementioned EPBC Act listed threatened fauna or migratory fauna species.

Environmental Impact Statement

for South of Embley Project

Section 8

Aquatic Ecology

8 AQUATIC ECOLOGY

8.1 Introduction

A summary of the biogeographic setting of the Project area is provided in **Section 7.1**. The Project area is essentially an elevated bauxite plateau that is fringed on much of its coastal margins by low cliffs and lateritic outcrop. The groundwater influenced ephemeral and perennial aquatic ecosystems within the Project area are typical of those occurring within the Weipa Plateau subregion within which the Project area is situated.

The SoE area sheds runoff from a centrally located topographic high to the west via Ina and Norman Creek (with four major tributaries), to the north via Triluck–Winda Winda Creek (with three major tributaries), Roberts and Leithen Creeks (the latter two primarily estuarine), to the east via unnamed tributary drainages of the Hey River estuary and to the south via the Ward River system (with two named tributaries, Coconut and Tappelbang Creek). A number of smaller, less defined drainage depressions also flow independently to the Gulf of Carpentaria between these named drainage systems. Coconut and Tappelbang Creeks have their headwaters in the Aurukun Project area to the east of the Project. Within the Project area there are also several swamps that occur in depressions within the bauxite plateau which are largely isolated from defined drainage networks**.**

Given the generally small size of these catchments and the highly seasonal rainfall of the region, many of the smaller streams and depressional swamps do not contain permanent aquatic habitats. However, shallow groundwater connectivity to surface water features is apparent throughout the Project area and semi-permanent groundwater discharge is observed to maintain streamflows and wetland water levels beyond the wet season period at many sites. The larger Norman Creek system includes perennial stream reaches and aquatic refugia and supports a host of aquatic habitat types including streams, tree swamps, sedge swamps, lagoons and lakes. This section describes freshwater and estuarine aquatic ecosystem survey results from a representative suite of sites within the Project area. It also identifies the potential impacts on these ecosystems from activities associated with mine development and identifies mitigation measures. Marine ecosystems are described in **Section 6**. The location of river systems and catchments described in this section can be identified in **Figure 5-1**.

8.2 Conservation Areas and Sensitive Environmental Areas

8.2.1 Conservation Areas

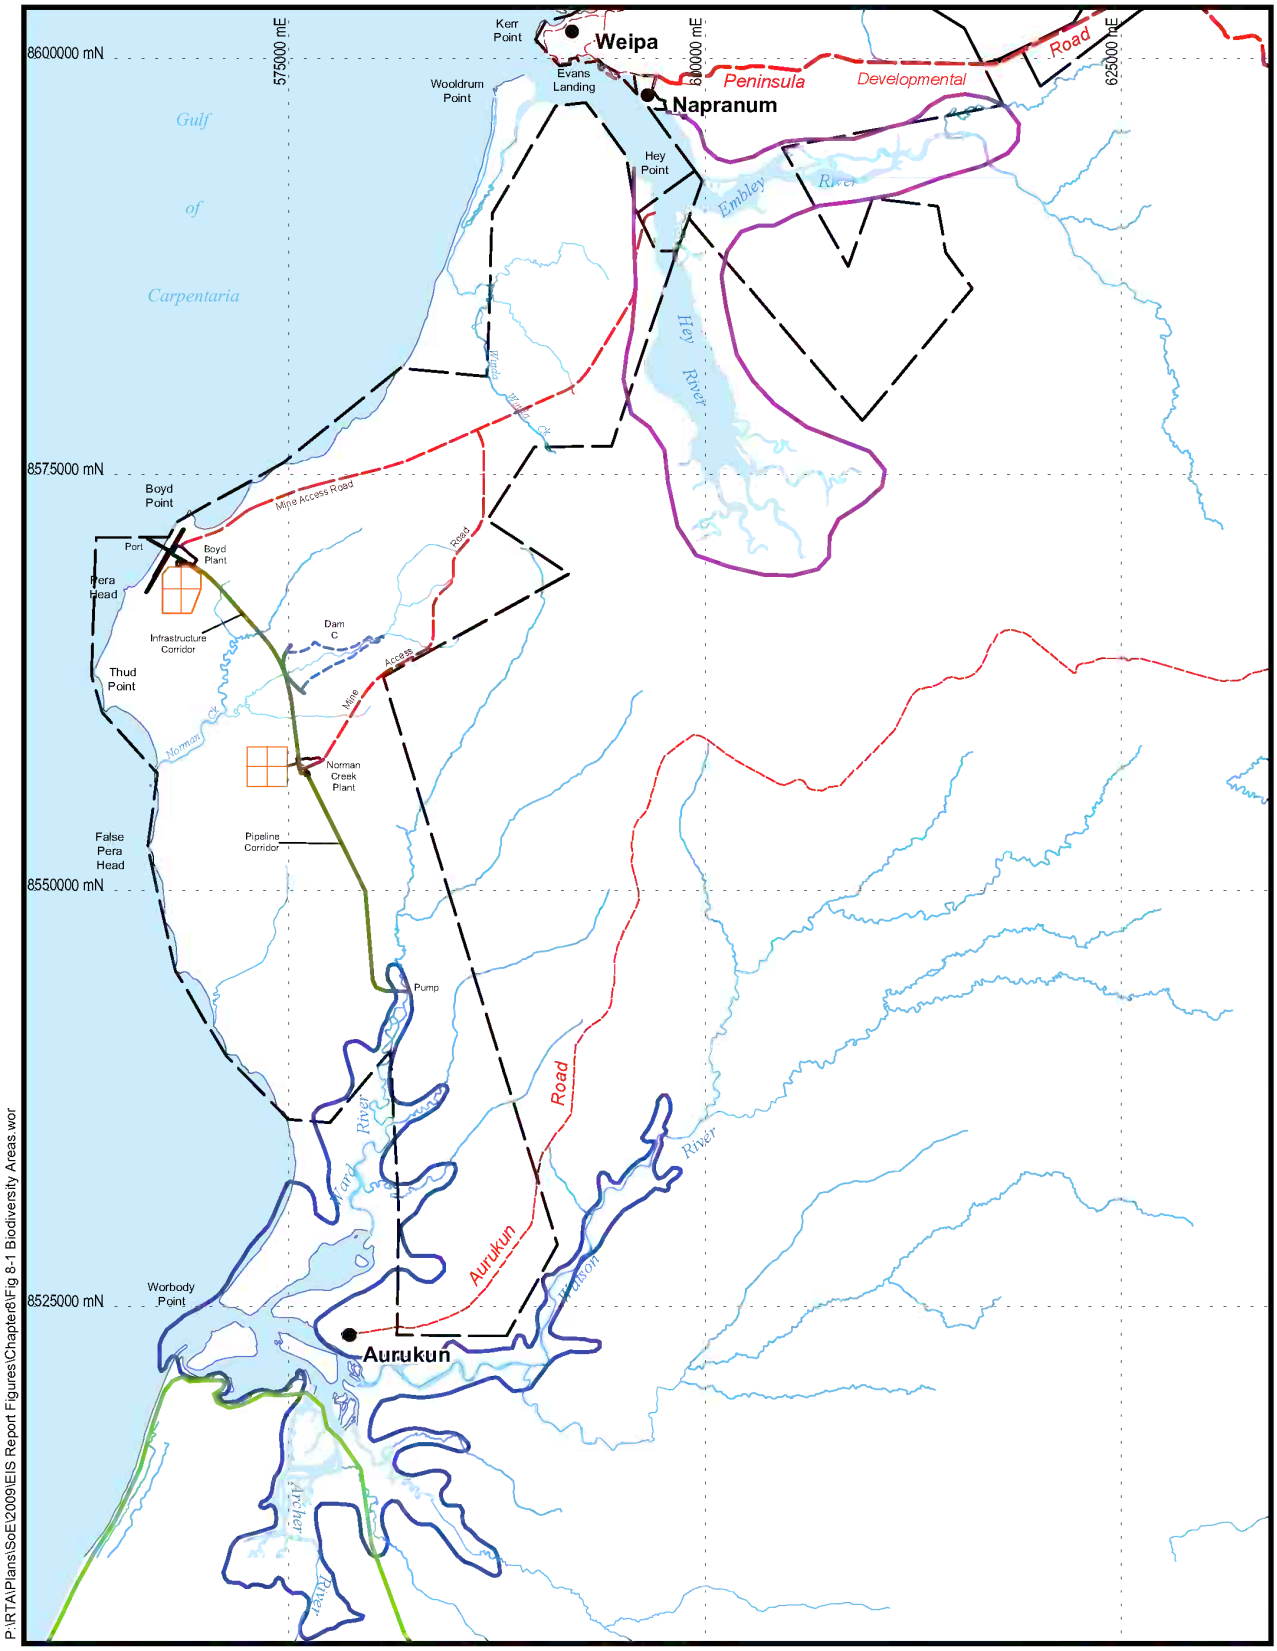
There are four conservation reserves located on northern Cape York (refer **Section 7.1** and **Figure 7-1**) each of which includes aquatic habitat to varying degrees. None of these reserves are located within or downstream of the Project area. The Mungkan Kandju National Park, located approximately 30km east of the southern portion of the Project area and the Jardine River National Park, approximately 125km north-east of the Project area, protect examples of the majority of aquatic ecosystems occurring within the Project area.

8.2.2 Directory of Important Wetlands in Australia

The southern extremity of the Project area overlaps with the Archer Bay Aggregation (refer **Figure 8-1**) which is a nationally significant wetland area listed in the Directory of Important Wetlands in Australia (DIWA) (Blackman *et al.* 1999). The Archer Bay Aggregation covers an area of 29,931ha and encompasses a large estuarine embayment at the mouths of the Ward, Watson and Archer Rivers together with their associated estuarine, riverine, lacustrine and palustrine wetlands. The DIWA area includes the lower freshwater and brackish reaches of the Ward River within the Project area.

The DIWA listing describes the significance of the area as follows:

> The aggregation is the best example of a large estuarine embayment with associated brackish and freshwater wetlands in the western Cape York Peninsula. It is significant for the extent of seagrass beds and the diversity of mangroves. The virtually pristine condition of much of the site adds to its significance.



P:\RTA\Plans\SoE\2009\EIS Report Figures\Chapter8\Fig 8-1 Biodiversity Areas.wor

Rio Tinto Alcan

South of Embley Project

Fig. 8-1: Areas of Conservation Significance

> A significant feature of the area are the grassy coastal flats that are supported by the large amounts of freshwater entering Archer Bay via the surrounding surface and groundwater drainage systems. Relatively constant freshwater inputs are provided by virtue of the laterite and basement aquifers to the north of Archer Bay [i.e. within and to the east of the Project area].

The DIWA listing also describes the occurrence of important or notable wetland flora and fauna species, populations and communities, including the following:

- Spotted Mangrove (*Rhizophora stylosa*) dominated mangrove communities grow on the islands in the bay and along the lower tidal reaches of the rivers and creeks entering it.
- *Eleocharis dulcis* closed sedgeland occurs throughout the Aggregation, being particularly extensive immediately to the west of Aurukun, on Long and Sydney islands and along the Ward River.

Listed species of conservation significance include:

- Little Tern (*Sterna albifrons*); and
- Estuarine Crocodile (*Crocodylus porosus*)

Important breeding and dry season populations of Magpie Goose (*Anseranas semipalmata*) occur on the *Eleocharis* swamps.

Important populations of other waterbird species include Wandering Whistling-duck (*Dendrocygna arcuata*), Green Pygmy Goose (*Nettapus pulchellus*), Brolga (*Grus rubicundus*), Sarus Crane (*Grus antigone*), Little Black Cormorant (*Phalacrocorax sulcirostris*), Little Egret (*Egretta garzetta*), Great Egret (*Ardea alba*), Intermediate Egret (*Ardea intermedia*), Black-necked Stork (*Ephippiorhynchus asiaticus*), Royal Spoonbill (*Platalea regia*), Glossy Ibis (*Plegadis falcinellus*), Australian White Ibis (*Threskiornis molucca*) and Straw-necked Ibis (*T. spinicollis*).

Traditional owners from the Aurukun area have also noted the presence of Dugong (*Dugong dugon*).

8.2.3 Other Identified Conservation and Biodiversity Areas

A full summary of the Cape York Peninsula Land Use Strategy (CYPLUS) (Abrahams *et al.* 1995) assessment of conservation values is provided in **Section 7.2.2**. With respect to aquatic ecosystems, two areas of conservation significance were identified adjacent to the Project area comprising:

- the estuary of the Embley River which is the only known habitat of River Garfish (*Zenarchopterus buffonis*) on Cape York Peninsula; and
- the Aurukun Wetlands to the immediate south of the Project area, which have natural conservation significance due to a number of wetland and terrestrial biodiversity attributes, including the following:
    - It contains some of the best quality coastal wetland habitats in western Cape York Peninsula.
    - The wetlands around the Kirke River (60km south of the Project area) support an abundant wetland fauna and are likely to be the most important dry season refuge for waterbirds on Cape York Peninsula.
    - It is the most important known breeding area for several waterbird species on the Peninsula.
    - It contains four large Magpie Geese breeding colonies and two large waterbird breeding colonies.
    - Two wader roost sites of over 5,000 birds and two each with between 1,000 and 5,000 birds have been identified in the area.

- It supports the richest collection of vegetation communities anywhere on the west coast of the Peninsula, and this is likely to result in a rich fauna;
- Several mangrove crabs which are either new species or new Australian records have been identified in the area;
- The beach ridge system to the south of Kirke River is the most extensive on the west coast of the Peninsula, while the saltpans in the Kirke estuary are unequalled anywhere in the Gulf of Carpentaria; and
- About 25% of the area is of very high wilderness quality.

The northernmost portion of the Project area is within the catchment of the Embley River. The southernmost portion of the Project areas is within the catchment of the Ward River, which drains to the Aurukun Wetlands.

8.3 Survey Methodology

Project area aquatic ecosystems were surveyed and sampled in May 2008 and May 2009, with additional observations made during site visits in August–September 2007, November 2007, February 2008 and December 2008, and February–March 2009.

Survey efforts for fish species were subject to a number of constraints associated with sampling efficiency, access and safety. Within the estuary proper, large populations of estuarine crocodiles limited night work due to safety concerns for samplers associated with potential crocodile attack and with the removal of enmeshed crocodiles from gill nets.

A total of 63 accessible and representative survey sites were selected by reference to satellite imagery, aerial photography and field reconnaissance, with field sites located and fixed using a handheld GPS (refer **Figure 8-2**). At each site biophysical habitat including riparian and aquatic vegetation were described and digital photographs taken. Aquatic ecosystem assessments were made at the same sites, generally concurrently with sampling of fish, larger crustaceans, macroinvertebrates and tissue metal samples, and overlapping with the fourth round of water quality sampling at each site. The sampling effort (measured in hours) at each site for each sampling method is presented in **Appendix 8A**.

Sampling of aquatic biota for the EIS comprised two post wet season sampling periods in May 2008 and May 2009 as this presented the optimal site conditions for sampling. During the wet season stream reaches could not be sampled due to the inaccessibility of sites due to wet season inundation of the landscape and the presence of debris laden high flows that prevented the safe and effective deployment of sampling equipment. While field observations were made at other times, the limited biological sampling cannot fully quantify seasonal and inter-annual variation in the Project area. However, when combined with information from surveys conducted by the same biologists elsewhere on the Weipa Plateau, the general composition of the aquatic biota can be suitably characterised for the purpose of the EIS. It also provides an initial baseline snapshot prior to commencement of mining.

Sampling was conducted by using a number of standardised quantitative and qualitative sampling methods, including:

- Electrofishing – Backpack electrofishing is a method of sampling fish and larger crustaceans from shallow, wadable waters that is highly effective in small freshwater streams. The instrument used for this study was a Smith-Root Model B-12 backpack mounted electrofisher. Due to the very low conductivities typical of streams in the Project area, voltages generally between 900 and 1100V were required for the instrument to operate effectively. Electrofishing was conducted as a single sampling pass at each site for a minimum of 10 minutes, restarting that 10-minute count each time a new species was collected.
- Gill Netting – The gill net set used consisted of two identical panel nets and three small meshed gill nets. Dimensions of the nets used are listed in **Table 8-1**. At freshwater

sites the nets were set from approximately 3pm to 8am on the following day. At estuarine sites only day-time gill net sets were employed (from approximately 7am to 5pm) as a measure to reduce the risk of crocodile entanglement and drowning. On all occasions the total actual set time was recorded and used to scale the catch in subsequent analyses. Gill netting can provide catch per unit effort measures and samples a wide range of fish sizes and species including some species and larger individuals that avoid electrofisher capture.

- Fyke Netting – Fykes (1.2m diameter, 6mm mesh, with two in-line funnels entrances and 5 × 1.5m wings of the same mesh size) were set overnight in stream sites with sufficient depth to ensure the fyke nets could be expanded to full length and the fyke net funnels were more than half immersed in the water. Fyke nets collected a wide range of species.
- Collapsible baited box traps (bait fish traps) – Traps were used in areas with low to moderate flows. These were left overnight in conjunction with the gill net set, and were baited with fish oil flavoured cat biscuits. These traps were effective in collecting small fishes and larger crustaceans.
- Crab trapping – Trapping was conducted at estuarine sampling sites in the Ward River and Norman Creek and utilised five each of two forms of commercially available set crab pots including a double entrance drum trap (730mm length x 280mm high x 300mm wide opening) with large (80mm) mesh and collapsible double entrance opera traps (600mm long x 450mm wide x 200mm high with 90mm opening) with finer (25mm) mesh. These traps were baited with fresh and frozen whole fish bait and set along mangrove fringes in conjunction with estuarine gill net sets.

Table 8-1 Dimensions of Gill Nets Used for Fish Sampling

Net Type	Quantity	Mesh Size (mm, stretched)	Length (m)	Depth (m)	Area (m²)
Panel	2	5m each of 75, 100 and 125	15	2	30
Fine monofilament	1	50	10	2	20
	1	35	10	2	20
	1	25	10	2	20

Fish and crustacean specimens were identified to species level and counted in the field, where possible or representative specimens were preserved and shipped to Brisbane for formal identification by the Queensland Museum. Up to 20 randomly selected specimens of each species from each sampling device were measured in the following manner: fish fork length to the nearest 0.5mm for fish less than 200mm in length and to the nearest 1mm thereafter; prawn post-orbital carapace length to the nearest 0.1mm; and crab carapace width to the nearest 0.1mm. Specimens were weighed to the nearest 0.1g up to 500g and the nearest 1g between 500g and 5,000g.

A macroinvertebrate sweep sample (250μm mesh) was collected using multiple sweeps over 10m of edge habitat at each site. This sampling technique produced a qualitative sample for the purpose of identifying the presence and absence of taxa and trophic guilds in a standardised habitat. Samples were then live-picked using the method of Conrick and Cockayne (2001). Macroinvertebrate samples were sent to Applied Freshwater Sciences for identification to the "Family" level of taxonomic classification.

Tissue samples for tissue metal analysis were taken from species that were found to be widespread in the areas sampled, and representative of the fauna in each habitat. The species used in the present study are listed in **Table 8-2.** An additional species and tissues were collected and archived for subsequent analysis if required. Tissue samples were taken from up to five specimens of each species per site.

Descriptions of riparian vegetation communities and identification of dominant flora species were undertaken at sampling sites and elsewhere within the Project area concurrently with sampling of in-stream fauna. Identification of some riparian and aquatic flora was made during the terrestrial flora surveys as the riparian and wetland habitats within the Project area represent an area of overlap between terrestrial and aquatic systems.

Mangrove communities were targeted to evaluate the likely sensitivity to potential changes in catchment flows associated with proposed mining and infrastructure development. Surveys were conducted at points along the salinity gradient from the upper to lower estuary of both the Ward River and Norman Creek systems (Mangrove sites MW1–5 and MN1–10) during May 2009. The objective of the survey was a qualitative assessment of mangrove community composition and species distribution in relation to site location within the estuary.

Table 8-2 Species Selected for Tissue Metal Concentration Analysis

Species	Tissue types	Common Name
Cherax rhynchotus	Cephalothorax and flesh	Yabby
Cherax quadricarinatus	Cephalothorax and flesh	Red Claw Crayfish
Neosilurus hyrtlii	Hind, Gill	Hytrl's Tandan
Lates calcarifer	Flesh, Liver and Gill	Barramundi
Megalops cyprinoides	Flesh	Tarpon
Toxotes chatareus	Flesh, Liver and Gill	Archerfish
Glossamia aprion	Hind	Mouth Almighty
Liza subviridis	Flesh, Liver and Gill	Brown Backed Mullet
Melanotaenia splendida inornata	Hind	Chequered Rainbowfish
Neoarius graeffei	Flesh, Liver and Gill	Lesser Salmon Catfish
Neoarius midgleyi	Flesh, Liver and Gill	Shovelhead Catfish
Dytiscidae sp. 1	Whole body	Giant Water Beetle
Scylla serrata	Claw, hepatopancreas	Female Mud Crab

Formal seagrass surveys and sampling to characterise the seagrass communities and gain baseline data was conducted in May 2009. Seagrass sampling and surveying was conducted using aerial photo definition of "photo unit" survey targets (primarily sand bars and shallow intertidal flats and channel margins), and on ground by use of 1m quadrant transects across exposed intertidal flats and via grab sample transects across estuarine channel profiles at upper, mid and lower estuary sites.

8.4 Description of Stream and Wetland Habitats

The catchments and stream drainage networks occurring within the SoE area are small in comparison to elsewhere in the Cape York region and this limits the extent and perenniality of freshwater habitats that occur there. Generally, more permanent streams and perennial aquatic refugia are associated with larger and lower catchment areas; however, extensive areas of seasonal freshwater habitats occur throughout the Project drainage network system during the wet season.

Generalised habitat descriptions are provided here for the range of encountered freshwater habitats. These stream and wetland habitats are usually equivalent to one or more of the Department of Environment and Resource Management's (DERM) Regional Ecosystems (REs) which have been described for Cape York Peninsula. The REs occurring in the Project area are described and mapped in **Section 7.5.2**; however, the corresponding RE(s) for each of the stream and wetland habitats described in the following sections are summarised in **Table 8-3**.

Table 8-3 Relationship between Stream/Wetland Habitats and Regional Ecosystems

Stream/Wetland Habitat	Corresponding Regional Ecosystems
Perennial Flowing Streams	3.3.5 3.3.9
Semi-Perennial Coastal Lakes and Lagoons	3.3.14a
Perennial Channel Hosted Pools and Lagoons	3.3.9 3.3.14a
Coastal Swale Swamps*	3.2.3
Tree Swamps	3.3.14a
Seasonal Stream Channels	3.3.5 3.3.9 3.5.22c
Seasonal Coastal Lakes	3.3.14a 3.3.63 3.3.63 3.3.65
Spike Rush Swamps	3.3.63
Drainage Depressions and Flood Runners	3.3.21 3.5.22c
Groundwater Seepage Zones and Springs	3.3.5 3.3.9 3.3.14a 3.3.21 3.5.22c
Estuaries	3.1.1a 3.1.1c 3.1.3 3.1.5 3.1.6

* Coastal Swale Swamp 3.2.3 is listed "Of concern" under the *Vegetation Management Act 1999* (Qld)

8.4.1 Perennial Flowing Streams

The full extent of perennial stream habitat within the Project area has not been fully ascertained by dedicated late dry season survey but observations of persistent base flows made in September and November 2007 and December 2008 suggested such habitat occurs primarily within the mid and lower reaches of Norman Creek, and the upper (i.e. Site 7A) to lower reaches of its main eastern tributary. Surveyed perennial stream sections included Site 5A, Site 1A, Site 7A and Site 11 within the Norman Creek catchment (refer **Figure 8-2**).

The Winda Winda Creek system was observed to have a more seasonal flow regime, although it did retain perennial freshwater pools through the dry season. Aerial photo interpretation and Traditional Owner reports suggest that perennial pools also occur in the upper reaches of Coconut Creek though no perennial pools or reaches were observed in the Project area. Only a

brackish tidally influenced perennial reach persists in the Ward River below the old road crossing at Site 25A through the late dry season.

Dry season streamflow is driven by groundwater discharge, with the sites that drain the broadest and most elevated area of the bauxite plateau, which seasonally hosts shallow groundwater aquifers, exhibiting persistent dry season base flows. Seasonal streamflow also occurs in other stream reaches in lower catchment positions and persists well into the dry season in some locations.

In the Norman Creek catchment, perennial stream habitat extends into the incised upper reaches of the eastern tributary (Site 7A) but also includes spring fed channels emanating from a tree swamp (Site 11) draining the "lowlands" of its north-western tributary. In the Ward River system, small but persistent dry season base flows were observed in lower reaches below the Tappelbang Creek confluence (Site 25A) in November 2007, but flow had ceased in December 2008, while flows in the upper Coconut Creek tributary reaches had ceased by the first dry season survey in August 2007. It is possible that in years with below-average wet season rainfall no system within the Project area would retain flows for the full duration of the dry season. Flow regimes within these systems vary markedly between the wet and dry season. Observations indicate recession in flow rate occurs over an extended period beyond the wet season with both the Ward River and Norman Creek systems exhibiting high discharge volumes and flow velocities that made biotic sampling difficult in late May 2008. These same systems had only trickling base flows when observed in September the preceding year.

Water quality within perennial stream systems was characterised by low conductivity and very high clarity with some variability in clarity observed between sites and season. Water clarity within the upper reaches of the Norman Creek system (Site 11, Site 2A, and Site 7A) was greatest during high base flows while the Ward River system and lower reaches of the Norman had some colloidal content creating a bluish hue to the water. Later in the dry season, under low base flow conditions, water clarity was observed to become murkier due to tannin staining and organic material in the water column in the Ward River (Site 25A) while other sites possibly close to source springs (11, 7A, 5A, 1A) still exhibited high water clarity. Sites with isolated pools that were used as wallows by feral pigs (Ina Creek at Site 26 and Winda Winda Creek at Site 9A) were murky. Water quality is described in more detail in **Section 8.5.1**.

In addition to submerged and emergent aquatic plants, other more common aquatic micro habitats in perennial stream reaches include riffles, runs, pools, undercut banks, large woody debris and leaf litter packs and beds.

Perennial stream reaches act as refugia for aquatic biota within a highly seasonal environment and consequently the most diverse fish and crustacean communities were recorded (refer **Section 8.7**) from these sites, including bigger body species which require larger and more productive habitats for survival. Top order predators including Estuarine crocodiles were also more commonly encountered in these larger perennial habitats.

The key values associated with perennial streams within the Project area include:

- the aquatic refugia they provide for freshwater biota in a highly seasonal environment;
- the populations of larger bodied, fishery significant and ecosystem keystone fish species they support;
- the food chain productivity and downstream nutrient export they contribute to via maintenance of wetland habitats and aquatic plant communities; and
- the habitat they provide for species of conservation significance, including the Estuarine crocodile.

Freshwater discharge from perennial streams also affects the salinity regime in downstream estuarine ecosystems, which in turn affects estuary biological community composition, primary productivity and fishery nursery values.

8.4.2 Semi-Perennial Coastal Lakes and Lagoons

Semi-perennial coastal lakes and lagoons occur in a number of geomorphic settings, usually as part of a complex wetland habitat aggregation that includes other described habitat types (i.e. 'Bulkuru' spike rush swamps, Tree swamps). They are commonly characterised by a semi-perennial open freshwater body of variable size (approximately 2ha to more than 8ha) in immediate proximity to the coast. These water bodies do not occur within defined stream channels but in broad drainage depressions or linear basins within the bauxite plateau, with or without significant contributory catchments. Within the Project area such systems were identified at Pera Head (Site 16A), adjacent and to the south of the mouth of Norman Creek, in the lower reaches of the Ina Creek system, in the upper Waterfall Creek system south of Ina Creek and adjacent to the lower Ward River estuary. Site 16A at Pera Head and Site 32 adjacent the lower Ward River were field-sampled as part of aquatic ecosystem investigations while other sites were field surveyed from the air. All of these water bodies are generally located above sea level and generally lack saltwater intrusion due to downstream drainage line barriers of outcropping bauxite ridges and/or contemporary beach ridges. Their semi-perennial nature is attributed to connectivity with the shallow groundwater aquifer.

8.4.3 Perennial Channel Hosted Pools and Lagoons

Lagoons and pools occur within perennial flowing stream reaches but also within larger seasonal stream channel networks. Perennial pools and channel hosted lagoons also occur within the mid and lower reaches of all tributary branches of the Winda Winda – Triluck Creeks estuary system, and within the lower Ina Creek system. These habitats are hosted within defined stream channels, although in the Triluck Creek estuary tributaries they include prior streams and abandoned channel networks. In the lower reaches of the two main Norman Creek tributaries (Site 3 and Site 8) perennial lagoons form the core of an "everglades" habitat complex that includes contiguous paperbark tree swamps and emergent spike rush sedgelands.

Although grouped on the basis of perenniality, these pool and larger lagoon systems have variable hydrological and salinity regimes. In the lower Ina, Norman Creek and Ward River systems pools appeared to be maintained by groundwater seepage contributions throughout the year, although in the Ward tidal ingress was dominant and water quality brackish by the late dry season. Other systems (Triluck estuary tributary lagoons, Winda Winda Creek system) appeared to be more seasonal and primarily supplied by wet season surface runoff. Sampled perennial channel hosted pools and lagoons included sites on Winda Winda Creek (Site 9A), Norman Creek (Site 1A) and Ward River (Site 25A, 20). While some sampled pools (Site 26A and Site 25A) had significant inflows at the time of biological sampling these habitats would be more typically characterised as still waters for a larger proportion of the year.

8.4.4 Coastal Swale Swamps

Coastal beach ridge swale swamp formation is constrained within the Project area by bauxite plateau cliff frontages on most of the exposed coastline and is limited to areas where the bauxite surface has been lowered through fluvial erosion or where coastal geomorphology enables beach ridges to establish in front of the plateau. Beach ridge swale swamps within the Project area are located between Leithen and Franjum Points in the Embley River estuary and adjacent to the northern tributary drainages of the Norman Creek estuary mouth immediately to the north of False Pera Head. More significant swale swamp aggregations occur outside of the Project area between Worbody Point and "The Lake" in the lower Ward River estuary and around Urquhart Point in the north. The hydrology of these systems varies. Examples in the north appear to be highly seasonal and supplied only by localised wet season runoff and shallow beach ridge aquifers. Systems to the north of the Norman Creek mouth appear less seasonal and to be partially supplied by groundwater seepage from the adjoining bauxite plateau as well as rainfall runoff and shallow beach ridge aquifers. The Norman Creek system also appears to be less perched and subject to some tidal influence. Swale swamps south of False Pera Head are perched, supplied by more significant catchments and have tidal intrusion limited by coastal lateritic outcrops within their drainage outlets.

8.4.5 Tree Swamps

Tree swamps include areas of seasonal or permanent shallow water that are dominated by *Melaleuca* swamp forest communities. Within the Project area these habitats occur in a number of geomorphic and hydrological settings including:

- bank margins and back levee depressions of the lower freshwater reaches of the main perennial and semi-perennial drainage systems (Ward River, Norman and Winda Winda Creeks);
- marginal communities on semi-perennial coastal lakes formed within linear drainage depressions in the bauxite plateau (lower Ina Creek, Waterfall Creek and tributary drainage depressions adjacent the lower Ward River estuary);
- isolated circular depressions within and on the margin of the bauxite plateau (between the Pera Head access road and the Boyd Bay coast, east and south-east of False Pera Head, east of the Hey Point access road, Hey Point, and Leithen Point); and
- adjacent to seasonal lakes on the floodplain interface between freshwater and tidally influenced areas in the lower catchment of the main drainage systems.

Water supply to these tree swamps varies in terms of the contribution of surface runoff versus groundwater seepage. Three of the tree swamp sites surveyed are circular depressions in the bauxite plateau. One occurs in an isolated small tributary drainage of the Hey River estuary on the margin of the bauxite plateau (Site 27); another (Site 22) is more centrally located within the bauxite plateau and connected to the Coconut Creek – Ward River drainage system. The third, the Boyd Bay tree swamp (Site 35), is also located within the bauxite plateau but has no apparent connectivity to adjoining drainage networks. Both Site 27 and Site 22 appeared to be partially supplied by the shallow groundwater aquifer as evidenced by outflowing springs observed in February 2008 and 2009, and late May 2008. Water samples, but not biological samples, were collected from a fourth tree swamp, Site 23, which is an isolated depression between the bauxite plateau and False Pera Head. Upwelling of groundwater was also observed at this location.

Numerous other tree swamps formed significant marginal habitats particularly adjoining semi-perennial coastal lakes and lagoons, perennial channel hosted lagoons and seasonal coastal lakes.

8.4.6 Seasonal Stream Channels

Seasonal stream channel habitats are defined on the basis of a stream bed and channel (often incised) and non-permanent flows. Most of the defined surface drainage channel network within the Project area is seasonal, although flows may extend into the mid dry season in years of above average wet seasons, as observed in 2008. Perennial and semi-perennial pools are present throughout the seasonal stream channel network. Seasonal stream channels occur in most upper catchment tributaries of the main drainage systems including Norman and Coconut Creeks and throughout much of the drainage network of the Winda Winda and Ina Creek systems. However, drainage depressions (refer **Section 8.4.9**) also constitute a significant proportion of the upper catchment drainage network in these systems. Seasonal stream channels also occur in lower catchment areas linking coastal tree swamps and lakes to the coast at False Pera Head and in both the lower Ina (Site 36) and Waterfall Creeks. Except for their size and flow duration, seasonal stream channel habitats share much in common with perennial stream channel habitats. Surveyed seasonal stream channel sites included Site 9A, Site 33 and Site 34 on Winda Winda Creek, Site 19 on the eastern tributary of Winda Winda Creek, Site 4 and Site 2A on Norman Creek and its eastern tributary branch, Site 14A on Coconut Creek, Site 24 on the un-named drainage near False Pera Head and Site 26 on Ina Creek. Although not sampled, seasonal stream channels on minor coastal catchments were also observed at False Pera Head and Pera Head (upstream of Site 16A).

8.4.7 Seasonal Coastal Lakes

Seasonal coastal lakes are generally non-permanent bodies of open water of varying size (up to and greater than approximately 8ha) located on the floodplain interface between freshwater and tidally influenced areas. Seasonal coastal lakes occur in the lower catchment of the main drainage systems (Winda Winda and Norman Creeks and Ward River). These lakes occur within larger wetland aggregations and are usually surrounded by spike rush swamps (refer **Section 8.4.8**) and/or tree swamps and are often connected to smaller more perennial water bodies. During the wet season these lakes are inundated by surface runoff but, as the dry season proceeds, water levels recede to leave dry basins at most sites. At some sites and in wetter years remote sensed aerial images suggest perennial freshwater bodies may persist through the dry season (lower Ward River and Winda Winda Creek systems). Stands of paperbark trees and spring-head riparian communities growing at the base of lateritic profiles on the margins of the coastal floodplains that host these lakes indicate groundwater seepage zones, and contribution from groundwater seepage forms part of the hydrological regime of at least some of these lakes. In May 2009 lake sites in the lower Ward River (Site 29) and Winda Winda Creek (Site 17) systems were observed to be discharging freshwater to the adjoining estuary, while Site 13 adjoining the Norman Creek estuary – while brackish and fringed by sedge communities – exhibited no freshwater discharge during low tide periods and was inundated by tidal ingress during high tide periods.

These lakes are formed on clayey soils, including old marine sediments which, when dry, have the appearance of salt pans. Their location adjacent to tidally influenced mangrove channels, and the salt tolerant plant communities they contain, indicates they are subject to some tidal influence. This influence is likely to be greatest in terms of ingress late in the dry season when freshwater levels have receded and spike rush vegetation is senescent. Only three of these systems were biologically field surveyed (Site 17 and Site 18 Winda Winda Creek system and Site 13 Norman Creek system) but not sampled due to access and safety limitations. Several of the lower Ward River seasonal lakes were also surveyed and sampled during December 2008. Most other seasonal lakes were aerially inspected and discharge confluences from Site 13 to the upper estuary of the Norman Creek system were sampled for fish.

8.4.8 Spike Rush Swamps

Spike rush (*E. dulcis* and *E. sundaica*) swamps commonly occur within coastal wetland aggregations. Dense stands of *E. dulcis* are present in seasonal, brackish water bodies which form seasonal lakes (refer **Section 8.5.7**) on the floodplain interface between freshwater and tidally influenced areas in the lower catchment of the main drainage systems. In lower Norman Creek, spike rush occur in shallow drainage depressions draining the back of the beach ridge swale system to the north of the estuary mouth. In the Winda Winda – Triluck Creek estuary system, spike rush also occur on a drainage depression network draining the back of the southern coastline. Smaller occurrences of brackish spike rush swamps occur between Leithen and Hey Points in the north of the Project area. Although *E. dulcis* commonly grows in brackish environments subject to tidal influence as it is also dependent upon freshwater inputs, it does not grow on salt pan basins that lack sufficient surface catchment areas or contributory groundwater seepage (Blackman *et al.* 1999).

Another form of spike rush swamp in the Project area located away from tidally influenced areas is dominated by less dense stands of *E. sundaica.* This habitat includes water bodies that occur in the centre of tree swamps and semi-perennial coastal lakes (refer **Section 8.4.2**) including those in lower Ina and Waterfall Creeks. Only one spike rush habitat within a tree swamp was field sampled (Site 27) due to access and safety limitations in the larger wetland systems. However, on-ground field inspections were made of these communities in the lowermost reaches of Norman Creek (Site 13) and Winda Winda Creek (Site 17 and Site 18) and adjoining estuarine sites in the lower Ward River system. These systems were also aerially surveyed.

8.4.9 Drainage Depressions and Flood Runners

Drainage depressions and flood runners represent some of the most extensive seasonal freshwater habitat within the Project area. These two habitats have distinctive geomorphic and hydrologic characteristics but are grouped here on the basis of similar habitat features and values. Linear drainage depressions occur across the bauxite plateau and generally represent the uppermost definable reaches of surface drainage systems. These are differentiated from the surrounding Darwin Stringybark woodland on the basis of being topographic low points and hosting species associated with riparian and "soak" communities (i.e. *Lophostemon*, *Banksia* and *Melaleuca*). These drainage depressions generally lack any defined channel and have no pool features other than minor scours that have formed downstream of large woody debris. They occur in low relief upper tributary reaches of all the named drainage systems and intervening catchments including unnamed drainages east of False Pera Head, south of Ina Creek and flowing north-westerly from the existing Pera Head access road. These drainage depressions convey both surface runoff and shallow groundwater discharges. Sampled sites comprising the eastern tributary of Winda Winda Creek (Site 19) and northern tributary of Norman Creek (upstream of Site 4) were flowing strongly in late May 2008. Other drainage depression sites that were field inspected included water quality sampling Site 12, Site 13 and Site 24. Only the latter of these sites contained water when visited during the 2008 wet season water quality sampling and all were observed to be dry by late February 2009.

Flood runners occur within broad alluvial corridors in the mid and lower reaches of the more major drainage systems. Like drainage depressions, these features convey flows through back of stream levee drainage depressions differentiated from surrounding Darwin Stringybark woodland on the basis of changes in vegetation community towards species associated with riparian and "soak" communities (i.e. *Lophostemon*, *Banksia* and *Melaleuca*). Subject to the extent of lateral shallow groundwater flow these systems are more seasonal than upper catchment drainage depressions with flows primarily restricted to periods of elevated/overbank streamflows during the wet season. Flood runner habitats did not contain sufficient water during surveys to enable biological sampling, though these types of habitats were field inspected during site surveys of adjoining stream channels (i.e. at Site 11, Site 2A, Site 1A, and Site 25A).

8.4.10 Groundwater Seepage Zones and Springs

A range of shallow groundwater aquifer dependent aquatic habitat types is collectively referred to under this grouping of groundwater seepage zones and springs. Groundwater has been identified as an important component in the hydrology of the majority of the habitat types identified in streams and wetlands. One of the main forms of connectivity between groundwater and these habitats are springs and seepage zones which feed into surface water features. However, such springs and seepage features occur widely through the Project area and in many instances do not contribute to large surface water features and it is these smaller groundwater dependent habitat types that are identified here. Considering the lateritic profile as the primary host material for the shallow seasonal groundwater aquifer in the Project area (refer **Section 5.3.2**), the occurrence of springs and seepage zones can most readily be related to the depth of surface incision into this profile. An illustration of the contribution of the bauxite profile comes in the form of numerous out flowing springs emanating from the bottom of the bauxite cliffs that fringe the Gulf coastline of the Project area. While these springs are most prominent immediately after the wet season, some exhibit flow until the mid dry season. Subject to the distance between the point of groundwater out flowing and the beach, some of these systems support short seasonal streams with or without pools. In some instances these systems drain to the coast via plunge pools and channels formed into the bauxite surface, creating seasonal cascades and locally significant perennial pool habitats (e.g. at False Pera Head).

Away from the immediate coastline, other topographic low points that provide an outlet for bauxite hosted groundwater include deeply incised tributary valleys in the upper reaches of some systems (e.g. Norman Creek Site 7A) and fluvial erosion corridors (valleys, drainage depressions) draining the bauxite plateau. Circular depressions, possibly caused by dissolution collapse of the underlying lateritic profile, also occur within the bauxite plateau and in some

instances appear to be conduits for surface out flowing of groundwater, often hosting tree swamp communities. Groundwater outlets within these surface features are most likely controlled by the underlying hydraulic connectivity of the lateritic profile and are evidenced at the surface by high soil moisture dependent vegetation types and often small pools and emergent fringing aquatic vegetation. Low contour "embayments" that back the estuarine outlets of surface drainage systems (i.e. lower Winda Winda Creek, Norman Creek and Ward River estuaries) also appear to be sites of groundwater seepage zone formation as evidenced by stands of *Melaleuca spp.* growing in narrow bands on the margin between dry woodland and tidally influenced estuarine habitats.

Groundwater seepage zones or springs were not specifically targeted as part of the aquatic ecosystem investigations though such habitats were often observed at sampled sites (e.g. the perennial Norman Creek tributary stream at Site 11, tree swamp Site 22 and Site 27, coastal lagoon Site 16A, Ward River tributary swamp Site 32, and drainage depression Site 19). Spring fed habitats were also inspected adjacent to False Pera Head. Groundwater appeared to discharge from macro pores on the stream bed in clearwater reaches of the upper Norman (Site MN8) and Ward (Site 28) estuaries in May 2009 and December 2008 respectively.

The Great Artesian Basin Resource Operations Plan (GAB-ROP) (DNRW 2007) defines three spring types associated with artesian water of the Great Artesian Basin, these are recharge, watercourse and discharge springs. An assessment of the potential for these springs, and the threatened ecological community, to occur in the Project area concluded that only recharge and watercourse springs (not discharge springs) occur in the Project Area (refer Section 5.3.4). Therefore the ecological community is unlikely to occur in the Project area.

8.4.11 Estuaries

The estuaries of the Project area are a complex of continuous wetland aggregations (Blackman *et al.* 1999) including swale swamps, spike rush swamps, paperbark tree swamps, seasonal lakes and saline coastal flats. They are characterised by a diverse mangrove forest community, which is partially related to the freshwater discharge they receive and the wide range of salinity regimes and geomorphic habitats that occur within them. Saline flats are common on the landward side of mangrove forests and are particularly extensive along lower Winda Winda Creek and Ward River. These are sparsely vegetated as their relatively high salinity in the late dry season tends to discourage plant growth. They are commonly dominated by marine couch *Sporobolus virginicus* or by *Xerochloa imberbis*. Sedges, particularly *E. dulcis*, may become prominent or dominant in these areas during the wet season.

There are six estuarine ecosystems in the Project area, three of which occur entirely within it (Norman, Leithen and Ina Creek estuaries) and three that only partially occur within the Project area but have catchments that drain it (Ward River, Triluck–Robert's Creeks and Hey–Embley Rivers).

The Ward River drains the southern portion of the Project area to an estuary that is contiguous with the Watson and Archer River systems which adjoin to the south. Collectively these systems form Archer Bay, an estuarine wetland aggregation listed in the Directory of Important Wetlands in Australia (Blackman *et al* 1999). Only the uppermost reaches of the Ward River estuary occur within the Project area. The northern boundary of the Project area abuts the large open Embley estuary that forms the southern boundary of the Weipa Peninsula, and drains to it via the Triluck–Robert's Creeks estuary (upper reaches of which occur within the Project area). The Leithen Creek estuary (entirely within the Project area) and minor drainage lines in the north-east of the Project area also drain to the Embley estuary via the Hey River.

There are also a number of smaller defined drainage systems to the Gulf of Carpentaria within the Project area. The three more significant systems include an unnamed drainage that flows to the sea at Pera Head, another immediately south of False Pera Head, and Waterfall Creek south of Ina Creek. These systems lack "true" estuaries due to their mouths being partially occluded by beach ridge swales and lateritic rock outcrops which limit tidal intrusion and the development of an "estuarine" mixing zone. These latter systems are more appropriately described as swale swamp ecosystems.

The "true" estuaries within the Project area lie within "embayments" of the bauxite plateau surface which have been created by fluvial erosion resulting in the presence of estuarine mixing zones in the lower reaches of the drainage systems. They also exhibit a range of hydrological regimes differentiated on the amount and seasonal duration of freshwater discharge to them. Leithen Creek estuary in the north of the Project area lacks a significant catchment area and appears to receive the majority of its freshwater input as surface runoff during the wet season, though some groundwater seepage to this system would be expected to be sustained beyond the wet season. The Triluck–Roberts Creeks estuary is fed by the large Winda Winda Creek catchment. The Norman Creek estuary is fed by wet season flows and more perennial catchment discharges. The Ward River estuary is fed by wet season flows and by perennial groundwater inflows at the estuary margin. Distinctions in estuarine catchment hydrology influence the composition and relative dominance of habitats and vegetation communities (e.g. salt pans, seasonal lakes, spike rush swamps, paperbark swamps, mangrove communities) that comprise each estuarine wetland aggregation and the water quality, salinity regimes and primary productivity within them.

The Australian Catchment, River and Estuary Assessment was undertaken as part of the National Land and Water Resources Audit (NLWRA) and aimed to assess the current condition of Australian estuaries. The first stage of the assessment was an initial condition assessment where estuaries were classified as in 'near pristine' condition, 'largely unmodified' condition, 'modified' condition or 'extensively modified' condition. The classification was qualitative and determined from information obtained from state agencies through workshops and interviews. Of the 979 estuaries assessed, half were classified as being in 'near-pristine' condition (National Land and Water Resources Audit, 2002). An estuary was classified as near pristine if it had:

- a high proportion of natural vegetation cover in the catchment;
- minimal changes to hydrology in the catchment;
- no changes to tidal regime;
- minimal disturbance from catchment land use;
- minimal changes to floodplain and estuary ecology;
- low impact human use of the estuary; and
- minimal impacts from pests or weeds.

The other three categories of the assessment - largely unmodified, modified and severely modified were used to indicate increasing levels of change for some or all of these criteria.

The Archer Bay and Norman Creek estuaries are classified as being in 'near pristine' condition, and the Embley River estuary is classified as being in 'largely unmodified' condition (National Land and Water Resources Audit 2010).

Water quality and biological sampling were conducted within three Project estuarine systems: Norman Creek (Site 10A and Site 12), Ward River (Site WP8, Site WP14, Site 28, Site 29 and Site 30) and Winda Winda – Triluck Creeks (Site 21) and within the Pera Head coastal lagoon (Site 16A). Visual observations and opportunistic angling also provided site data for the Ina Creek estuary.

8.5 Water Quality and Hydrology

8.5.1 Water Quality

The surface water quality characteristics of the Project area including the sampling methods used and parameters sampled are summarised in **Section 5.1.4**. The fresh surface water quality of the Project area is generally similar to other tropical waters in northern Australia and can be summarised as mildly acidic with low conductivity and very low hardness. Aluminium and iron concentrations are elevated due to the influence of the bauxite plateau.

Low conductivity can potentially be the cause of osmotic (salt regulation) stress for many organisms, particularly those with recent marine affiliations. For organisms with calcareous body parts, the low hardness, and very low calcium concentrations are likely to make accumulation of this metal and secretion of calcium carbonate structures difficult. This may explain the absence of freshwater molluscs and the "soft" exoskeleton crayfish (*Cherax rhynchotus*) in the fresh waters of the Project area.

The lack of solutes in the waters of the Project area indicates there is little pH buffering capacity, and there can be a strong response to minor changes in the geochemistry. For example, **Figure 8-3** shows a stream in a bauxite plateau north of Weipa at a site where groundwater inflows were dominant over surface flows. Iron oxidation from Fe^{2+} to Fe^{3+} and the subsequent formation of iron oxy-hydroxides ($Fe_xO_yOH_z$) resulted in the release of sufficient H^+ ions (released from water in this process) to cause a drop in pH of almost 1 unit from that upstream of the point of groundwater inflow. Re-equilibration with atmospheric CO_2 caused a return to ambient pH within approximately 500m. Such geochemical processes occur naturally to some extent in most streams, but generally inherent buffering of pH reduces the influence of iron oxidation chemistry in harder waters. The pH level is a major influence on the chemistry of other solutes, including trace metals, many of which are also more soluble under low pH. Variations in surface water chemistry need to be taken into account when assessing the potential risks for mine-related alteration to water quality, particularly in relation to potential changes in surface and groundwater contributions.

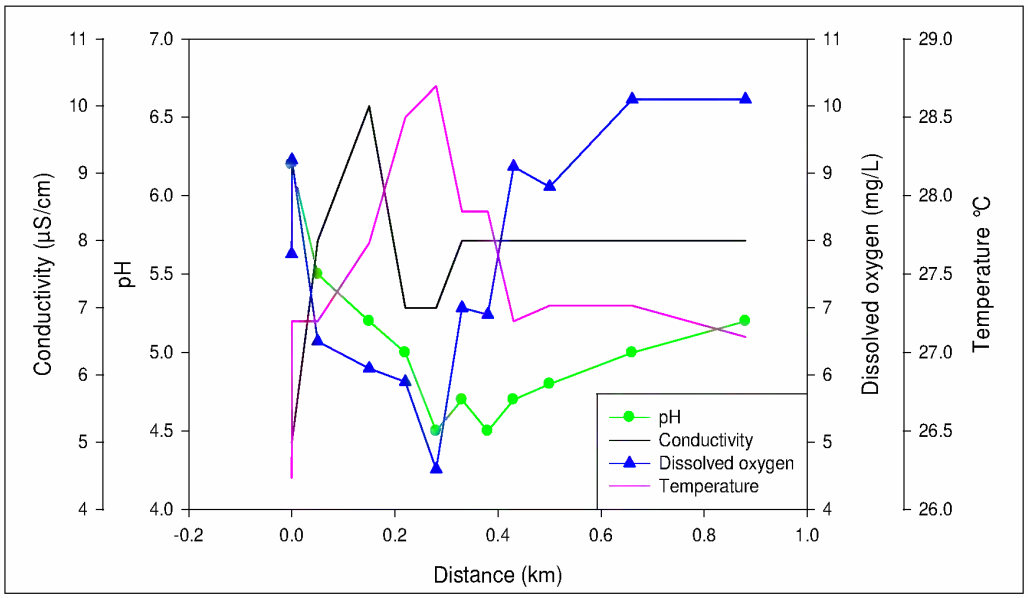

Figure 8-3 Field Parameters in Stream Downgradient from Groundwater Inflows

In soft waters geochemical mitigation processes to reduce the bioavailability of metals present may be inhibited. The hardness of the Project area freshwater streams and tree swamps is low and thus the default ANZECC/ARMCANZ (2000) water quality guidelines for protection of aquatic ecosystems for chromium, copper, cadmium, lead, nickel and zinc require correction for hardness.

The hardness of Project area freshwaters ranges from 0.36 to 9.7mg$CaCO_3$/L with a median of 1.3mg$CaCO_3$/L. ANZECC/ARMCANZ (2000) states that the hardness correction algorithms may be applied for hardness outside the 25 to 400mg$CaCO_3$/L range used to derive the relationships; however, Markich *et al.* (2001) in their derivation of the guidelines note that the

slope of the relationship (the exponent in the equations provided in ANZECC/ARMCANZ (2000) Table 3.4.3) is zero for extremely low hardness (ca. 1mg$CaCO_3$/L, which is quite typical of the Project area freshwaters), meaning that extrapolation of the standard algorithms will be overly protective for the Project area streams. In addition, commercial laboratories may not be able to consistently achieve such low reporting levels for the hardness dependent metals.

Metal toxicity in very soft waters has been investigated in Australia and elsewhere (Markich and Camilleri 1997), and generally the toxicity of metals for which hardness affects bioavailability, such as copper, is greater in very soft waters. For example, the default ecosystem protection trigger value for copper in ANZECC/ARMCANZ (2000) for water with hardness of 30mg$CaCO_3$/L ("soft waters") is 1.4µg/L, but Markich and Camilleri (1997) recommended a trigger value of 1µg/L for copper for waters with hardness <10mg$CaCO_3$/L. The standard commercial laboratory reporting limit for copper in analysis suites for environmental monitoring is 1µg/L. Therefore, it is likely that appropriate trigger values for metals in solution in soft waters such as found in the Project area would be lower than default trigger values of ANZECC/ARMCANZ (2000), but higher than that indicated by simple extrapolation of hardness correction algorithms.

The softest water that has been used for toxicity testing in Australia, or found in international literature, was 3.2mg$CaCO_3$/L in Buffalo Billabong water by the Environmental Research Institute of the Supervising Scientist, Northern Territory, Australia (then the Alligator Rivers Region Research Institute) (Markich and Camilleri 1997). The median hardness of the samples of freshwaters from the Project area ranged from 0.36 to 9.7mg$CaCO_3$/L. Given the lack of toxicity testing with soft waters it is not possible to rely on existing toxicity testing as a guide to assess site water quality.

In the absence of dedicated toxicity testing, a conservative approach is to assume that all dissolved metal concentrations in the site waters are bioavailable. The background dissolved concentrations in fresh surface water of metals requiring hardness correction are less than the default guideline values.

While acknowledging they are overly conservative, the hardness modified trigger values were calculated for applicable metals (**Section 5.1.4**) to evaluate if these are potential constituents of concern at the Project area. All hardness modified trigger values were less than commercial laboratory reporting levels. The concentration of metals in freshwaters compared with the hardness modified trigger values are discussed below.

- The maximum concentration of dissolved nickel and cadmium was less than the hardness modified trigger values in all freshwater samples.
- The maximum concentration of dissolved lead in freshwater stream samples (0.65µg/L) was greater than the hardness modified trigger value (0.066µg/L); however, the 80th percentile concentration was less (0.05µg/L). Both the maximum and 80th percentile concentrations of dissolved lead in freshwater tree swamps was less than the hardness modified trigger value.
- The maximum dissolved concentration of copper and zinc in freshwater streams and tree swamps was greater than respective hardness modified trigger values; however, the 80th percentile concentrations were less than hardness modified trigger values.
- The 80th percentile concentration of chromium in freshwater tree swamps was 0.10µg/L and in streams 0.08µg/L, both slightly greater than the hardness modified trigger value of 0.078µg/L.

Aluminium (along with iron and manganese where groundwater inflows are dominant) is naturally elevated in the surface waters of the Project area. The toxicity of aluminium in fresh water varies with pH, being more toxic below pH 5.5 and above 9 (ANZECC/ARMCANZ 2000), and separate trigger values are provided in the guidelines for freshwaters with pH below 6.5 (0.8µg/L, low reliability) and pH above 6.5 (55µg/L, moderate reliability). For some constituents there is insufficient data available for ANZECC/ARMCANZ (2000) to develop a high or moderate reliability trigger value, and a low reliability trigger value may be available to be used as an indicative interim working level. For marine waters there is insufficient data available for

ANZECC/ARMCANZ (2000) to develop a moderate reliability trigger value, and a low reliability value of 0.5µg/L was derived from the most sensitive test result.

The aluminium concentrations in fresh surface waters are generally above the ANZECC/ARMCANZ (2000) default trigger values. The concentration of iron in freshwaters exceeded the ANZECC/ARMCANZ (2000) interim working level of 300µg/L on occasions. Aluminium, iron and manganese may be affected by geochemical changes arising from mining impacts or natural causes. It is proposed to set Project trigger values for aluminium, iron and manganese based on the 80th percentile of the baseline data set for freshwaters. If, during operations, the median concentration of aluminium, iron or manganese exceeds the Project trigger value, an investigation would be carried out to determine the possible causes.

All estuarine samples, except for the September 2007 sample from Norman Creek, exceeded the low reliability default trigger value for aluminium in marine waters of 0.5µg/L. It is proposed to set Project trigger values for aluminium based on the 80th percentile of the baseline data set for estuarine and marine waters. If, during operations, the median concentration of aluminium exceeds the Project trigger value, an investigation would be carried out to determine the possible causes.

Note that for some site-specific guidelines to be developed, additional sampling over that achieved to date would be required in order to determine the 80th percentile of background concentrations, and additional sampling would improve the accuracy of the estimate of the 80th percentile for all sites.

The natural mineralisation of the Project area has resulted in dissolved aluminium concentrations that are higher than default ANZECC/ARMCANZ aquatic ecosystem protection trigger values. As this is natural, it is likely that the local ecosystems have adapted to the naturally high aluminium concentrations, at least to the extent that only those taxa able to tolerate those levels will persist (discussed further in **Section 8.15**).

8.5.2 Hydrology

The surface and groundwater hydrology of the Project area and potential impacts and mitigation measures are detailed within **Section 5**. The catchment hydrology of the Project area is characterised by naturally high inter-annual and inter-decadal variability in response to the summer monsoon, cyclonic rain depressions and El Niño – La Niña cyclical influences. Potential impacts on surface water and the shallow groundwater aquifer that may impact upon aquatic ecosystems have been identified. Modelling of catchment behaviour within the Project area (**Section 5.2.4**) indicates potential changes to catchment discharge associated with mining development fall within plus or minus 1% of mean annual discharge. This section provides a summary of the specific linkages identified between surface and groundwater hydrology and the character and values of Project area aquatic ecosystems.

8.5.2.1 Drainage Channel Morphology

The morphology of drainage channels and associated floodplain features in surface drainage catchments is determined by the scouring and sediment transport capacity of the flow regime. In the Project area, peak flow events are largely responsible for the geomorphology of stream valleys, including scour-formed pools, floodplains and associated flood runner channels and the estuary (**Section 7.2.5**). High within-channel flows in the Project area are often attributed to the hydraulic gradient between the contributing groundwater aquifer and the surface channel network, and are responsible for a large proportion of the sediment transport capacity of the drainage network. Alterations to the flow regime, particularly to extreme peak flows or modal flow characteristics, are likely to result in changes to channel and floodplain form, depending on the magnitude of the alteration. Alterations to the peak and modal flow characteristics may occur as a result of rainfall-runoff retention in mining pits, construction of water storages and alterations to shallow groundwater hydrology. Such changes would be likely to result in some geomorphic changes in the receiving drainage network.

8.5.2.2 Water Quality

The water quality of surface waters throughout the Project area is largely related to the infiltration and residence of rainfall and surface runoff within the seasonal aquifers provided by the bauxite lateritic profile, which effectively filters water before releasing it to perennial and seasonal flowing drainage networks. Alterations in surface and groundwater hydrology that change the residence time of water within these seasonal aquifers and/or the relative contribution of surface runoff and groundwater discharge to the surface drainage networks, particularly more seasonal ones, are likely to result in some alterations of the water quality characteristics of these systems.

8.5.2.3 Flow Associated Habitat Availability

In the Project area, groundwater discharge to surface drainage networks enables persistence of flowing stream reaches for extended periods into the annual dry season. Results from biological sampling within the Project area indicate some fish and macroinvertebrate community compositional differences that can be related to the relative availability of flow-associated habitats (e.g. riffles and runs), within different stream catchments. Alterations in surface and groundwater hydrology that change the extent and persistence of flow-associated habitats within these drainage networks could be expected to drive shifts in faunal composition at the reach and sub-catchment scale, depending on the magnitude of the alteration.

8.5.2.4 Habitat Connectivity

The duration and depth of surface drainage network flows is an important determinant of the level of connectivity between perennial freshwater habitats. Inter-habitat connectivity influences the diversity of fish communities including the distribution of migratory and larger bodied species (**Section 8.7**). Changes to inter-habitat connectivity through reduced surface water flow volumes or duration, or the construction of on stream storages, could affect the recruitment of fish species to upstream habitats, particularly those that already have some degree of isolation or intermittency. Refer to **Section 8.16** for further discussion on the magnitude of change to habitat connectivity associated with Dam C on a freshwater tributary of Norman Creek and proposed mitigation measures and **Section 8.14** for discussion on potential impacts to hydrology and proposed mitigation measures. An assessment of the potential impacts on listed species associated with habitat connectivity is in **Section 8.17** for freshwater species and **Section 6.9.5** for marine species.

8.5.2.5 Habitat Perenniality and Flow Duration

Perennial freshwater habitats are widely distributed throughout the Project area. In a highly seasonal environment, perennial water bodies influence the diversity of obligate freshwater biota retained within isolated sub-catchments, such as those typical of the bauxite plateau in the Project area. The potential for mining associated impacts to alter the duration of groundwater discharges to surface drainage networks, particularly in reaches hosted topographically higher in the bauxite lateritic profile, could impact upon the aquatic refugial value of individual stream reaches or sub-catchments during extended dry season periods. Initiation of flow with the onset of the wet season and persistence of flow for some time post wet season, is important to the total productivity of aquatic ecosystems and the populations of fauna and flora within them. Although population persistence through the dry season would require access to perennial habitat for obligate freshwater taxa, overall population productivity and hence probability of persistence would also be related to access to seasonally inundated habitats. Therefore, reduction in the total flow-duration in the drainage network may also impact total population productivity and likelihood of persistence of populations year by year. For those species with the ability to aestivate, having terrestrial life stages, or that have other mechanisms to persist through the dry without access to surface water, seasonally available surface water may be a substantial proportion of the habitat used by the population and supply much of the annual population productivity.

8.5.2.6 Ecotonal Zonation

Ecotonal riparian and wetland vegetation communities associated with perennial and seasonal surface water features in the SoE area, display a high degree of zonation occurring in linear or concentric bands of different species dominated communities, relative to the hydrological influence of the surface water feature. Hydrology (and associated soil typology) is one of the most important determinants of the location of these ecotonal zones governing plant survivorship and recruitment success via the inundation tolerances, soil moisture and germination requirements of individual species. Mining development associated impacts that result in alteration to catchment and groundwater hydrology that impact upon the inundation and/or soil moisture regimes experienced by ecotonal vegetation communities may drive changes in the location of ecotonal boundaries via the death of mature trees and migration of different vegetation zones in response to preferred germination conditions for individual species.

8.5.2.7 Fire Refugia

In the seasonal dry tropics within which the Project area is situated, fire regime interacts with many other drivers of ecosystem condition, including hydrology. In the Project area the distribution of fire-sensitive closed riparian forest communities is closely related to the fire refugia provided by channel form and soil moisture conditions. The potential for mining associated impacts to alter the seasonal duration of groundwater discharges to surface drainage networks could lead to impacts upon the seasonal soil moisture conditions experienced by some riparian vegetation communities and affect their fire regime. In reaches hosted higher topographically in the bauxite lateritic profile any potentially reduced base flow duration could potentially generate hotter fire conditions capable of driving fire-sensitive rainforest associated riparian vegetation toward replacement by more fire-hardy sclerophyll riparian vegetation. Lower in catchments, the potential for extension of basement aquifer base flow duration could perceivably increase the fire refugia function associated with moist alluvial landforms and generate vegetation changes toward greater representation and development of fire-sensitive riparian rainforest species.

8.5.2.8 Ecosystem Productivity

Most surface waters sampled over a range of seasonal flow conditions within the Project area have low nutrient values associated with their groundwater sources. The main sources of primary production input identified for the food chain of Project area aquatic ecosystems include leaf litter associated with riparian and swamp forests and in-stream algal and aquatic macrophyte growth in lower catchment wetland aggregations. Both of these sources of primary productivity are maintained to some degree by the hydrological conditions (riparian forests discussed above) of the catchment, particularly the sustained discharge of groundwater to surface drainage systems through a significant proportion of the dry season. Mining or infrastructure associated impacts that alter the initiation of flows and/or the seasonal duration of groundwater discharges to surface drainage networks could affect both the in-situ and exported productivity of lower catchment wetland aggregations, though the direction of such impacts could vary between catchments. Deferral of wet season onset flows due to water harvesting could delay the post dry season inundation of lower catchment wetlands and primary production exports or pulses from them. Conversely, increased base flow discharges from groundwater aquifers may have the capacity to drive increases in lower catchment primary productivity. If a truncation of base flows is experienced this could result in accelerated rates of wetland water level recession and associated declines in stream primary productivity with some potential also for increased tidal ingress and associated impacts at the estuarine interface of these systems.

8.5.2.9 Salinity Regimes

Sustained discharge of groundwater to surface drainage systems through a significant proportion of the dry season in some Project area catchments results in the maintenance of brackish environments within lower catchment wetland aggregations, including the upper reaches of estuarine systems. These brackish environments support a number of ecological

processes – e.g. enhanced fish recruitment (Robins *et al*. 2006, Halliday *et al*. 2008) – and valuable wetland habitats including 'Bulukru' spike rush *E. dulcis* swamps, seasonal coastal lakes (fishery nursery) and brackish mangrove communities. Potential mining associated impacts that alter the seasonal duration of groundwater discharges to surface drainage networks could result in the landward retreat of the extent of these brackish environments with an associated loss of habitat diversity and associated ecological values.

8.6 Riparian and Aquatic Flora

Generalised descriptions of the riparian and aquatic vegetation within the Project area are provided in **Section 8.4**. More specific floristic information is presented here for the two main vegetation community types comprising riparian overstorey communities and aquatic macrophytes. Detailed mapping of vegetation and associated Regional Ecosystems is provided in **Section 7.5**.

8.6.1 Riparian and Mangrove Communities

Riparian overstorey vegetation communities within the Project area can be classed into five generalised categories, though transitional and mixed communities including those categories occur in some geomorphic/hydrologic settings. The five categories are discussed below.

8.6.1.1 Closed Riparian forests

Closed riparian forests occur along most of the perennial and semi-perennial (seasonal) stream network within the Project area. These communities contain many rainforest-allied species and are fire sensitive. They generally occur on moist but well drained higher fertility alluvial soils on stream banks and levees and also within fire refugia created by incised channels and valleys (e.g. incised upper reaches of the Norman Creek system Site 7A), and on moist beach swales and areas of outcropping rock adjoining drainage lines. Closed riparian forest communities, particularly those associated with perennial stream reaches, showed a high level of compositional similarity throughout the Project area though the extent of their development varied in response to the level of fire refuge provided by channel and bank morphology. They develop their broadest expression in mid and lower catchment areas where alluvial deposits extend beyond stream banks and are fire protected by back levee flood runner channels. Elsewhere, such communities extend only one canopy tree diameter beyond the immediate stream channel bank. Common canopy trees within these communities include *Lophostemon suaveolens, M. leucadendra, Carallia brachiata, Dillenia alata, Syzygium suborbiculare, Syzygium spp. (~ ×2), Garcinia warrenii, Terminalia spp., Buchanania arborescens, Parinari nonda* and palms *Livistona muelleri,* and *Hydriastele wendlandiana* (only Site 7A). Where these closed forest communities occur they limit incident sunlight and in-stream aquatic plant growth and associated primary productivity but contribute leaf litter and snags. At sites where perennial streams occur in conjunction with tree swamps (i.e. Site 11 and the lowermost freshwater reaches of Norman Creek) closed riparian forests tend toward compositions more typical of swamp forest communities and include an increased dominance of paperbarks *M. quinquenervia* and *M. leucadendra*. Understorey vegetation is typically sparse on account of canopy shading.

8.6.1.2 Open Riparian Forests

Open riparian forests predominantly occur on the banks of more seasonal streams, or on reaches of perennial streams where banks are drier and more fire exposed due to non-conductive heavier soils or low water levels relative to bank levee heights (i.e. Ward River Site 25A). These open riparian forests comprise dry sclerophyll species including *Eucalyptus brassiana*, *E. polycarpa*, *Lophostemon suaveolens, Leptospermum longifolium, Calycopeplus casuarinoides, Banksia dentate* and *Livistona muelleri.* Subject to catchment location, bank margins will also usually have one or more species of paperbark present, most commonly *M. leucadendra*, *M. symphyocarpa, M. viridiflora* or *M. quinquenervia*. More fire-hardy representatives of the closed forest community, e.g. *Syzygium suborbiculare* and *Carallia brachiata*, are also commonly observed within these open forest communities. Understorey vegetation is usually a mixture of grasses associated with alluvial soils and a diverse mix of

sedges *Cyperus spp.* Sprawling twig rush *Dapsilanthus elatior* is also a common emergent macrophyte species encountered in the understorey and is found on seasonally waterlogged soils and stream and flood runner bank margins.

8.6.1.3 Swamp Forests

Swamp forests dominated by *Melaleuca spp.* occur in a range of catchment settings where soils are seasonally or permanently waterlogged, including depressional areas within the bauxite plateau, waterlogged lower catchment stream reaches of the major drainages, adjacent seasonal and permanent coastal lakes and within beach ridge swale systems. There are more than five species of *Melaleuca* recorded from the SoE area and each favours a specific set of soil and hydrological conditions. Some swamp forests comprise mono-specific stands of a single *Melaleuca* species, e.g. *M. leucadendra* in costal swale swamps or *M. quinquenervia* on coastal lakes and waterlogged lower stream reaches. While some communities, e.g. seasonal tree swamps in depressional areas within the bauxite plateau, host a mix of species which are arranged in ecotonal bands related to the variable hydrological conditions of the site, experienced in terms of different seasonal inundation and soil moisture regimes. These types of communities would be vulnerable to changes in catchment hydrology that result in spatial displacement of the conditions underlying these ecotonal zones. In dense mono-specific communities, canopy cover is often closed and there is limited understorey vegetation and the substrate is covered in leaf litter. In seasonal tree swamps in depressional areas within the bauxite plateau, canopy density is more variable and often includes open areas in the deeper central basin of the swamp and on the seasonally exposed outer margins. These open areas usually support emergent and aquatic macrophyte communities (discussed below). Transitioning from the deeper more permanently inundated areas of such swamps toward the upland margins, the sequence of *Melaleuca* species encountered includes *M. quinquenervia, M. symphyocarpa, M. leucadendra, M. viridiflora,* and *M. dealbata*. Other species that may be co-dominant in these tree swamps include *Lophostemon suaveolens* and *Calycopeplus casuarinoides. Livistona muelleri* is also often present on the upper margins of these tree swamps.

8.6.1.4 Drainage depression and Flood runner woodlands

These communities occur in association with the seasonal aquatic habitats created by wet season flooding and surface runoff and are also maintained post wet season by groundwater discharge and seepage. The boundaries of drainage depressions are demarcated by a transition from the Darwin Stringybark *Eucalyptus tetrodonta* woodland to *Banksia dentata* and *Lophostemon suaveolens* dominated woodland. Where these drainage depressions sustain flows for a greater proportion of the dry season, overstorey riparian vegetation trends more toward a swamp forest community and includes *M. symphyocarpa* and False Casuarina *Calycopeplus casuarinoides.* Equivalent vegetation communities are observed in flood runner habitats with the addition of more closed forest community representatives, e.g. *Syzygium suborbiculare* and *Carallia brachiata*, and alluvial levee associated eucalypts, e.g. *Eucalyptus brassiana* and *E. polycarpa.* Understorey vegetation in these habitats is also very similar, with a dominance of sedges *Cyperus spp.* and semi-aquatic grasses. Drainage depressions that have sustained dry season flows have a more developed aquatic macrophyte community dominated by emergent species (discussed below). Algal films and charophyte algae beds are also conspicuous in these habitats.

8.6.1.5 Mangrove Communities

The composition, distribution and extent of mangrove communities are associated with biophysical features of the intertidal environment including salinity, nutrient availability, oxygen levels in soil, and wave energy (Lovelock 1993). In the Archer Bay Aggregation, which includes the Ward River estuary, Blackman *et al.* (1999) noted that Spotted (= Red) mangrove *R. stylosa* dominated mangrove communities commonly occur along the lower tidal reaches of the rivers and creeks entering the estuaries and that only a few small patches grow along the main tributary stream of the Archer River due to the high volume of freshwater it carries. They also observed that on the landward side of the mangroves Yellow mangrove *Ceriops spp.* and Grey mangrove *Avicennia marina* var. *eucalyptoides* become dominant and the forest lower.

Other species previously recorded in these mangrove communities include Holly mangrove *Acanthus ilicifolus,* Kapok mangrove *Camptostemon schultzii*, Black mangrove *Lumnitzera racemosa*, Blind Your Eye *Excoecaria agallocha*, Wrinkle pod mangrove *Cynometra iripa,* Cannonball mangroves *Xylocarpus granatum*, *X. australasicus,* River mangrove *Aegiceras corniculatum*, Club mangrove *Aegialitis annulata*, Large-fruited orange mangrove *Bruguiera gymnorhiza,* Small leafed orange mangrove *B. parvifolia, B.cylindrica, B. sexangula,* Yellow mangroves *Ceriops decandra, C. tagal,* and Tall stilted mangrove *R. apiculata* (Blackman *et al*. 1999, Saenger 1982*).*

A total of 19 mangrove species was recorded during May 2009 surveys (**Table 8-4** and **Table 8-5**) including 4 species not recorded by previous surveys (Freshwater *Caralia braciata*, Mangrove Apple *Sonneratia alba*, Myrtle *Osbornia octodonta* and Looking Glass *Heritiera littoralis*). Five previously recorded species were not observed during current investigations including *Ceriops decandra, Xylocarpus australasicus, Aegialitis annulata, Bruguiera cylindrica* and *B. sexangula.*

Thirteen species of mangroves were recorded from Ward River sites and 18 species from Norman Creek sites. The greater diversity recorded in the Norman Creek estuary could be associated with greater sampling effort (10 versus 5 sites), broader range of sampling locations (uppermost tidal to estuary mouth c/f uppermost tidal to mid estuary) and/or intrinsically greater mangrove species diversity in Norman Creek in comparison to the Ward River estuary. The maximum number of mangrove species found at any one site (9) was equivalent for both systems.

Survey results indicated some broad compositional shifts from upper to lower estuary sites including an increased dominance of Red, River and Grey mangroves in lower estuary sites and an increased occurrence of Mangrove Fern, Wrinkle Pod and Cannonball mangroves in upper estuary areas. Many other species occurrence in upper or lower estuary sites was consistent with published salinity/estuarine zonal preferences (Lovelock 1993), but did not occur at a sufficient number of sites to draw such conclusions from survey observations alone. Recognised upper estuary / freshwater influenced species include Holly, Large-fruited orange, Cottonwood, Tall stilted and Looking glass mangroves. Lower estuary / higher salinity preferring species include Yellow, Black and Myrtle mangroves.

However, survey observations also indicated that site scale variations in salinity and tidal regime exposure associated with lateral inflows of freshwater and location in relation to bank/levee height, often generated local mangrove community zonation that served to mask broader scale compositional changes that may have been associated with site location within the broader estuary.

At the time of the May 2009 survey, freshwater influences on the mangrove ecosystems were readily apparent in terms of the freshwater salinities recorded from main channels of the upper estuaries and the open bodies of freshwater, with freshwater macrophyte and emergent plant communities observed in back levee sites behind mangrove forests fringing tidal main channels. Some of the species observed to occur on these freshwater swamp margins (e.g. Black Mangrove) are characteristic of higher salinity settings and indicate that in the absence of freshwater bodies being present, high spring tides must inundate these back levee sites. Emergent paperbark trees *Melaleuca spp*., indicative of freshwater seepage, also occurred at many mangrove survey sites including mid and lower estuaries. At one site in the Norman Creek estuary (Site 8), groundwater macro pores were observed discharging through the stream bed.

To identify high salinity constraints on mangrove community composition, conditions during the dry season, saline phase of the estuary need to be examined. Dry season observations (December 2008) in the Ward River estuary indicate that groundwater discharges continue to mitigate salinity levels in the uppermost Ward River estuary system into the late dry , albeit in the absence of surface freshwater flows. However, dry season observations (December 2008) in the Norman Creek estuary indicate that the upper Norman estuary continues to receive some surface flow presumably in addition to groundwater inputs.

Table 8-4 Ward River Mangrove Species Surveyed in May 2009

Species	MW1 (Upper Estuary)	MW2	MW3	MW4	MW5 (Mid Estuary)
Red *Rhizophora stylosa*	X – Isolated individuals and stands on stream margin	X – Dominant mangrove isolated stands on stream margin	X – Dominant mangrove semi continuous band on both banks	X – Dominant mangrove on stream margin	X – Dominant mangrove semi continuous band on both banks
Large-fruited Orange *Bruguiera gymnorrhiza*	X – Isolated individuals on stream margin	X – Isolated individuals on stream margin	X – Isolated individuals north bank forest band	X – Isolated individuals on stream margin	X – Isolated individuals in riparian forest band
Small Leafed Orange *Bruguiera parviflora*	—	—	X – Isolated individuals north bank forest band	—	X – Isolated individuals in riparian forest band
Blind Your Eye *Excoecaria agallocha*	X – Isolated individuals on stream margin	X – Isolated individuals on stream margin	X – Isolated individuals north bank forest band	X – Isolated individuals on stream margin	X – Tall individuals emergent in riparian forest band
River *Aegiceras corniculatum*	—	—	X – Sub-dominant mangrove on both banks	X – Sub-dominant mangrove forming thicket behind water margin	X – Isolated stands behind stream margin

Note: "X" indicates positive record of species presence.

The greater perenniality/dominance of freshwater inputs to the Norman Creek estuary is reflected in the mangrove communities of that system in that Cannonball Mangrove, a species characteristic of freshwater reaches of estuaries in the Wet Tropics of north Queensland, is a dominant species in mid upper reaches (Sites MN7-9). This species was not recorded from Ward River sites. The fact that Red mangrove, a species associated with higher salinities, was recorded at all sites to the uppermost estuarine reaches of both systems suggests that salinity regimes in both upper estuarine systems undergo a major swing to a saline phase during the dry season and also that the dominance of freshwater associated Cannonball mangrove in the mid upper reaches of the Norman may be associated with local inflows / seepages of freshwater.

Approximately 400m^2 of mangroves would be removed to construct the Hey River barge/ferry terminal (refer **Section 6.3.3).** At this location there is a narrow band of low-growing mangroves fringing the high tide zone. The mangrove species in the Hey River estuary include:

- *Rhizophora stylosa* (Red Mangrove);
- *Bruguiera gymnorhiza* (Large-fruited Orange Mangrove);
- *Avicennia marina* (Grey Mangrove); and
- *Aegiceras corniculatum* (River Mangrove).

8.6.2 Freshwater and Estuarine Aquatic Plants Communities

In-stream aquatic macrophytes are uncommon and sparse throughout much of the Project area stream network due to shading by closed riparian forests, generally nutrient poor water, leaf litter dominated substrates and high discharge rates. Sparse aquatic plants communities observed at a few perennial stream sites (mainly Site 14A, Site 25A and Site 2A) were predominantly emergent species and included *Eriocaulon setaceum, Limnophila brownie, Nymphoides geminate, Cyperus trinervis* and Sprawling Twig Rush *Dapsilanthus elatior.* The latter is also a common emergent species on elevated stream banks.

The most developed submerged aquatic plant communities occurred in the lower reaches of the perennial streams where channels are broader and host sunlit pools and lagoons with low flow velocities (i.e. the lowermost freshwater reaches of Norman Creek), in seasonal streams with open riparian vegetation and larger open pools (e.g. Winda Winda Creek) and in the seasonal and permanent coastal lake systems.

In the lowermost flowing freshwater reaches of Norman Creek, *Eriocaulon setaceum* and *Blyxa sp.* formed dense mixed submerged beds along bank margins. Dense *Blyxa sp.* beds co-dominant with Water Snowflake *Nymphoides indica* were also observed in the lowermost reaches of the Winda Winda Creek system in areas that had bank vegetation dominated by mangrove vegetation, indicating the sustained post wet season dominance of freshwater discharge within this upper estuarine system. An equivalent macrophyte community was also observed in nearby seasonal lake systems that are seasonally subject to significant inputs of freshwater flows.

The open canopied upper reaches of the seasonal Winda Winda Creek system had one of the most diverse in-stream aquatic macrophyte communities including submerged and emergent beds of *Eriocaulon setaceum*; submerged beds of Water Ribbon *Triglochin multifructum, Cyperus trinervis* and *Blyxa aubertii*; floating beds of Water Snowflake *Nymphoides indica* and Entire Marshwort *N. germinata*; and emergent fringing communities of *Cyperus spp.* Perennial coastal lakes contained a less diverse macrophyte community dominated by Water Snowflake *Nymphoides indica* and marginal beds of emergent spike rushes *E. dulcis* and E. *sundaica.*

Emergent mono specific beds of 'Bulkuru' spike rush *E. dulcis* form one of the most extensive aquatic macrophyte communities in the study area occurring in brackish floodplain areas adjoining the lower reaches of most of the major drainage systems. The brackish salinity regime preferred by these communities appears to be at least partially maintained by groundwater seepage emanating from the toe of adjoining bauxite uplands and, as noted in the

habitat section above, significant ecological values are associated with these spike rush swamps.

Emergent macrophyte species are also the dominant aquatic plants in tree swamps within the bauxite plateau. Deeper central basin areas support spike rush *E. sundaica* stands while bank margins exposed by receding water levels have a "wet meadow" community comprising *Eriocaulon depressum, Cyperus spp., Sclhoenoplectus sp.*, Frogsmouth *Philydrum lanuginosum* and Sprawling Twig Rush *Dapsilanthus elatior*. This "wet meadow" community also occurs within drainage depression areas that retain post wet season flows (e.g. Site 19) with the addition of *Eriocaulon setaceum* and *Cyperus trinervis* in areas exposed to flow.

8.6.2.1 Algae

Filamentous algal films and charophyte algae beds occur throughout freshwater habitats of SoE, although only in rare scattered occurrences in stream reaches with closed riparian forest canopies, forming swaying filamentous clumps in sunlit riffles and cauliflorous beds on the margins of sunlit pools. Submerged aquatic plants are also commonly coated in algal films, particularly in sunlit areas with low flows. In broad sunlit lower catchment stream reaches channels beds are covered with dense stands of both filamentous and cauliflorous charophyte. Similar beds of charophyte algae were also observed during aerial flyovers of coastal lake habitats. Collectively, the biomass produced by these lower catchment algae beds represents a significant source of primary production within these generally nutrient poor systems and is likely to constitute an important foundation of the food chain within these reaches and receiving estuarine ecosystems downstream.

8.6.2.2 Estuarine Seagrass Communities

Extensive seagrass communities including the species *Halophila decipiens, H. ovalis, Halodule uninervis* and *H. pinifolia* are a noted feature of the lower estuaries of the Archer Bay Aggregation, which includes the Ward River estuary (Blackman *et al.* 1999, Bucher and Saenger 1989; Poiner *et al.* 1987). During the current study, estuarine seagrass beds were first observed within the Project area at Norman Creek during water quality investigations in August 2007 and subsequently in the Ward River during December 2008 estuary scoping investigations and in both systems during the February 2009 estuarine water quality sampling program. Given the ecological importance afforded seagrass habitats and their vulnerability to water quality and flow impacts associated with catchment development (Coles *et al.* 2004), formal seagrass surveys and sampling to characterise the seagrass communities and gain baseline data was conducted in May 2009. The objective of surveys was to characterise the estuarine seagrass communities in terms of abundance, diversity and extent within the estuaries as a basis for identifying their broader ecosystem values. An attempt was also made to identify habitat controls such as depth, substrate type and water quality on the distribution and abundance of observed seagrass beds.

Three species of seagrass were recorded by observations preceding the formal surveys: *Halophila ovalis, Halodule pinifolia,* and *Enhalus acoroides* (the latter only in Norman Creek). However, only *Halodule pinifolia* was recorded during surveys of the Ward River and Norman Creek estuary in May 2009.

In the Ward River, seagrass sampling was focussed in the lower estuary within the "Ward Lake" (seagrass Sites SSW1–SSW5) following visual observations and invertebrate grab sampling at upstream sites that indicated that seagrass distribution did not extend upstream of this reach. Two of the sampled intertidal flat sites within the upstream section of the Ward Lake reach (SSW4 and SSW5) also lacked seagrass. Quadrant transects across exposed intertidal flats conducted during low tide in the lower Ward Lake (SSW1–3) established that seagrass occurred patchily on exposed sand bars with cover ranging from 2–65% (average 34%) at Site SSW1, 5–100% (average 56%) at Site SSW2 and 0–40% (average 7%) at Site SSW3. Site SSW3 lies to the north of the main channel in Ward Lake in a shallow backwater area and appeared to have finer grained silty sediment which was readily resuspended by wave action when inundated, possibly imposing a constraint on seagrass bed development. At Sites SSW1 and SSW2 the wet margin areas of exposed beds that were dominated by coarser shell grit sediment, indicative of

higher flow velocities when inundated, also lacked seagrass cover. Cross channel profile grab sampling at these sites indicated that seagrass did not occur in active tidal channels or at depths >1.5m. As reflected in the surveys of the exposed tidal flats, abundance and cover was greatest in the southern sampled portion of the Ward Lake in mid depth areas, not on the central channel but in broad shallow channel areas that experienced good tidal exchange and had sandy grain size substrate (e.g. Site SSW2).

In the Norman Creek estuary seagrass was also patchily distributed and primarily restricted to shallow intertidal flats, most of which occurred on the main channel margins. Seagrass density on sand bars exposed during low tide was generally lower than that observed in the Ward estuary; i.e. from 0–40% (average 5%) at Site SSN1, 0–35% (average 6%) at Site SSN2, 0–30% (average 4%) at Site SSN3 and 0–60% (average 9%) at Site SSN4. On exposed sand bars seagrass cover was greatest in depressions and tidal drainages particularly near mangrove littoral margins that did not dry out during low tide exposure. Grab sampling of central main channel areas indicated hard clay, coarse shell grit or lateritic rock bottom with no seagrass.

Seagrass did occur at two submerged (0.5–1m depth) mid channel sites in the Norman Creek estuary (SSN5 & SSN6) where estimated cover was much greater (~70%) than observed on exposed marginal sand bars. At one of these sites (SSN5) grab sampling produced abundant catches of marine polychaete worms that inhabited the substrate bound by seagrass roots. Both these sites occurred in areas where the estuary channel broadened and shallowed providing greater incident light, lower flow velocities and sandy substrates apparently preferred by *Halodule pinifolia.* Site SSN6 was analogous, albeit smaller sized, to the Ward Lake in that it represented a broad sedimentary basin. No seagrass was recorded upstream of this "Norman Lake" site. Sampling at Site SSN7 indicated fine mud substrate and no seagrass. Dry season observations in the Norman Creek estuary in the vicinity of Site SSN4 have indicated that beds of a taller, broader leaved species *Enhalus acoroides* were established at that time.

The biomass and diversity of seagrass communities is recognised to vary seasonally with the maximum abundance often being obtained late in the dry season (October–December) following months of clear skies, increasing day length and rising temperatures that provide optimal conditions for growth (Coles *et al.* 2004). Summer (wet season) freshwater flows and runoff are known to reduce seagrass abundance.

Seagrass sampling conducted during May 2009 therefore only represents a snapshot of the status of estuarine seagrass communities during the latter stages of the freshwater phase of the estuaries at a time when they are likely to be undergoing recolonisation following the wet season. Seagrass abundance, diversity and overall community extent would be expected to be more developed late in the dry season. Observations on exposed sand bars in the lower Ward River estuary in December 2008 support this as apparently denser seagrass cover, comprising two seagrass species *Halophila ovalis, Halodule pinifolia* was observed, and up to 1m broad flotsam bands of accumulated uprooted *Halodule pinifolia* were also observed in the prop roots of fringing mangrove forest. The observation of Dugong feeding trails within seagrass beds made at this time, but not in May 2009, also suggests that seasonal seagrass abundance and utilisation by herbivores is greatest in the dry season. Green Turtles observed in the Lake reach of the Ward estuary and reported by Traditional Owners to have been captured there are also likely to be feeding on *Halophila ovalis* and *Halodule pinifolia* beds, both of which are preferred food species for Dugong and Green Turtles (Coles *et al.* 2004).

In addition to the value seagrass has as food for fauna such as Dugong and Green turtles, seagrass beds are also recognised to provide important fishery nursery habitats and play key roles in binding sediment, controlling turbidity and in the uptake of nutrients (Coles *et al.* 2004). Although seagrass beds occupied only a limited extent of the Ward River and Norman Creek estuaries at the time they were surveyed, available evidence indicates that they represent an important component of the estuarine ecosystems of the study area and that they would be more extensive during the dry season saline phase of the estuary, due to reduced freshwater inputs.

8.7 Fish and Crustacean Community

8.7.1 Fish Diversity and Community Composition

The methods used to determine the composition and diversity of the fish and crustacean communities within the Project area are summarised in **Section 8.3**. A total of 45 species of fish was recorded from the study area from combined field sampling conducted during May 2008 and 2009. Details of recorded species numbers are summarised by site in **Table 8-6** and by species in **Table 8-7.**

Twenty one (21) species were recorded only from estuarine sites and 10 species from freshwater sites. Fourteen (14) species were recorded from both estuarine and freshwater sampling sites, highlighting the broad salinity tolerances of these species and the prevalence of fish with life history strategies that involve utilisation of both freshwater and estuarine habitat types. Other than visual observations recorded at other times, fish sampling was conducted in May 2008 and 2009. Seasonal variability in fish communities, particularly those associated with the saline dry season phase of estuaries, may not be reflected in sampling results.

The Ward River catchment, the largest of those sampled, had the most diverse fish community with 34 species recorded including 27 from estuarine sites and 16 from freshwater sites. A near equivalent 32 fish species were recorded from the Norman Creek catchment including 24 from estuarine sites and 15 from freshwater sites. Lower numbers of species were recorded from smaller catchments including 18 from Winda Winda Creek (9 from estuarine sites and 9 from freshwater sites), 8 from Ina Creek (6 from estuarine sites, 3 from freshwater sites), 6 from Pera Head Lagoon (a brackish site) and 1 from an isolated tree swamp in the Hey River catchment. Lower species numbers recorded in smaller catchments particularly for estuaries would also reflect less sampling effort expended there.

The proportionally dominant species by sample catch numbers and biomass from freshwater and estuarine sites in each of the three main catchments of the study area are illustrated in **Figure 8-4** to **Figure 8-7**.

Catches from most freshwater sites were numerically dominated by small to medium sized species including rainbowfish (two species), Eel-tailed Catfish (two species), Mouth Almighty and Sailfin Glassfish. Distinctions in the relative dominance and dominance priority of species were observed between catchments. Black-banded Rainbowfish were most common at flowing sites and dominated catches numerically within the semi-perennial to perennial reaches of the Norman Creek catchment. They were absent from the more seasonal Winda Winda Creek system and co-dominant with Chequered Rainbowfish in the freshwater reaches of the Ward River catchment. Sailfin Glassfish, which have a preference for aquatic plant habitats, were the second most numerically dominant species in the Winda Winda Creek system and a prominent component of the catch from Ward River freshwater sites, but were absent from all but the lowermost reaches of Norman Creek.

Other than Tarpon, larger bodied species, including those with estuarine affinities or life history requirements, were largely absent in catches from freshwater sites in the Winda Winda and Norman Creek catchments but were prominent both numerically and in terms of biomass in the lower freshwater reaches of the larger Ward River system. Archerfish dominated freshwater riverine sites in the Ward River, representing more than a third of catch numbers and biomass. Longtom were also prevalent numerically at these sites while large bodied Shovel-nosed Catfish and Barramundi comprised 31 and 21% of catch biomass respectively. While the predominance of larger bodied fish records within the Ward River reflects the larger size of that river system, the absence of these species in Norman Creek freshwater catch data was partially an artefact of sampling site accessibility as most of those species were visually observed (albeit in low densities) in the lowermost freshwater reaches of Norman Creek in areas that were inaccessible with sampling equipment. Many (but not all) of the observed fish community compositional distinctions can be readily explained in terms of the habitat affinities of individual species and the habitat suite available within individual catchments discussed in **Section 8.7.3**.

Note: "X" indicates positive record of species presence.

The study area's estuarine fish catch also exhibited unique compositional features and distinctions between sites and catchments.

The combined catch from all three (upper, mid and lower) Ward River estuarine sites were dominated both numerically and in terms of biomass by Archerfish (46% & 39% respectively), a typically freshwater species that also dominated catches in the lower freshwater reaches of the system. Note that at the time of sampling in May 2009, the salinity in the estuarine sites in the Ward River was low (e.g. Site WP8) at sites upstream of the Ward Lake area.

Archerfish, mullet (two species) and Bony Bream comprised more than two thirds of the Ward estuarine fish catch numerically and these species in combination with other larger bodied freshwater associated species, Barramundi and Fork-tailed catfish (two species) comprised 86% of the catch biomass of combined Ward River estuarine samples. The capture of large Black catfish *Neosilurus ater*, a typically freshwater species, within the mangrove fringes of the middle estuary site (29) in the Ward River highlights the "fresh" characteristics of the Ward estuary at the time of sampling.

In comparison to the Ward River, the estuarine catch from Norman Creek was numerically more dominated by typically estuarine and marine species including Silverbiddy, Queenfish and Scats. Of the 22 fish species recorded from Norman Creek estuary sites, 13 were recorded only from estuary sites and of these 9 could be considered marine species not capable of inhabiting lower reach freshwater habitats. Of the 27 fish species recorded from Ward River estuary sites, 16 were recorded only from estuary sites but of these only 4 could be considered marine species not capable of inhabiting lower reach freshwater habitats (**Table 8-6**). The prevalence of freshwater adapted species within the Ward and Norman estuaries is indicative of the influence of freshwater flows within these estuarine ecosystems which extended post-wet season, at least until the main sampling periods of May 2008 and 2009.

The greater proportion of strictly marine species recorded in the Norman Creek estuary was potentially related to the proximity of the main estuarine sampling site to the mouth of the system, and the amount of tidal exchange that occurs within that sampling reach. In comparison, the three estuarine sampling sites within the Ward River all occurred upstream of the expansive, shallow Ward River "Lake" which retards tidal ingress and may lead to a greater dominance by freshwater flows upstream of this point, particularly during active catchment discharges post wet season.

While the Embley River to the immediate north of the study area is characterised by a diverse chondrichthyan (shark and ray) fish fauna (Barletta and Blaber 2007), no sharks or rays were captured in the study area, although stingray impressions were observed on exposed sand bars in lower estuary areas and Cowtailed Rays were observed in the Norman Creek and Ward River lake areas. This result could be partially related to the deployment of gill nets only during daylight hours, to prevent crocodile entanglement. Sharks are more typically captured at night in gill nets, though the complete lack of shark captures would appear to be at least indicative of a genuine low abundance of shark species, several of which were recorded within the upper reaches of the adjoining Embley River estuary (Blaber *et al.* 1990b).

Although fish sampling conducted within the study area could not be considered exhaustive, results suggest that fish communities present were depauperate in comparison to the species diversity recorded from adjoining catchments and estuaries in the Western Cape region. Blaber *et al.* (1990b) recorded a total of 197 species from the adjoining Embley River estuary in the north of the study area including 56 species from upper estuary sites alone. Fish survey results compiled within the North Australian Freshwater Fish Atlas <http://www.jcu.edu.au/vhosts/actfr/Projects/FishAtlas/Index.htm> show freshwater fish species for the Embley River catchment, 45 freshwater fish species from the Archer River catchment which joins the Ward River at its mouth, and 62 freshwater fish species from the Wenlock River catchment which adjoins the Embley River catchment to the north. Comparisons with these regional fish faunas and possible reasons for the lower species diversity observed within the study area are discussed further in **Section 8.7.4**.

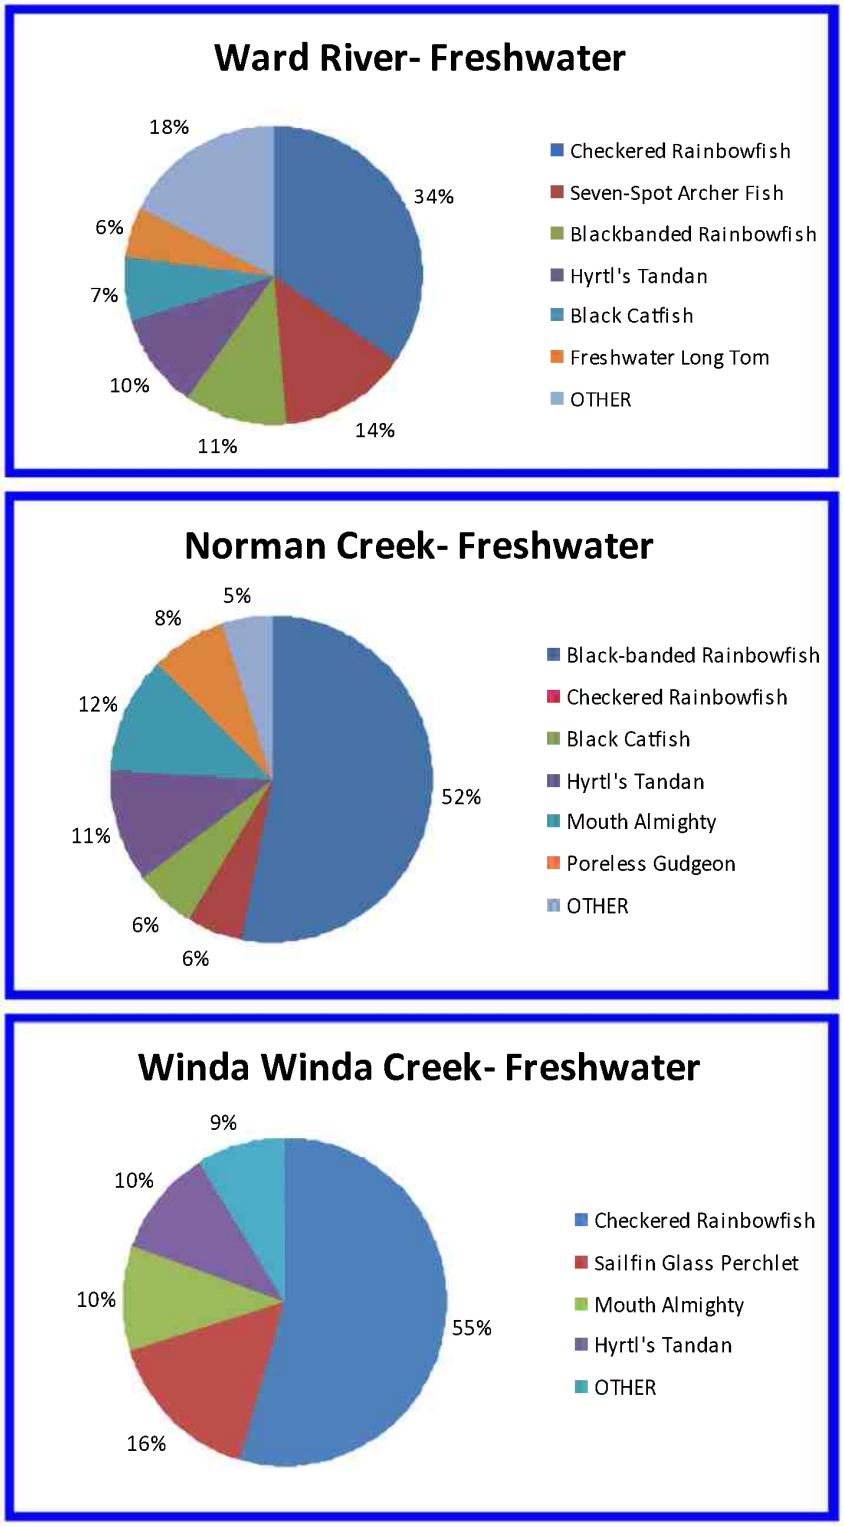

Figure 8-4 Composition of Freshwater Fish Catch from Main Catchments by Numbers

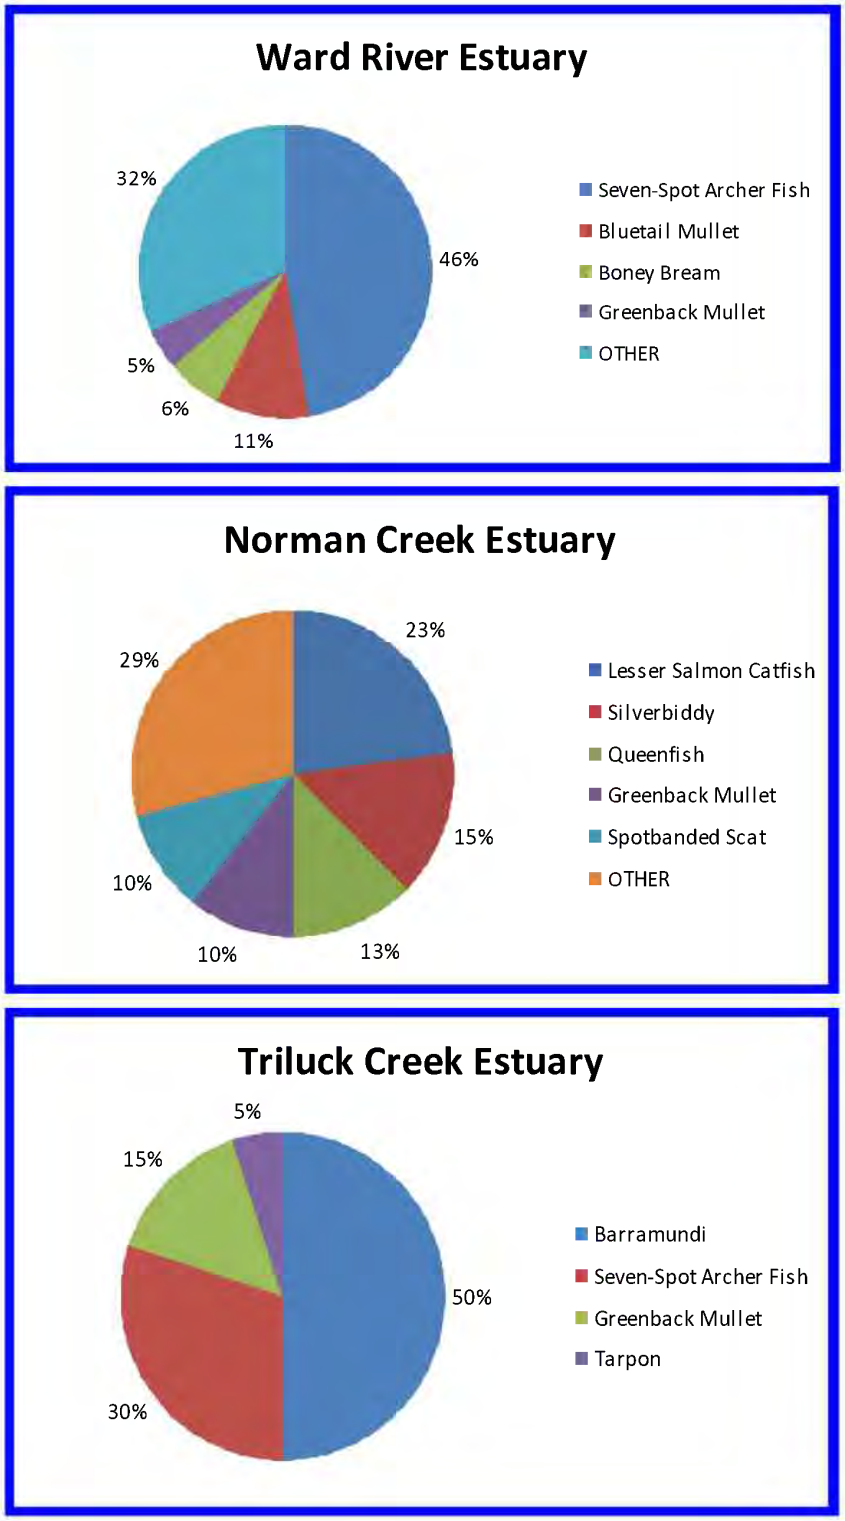

Figure 8-5 Composition of Estuarine Fish Catch from Main Catchments by Numbers

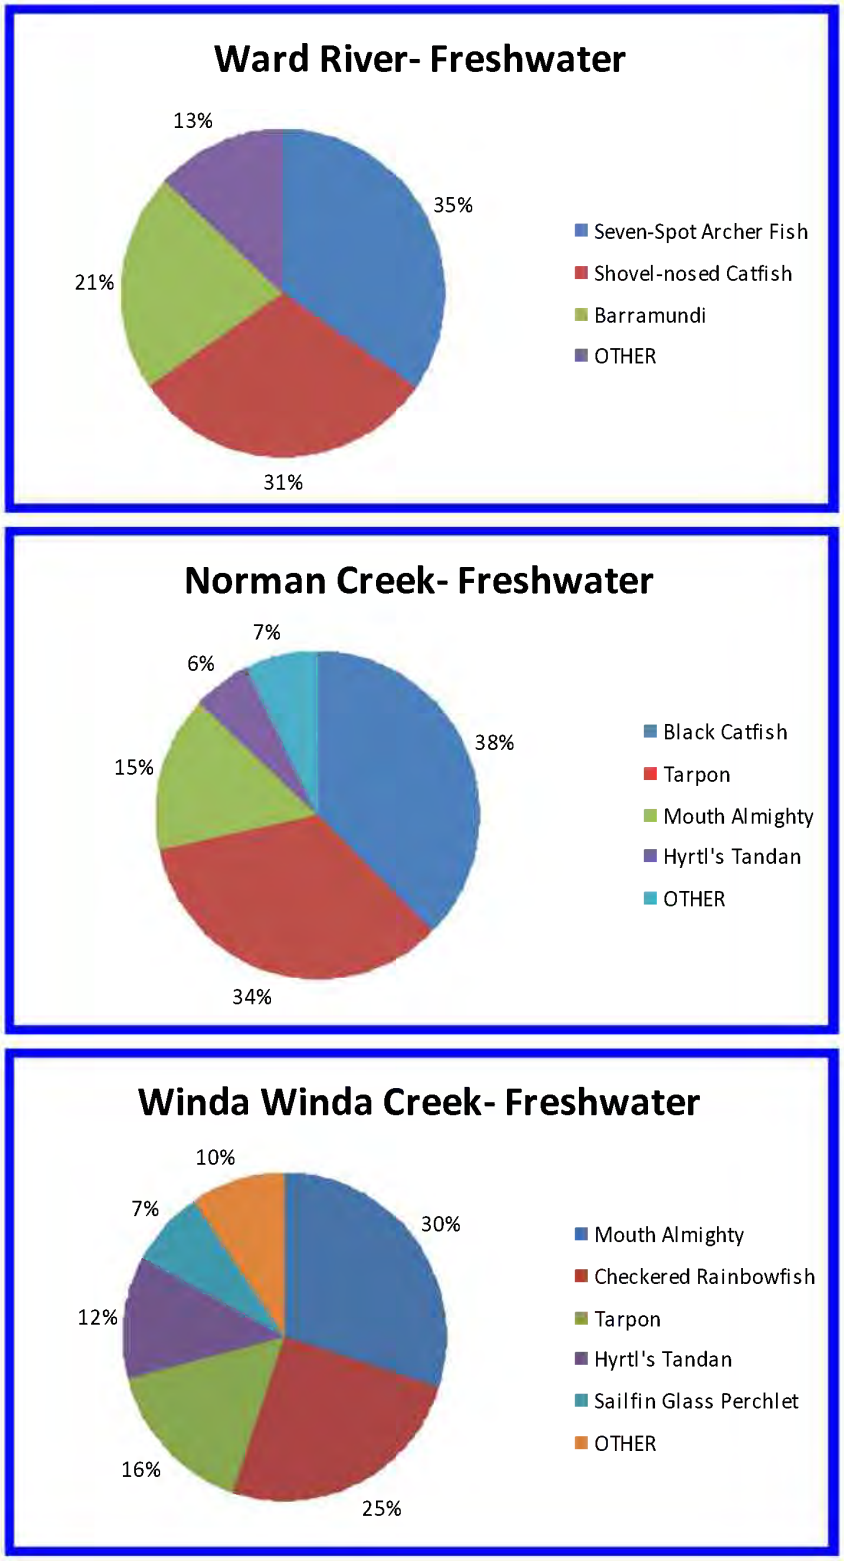

Figure 8-6 Composition of Freshwater Fish Catch from Main Catchments by Biomass

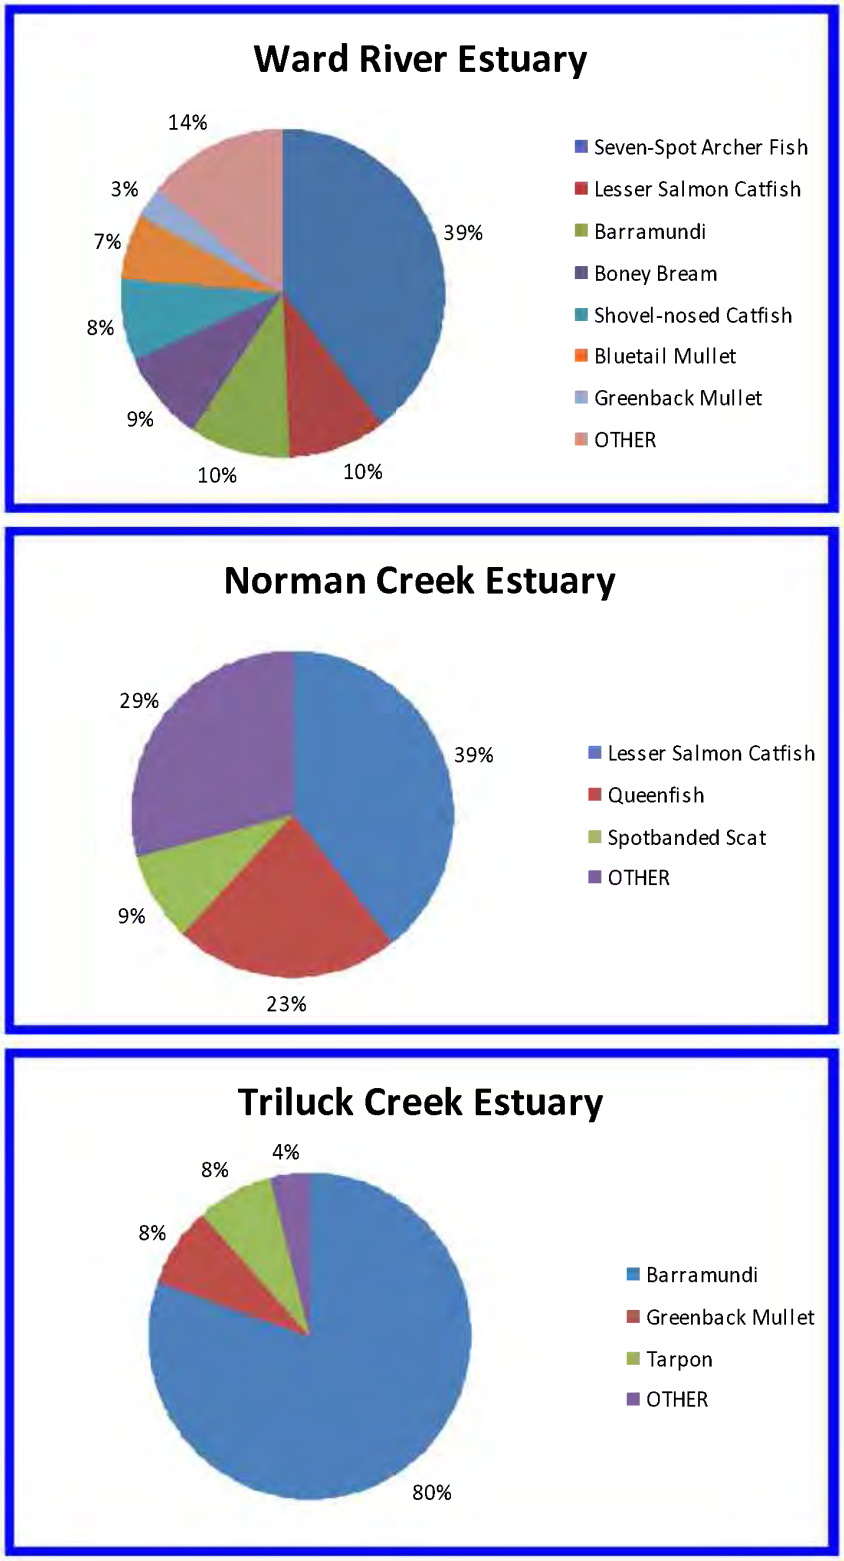

Figure 8-7 Composition of Estuarine Fish Catch from Main Catchments by Biomass

Low species diversity notwithstanding, the survey results, including visual observations and opportunistic angling, indicated a productive fish fauna within the study area including a

substantial biomass of species of importance to recreational, commercial and indigenous fisheries. Several of these species including Barramundi, Mangrove Jack, Fork-tailed Catfish and Archerfish predominantly occurred in the mid and upper estuary and lowermost fresh reaches of surveyed catchments. Large feeding schools of these species were commonly observed in all three catchments in association with drainage confluences from adjoining floodplain swamps. The productivity linkage between these swamps and the estuarine ecosystems is a significant feature of the trophic ecology of the study area's aquatic ecosystems.

8.7.2 Crustacean Catch

Sampling of freshwater sites in May 2008 and 2009 produced a total catch of 360 crustaceans from six species (two each of crayfish, crabs and prawns) with a maximum of three species per site. Details of the catch are summarised by site in **Table 8-8**. Abundances of crustaceans were highest at Winda Winda Creek Site 9A (3 species – Unidentified Freshwater Crab, Swamp Crayfish and Freshwater Prawn *M. rosenbergii*) and Pera Head Lagoon Site 16A (two species – Swamp crayfish, Freshwater Prawn *M. idea*), the former an open seasonal stream with diverse habitats and the latter a coastal lagoon only seasonally occupied by fish. Recorded catch biomass generally reflects specimen abundance. Larger bodied Red Claw Crayfish *Cherax quadricarinatus* dominated crustacean catches from the Norman Creek sites, which also recorded Swamp Crayfish and Freshwater Prawn *M. rosenbergii.* Red Claw Crayfish *Cherax quadricarinatus* were also present in Coconut Creek, though at lower abundances, with Swamp Crayfish *Cherax rhynchotus* subdominant at that site. The Freshwater Prawn *Macrobrachium rosenbergii* was found in all catchments and also in an isolated tree swamp (Site 27) although mostly in lower reaches and in low abundances. An isolated drying tree swamp in the Boyd Bay area (Site 35) was the only site that recorded an abundant population of Freshwater Crab *Austrothelphusa raceki*.

Despite locally dense populations of some crustacean species, particularly Swamp Crayfish, at a few sites, a generally low abundance of crustaceans characterised most freshwater sites (refer **Table 8-9**). A conspicuous absence of families and species usually ubiquitous in tropical freshwaters of northern Australia (i.e. Freshwater Shrimp *Caradina* species and Freshwater Prawn *Macrobrachium australiaense*) is also notable. It is possible the very low conductivity and softness of the study area's freshwaters impose physiological constraints on many crustaceans. Swamp Crayfish *Cherax rhynchotus* were often observed to have a non-rigid exoskeleton, possibly associated with the low availability of calcium in freshwater habitats of the study area.

Although locally abundant at some sites within the Project area, both Swamp Crayfish *Cherax rhynchotus* and the Freshwater Crab *Austrothelphusa raceki* have restricted distributions in a northern Australia context. Swamp crayfish *Cherax rhynchotus* is restricted to northern Cape York and Badu Island, Torres Strait. In the Project area it is largely restricted to bauxite plateau habitats, being replaced by Red Claw Crayfish *Cherax quadricarinatus* in other areas. The Freshwater Crab *Austrothelphusa raceki* is restricted to the area between the Archer and Wenlock Rivers in western Cape York, with an apparently isolated population near Port Stewart on the east coast. The western population appears to be largely restricted to bauxite plateaux. It was recorded from only Site 35 within the Project area.

An unidentified species of Freshwater Crab *Austrothelphusa* sp. first recorded in 2008 from Winda Winda Creek (Site 9A) has been assessed by the Queensland Museum as possibly representing a new undescribed species (P. Davie Pers. Comm.). Further survey work in 2009 extended the species recorded range beyond the original record site to upstream and downstream locations (Site 33 and Site 34) but not beyond the Winda Winda Creek catchment.

Standard estuarine sampling methods including baited recreational crab pots and finer meshed "opera" traps produced very small catches comprising four species of estuarine crustacea. These species included Mud crabs *Scylla serrata*, unidentified Hermit Crabs, Freshwater Prawn and Greasyback Prawn (refer **Table 8-10**). Several other unidentified crab species were observed at low densities within mangrove habitats but were apparently not attracted to baited traps set in these habitats and were not captured by other methods. Unidentified Mysid shrimps were also observed but not captured in a tidal interface swamp (Site 13) in the mid estuary of Norman Creek.

Table 8-9 Distribution of Freshwater and Estuarine Crustacean Species at SoE Catchments and Sites

	30	*Penaeus ensis*	Greasyback Prawn	1
Total				**10**

Mud Crab abundance as reflected by trap captures at estuarine sites in May 2009 appeared exceptionally low and dominated by sub adults. All of the captured Mud Crabs were smaller than the recreational minimum size limit of 150 mm carapace width. This contradicted expectations as a commercial Mud Crab fisher periodically operates in the lower Ward River estuary and there are anecdotal reports of recreational and Indigenous fisher catches within the Ward River and Norman Creek estuary. Mud Crab catch rates are known to be seasonal and affected by temperature and freshwater flows (Robins *et al.* 2005). As April–June is a recorded peak maturation period for tropical Australasian Mud Crab populations (Le Vay 2001), it is possible that mature crabs were not available for sampling due to moulting or off-shore migration during May 2009. Reduced estuarine abundance and displacement of adult crabs downstream by freshwater flows has been cited as having a positive influence on the recruitment of juvenile Mud Crabs due to reduced burrow competition (Robins *et al.* 2005). In contrast to the small numbers of juvenile crabs captured from upper (freshwater dominated) estuarine sites in the Ward River, no Mud Crabs were captured from the lower estuarine site in Norman Creek, suggesting salinity alone was not affecting catches and that adults were not available for other reasons, i.e. moulting or off-shore movement. The presence of juvenile Mud Crabs in the upper estuarine reaches of the Ward River, the extent and quality of intertidal Mud Crab habitat and anecdotal fishery reports would suggest that estuarine systems of the study area seasonally host substantive Mud Crab populations.

Catch per unit effort (CPUE) data for fish and crustaceans form part of the baseline monitoring dataset being held for future reference. The remainder of the discussion of fish and crustacean catches concentrates on the ecosystem composition and how that relates to potential sensitivity to mining-related impacts.

8.7.3 Habitat Affinities

An interesting finding regarding freshwater fish species diversity and distributions, gained from these survey results and experience in bauxite plateau streams in adjoining regional catchments, is that while a generally equivalent suite of aquatic habitat types is encountered in streams across these areas, fish community composition appears to vary independently of habitat availability. This suggests that biogeographic controls on species distribution and chance species extinction and recruitment events are a more significant driver of community compositional differences at the catchment scale than habitat availability. However, a number of habitat conditions common across these areas still appear to play a role in determining the make-up of the total fish community encountered across this broader geographical area. Reach and sub-catchment scale variability in habitat availability is also reflected in fish community compositional differences at these scales. Understanding these habitat affinities is important for identifying potential Project related impacts that may affect the availability or condition of preferred habitat types.

The high water clarity, low conductivity (refer **Section 5.1.4**) and sustained post wet season flow characteristics of those Project area's aquatic habitats that are fed by groundwater discharge affect the structure and functioning of the fish assemblages. Key features of the fish assemblage include a predominance of species that are visual predators, utilise visual courtship displays, have a dependence upon submerged aquatic plants (macrophytes) as egg laying habitats, and have some affinity to flowing habitats.

In stream reaches where sunlight penetration is not prevented by a riparian forest canopy, macrophyte beds are able to develop. A number of the fish species collected from the Project area have some life history dependence upon macrophyte cover, including Black-banded and Chequered Rainbowfish, Empire Gudgeon, Northern Trout Gudgeon and Mouth Almighty. Macrophyte cover is used by juvenile fish to hide from predators and, in the case of Mouth Almighty, to ambush prey. Black-banded and Chequered Rainbowfish and Sailfin Glassfish eggs are adhesive and are laid so as to attach to vegetation. The Spotted Blue-eye is also commonly associated with vegetation and other forms of cover, and deposits eggs amongst vegetation to mature (Pusey *et al*. 2004).

Macrophytes thus provide important habitat to fish in these ecosystems. However, the predominance of closed riparian forest within the Project area stream network tends to limit the development of substantive submerged macrophyte beds to more open lower reaches and seasonal steams with open riparian vegetation communities (e.g. Winda Winda Creek). This suggests that species that have some macrophyte dependence, particularly for egg laying, require access to reaches where such limited resources are available. In the case of Empire Gudgeons, which are considered to be a facultative amphidromous species (larvae dispersed to downstream estuarine reaches), utilisation of macrophyte rich lower catchment reaches as breeding and recruitment areas is consistent with this optional life history. This strategy may also be employed by Chequered Rainbowfish and Mouth Almighty which have a good capacity for intra catchment recruitment movements during wet season flows. Another strategy that is possibly employed by species that require macrophyte habitats for breeding is the utilisation of seasonally submerged terrestrial and emergent marginal vegetation during the wet season. This ties in with observations of substantial populations of Black-banded and Chequered Rainbowfish and Spotted blue-eyes, including juveniles, within the seasonal aquatic habitats occurring within the inundated margins of drainage depressions, flood runners channels and tree swamps. These species may also use tree roots as spawning sites in the absence of macrophytes. Where species are not as adaptive in terms of meeting their macrophyte habitat dependence, macrophyte habitat availability has a more significant influence on their distribution. This may explain the limited distribution of Sailfin Glassfish within the Project area, which was absent from all but the lowermost reaches of Norman Creek systems but occurred within the seasonal and macrophyte rich Winda Winda Creek and the Coconut Creek – Ward River system, which have more open riparian forest and associated development of macrophyte habitats. The submerged macrophyte habitat affinities and dependencies of these species have implications for managing potential Project related impacts such as increased turbidity and the development of hydrological or physical barriers that could reduce dependent species access to macrophyte (or equivalent) rich stream reaches.

Access to sand/gravel beds for spawning required by Hyrtle's and Black Catfishes (Orr and Milward 1984, Pusey *et al*. 2004) is another example of a potentially limited habitat resource that may require longitudinal connection to enable successful spawning.

The high water clarity of the Project area streams and swamps, with median turbidity commonly below 5NTU and below 1NTU at some sites, also enables the use of visual cues related to mating for several species. The males of the Chequered Rainbowfish perform elaborate courtship displays. Spotted Blue-eye males vigorously court females, flashing dorsal and anal fins. Empire Gudgeon males develop intense red colouring during breeding. Black Catfish change colouration during spawning runs (Pusey *et al*. 2004). Water clarity is also likely to be important in hunting/foraging activities for visual predators. Vision is often important for macroinvertebrate feeders in locating insects, and reduction in visibility could hinder feeding success.

However, all of these species are recorded (Pusey *et al.* 2004) in river catchments known to experience short-term water quality stress in terms of elevated turbidity associated with the initial catchment flushes of wet season runoff. Wet season runoff in streams of the Project area has been observed to clear rapidly following the initiation of wet season flows. Impacts to the ambient turbidity of sustained wet season and post wet season flows would present the greatest risk to these fish species and their habitats. Given the very small component of catchment rainfall that is shed as surface flow and the limited area of cleared catchment that would exist outside of controlled drainage networks, this risk is considered small.

The Project area streamflow persists for variable lengths of time after the wet season, depending on the nature of the surrounding seasonal and perennial aquifers, the topography and the extent of rainfall. One apparently flow-associated species is the Black-banded Rainbowfish which unlike many other rainbowfish has a very fusiform body shape and appears to specialise in inhabiting and utilising shallow flowing waters. This species was common at sites that had perennial to semi-perennial flows (i.e. Norman and Coconut Creeks), but was absent from the more seasonal Winda Winda and Ina Creek systems. Such habitat affinity could make these species susceptible to impacts that affected the seasonal duration of flowing habitats within the study area.

Larger-bodied species, such as Tarpon, Fork-tailed Catfish (Ariidae) and Barramundi, prefer deep water areas with large in-stream cover such as macrophytes, logs, and bank overhangs. Tarpon and Barramundi are catadromous, requiring access to estuaries to breed and longitudinal connection from the estuary to facilitate upstream recruitment of juveniles. Observations of catfish occurrence in other small bauxite plateau streams of the broader region also suggests that they are functionally migratory, moving upstream during the wet season to utilise seasonally available resources and retreating downstream before flows subside and habitat size becomes a constraint. All these species were only found at sites that held larger deep pools and had ready access to lower estuarine or deeper riverine reaches in the lower reaches of the Ward River and Norman Creek.

8.7.4 Zoogeography and Regional Affinities

The Project area is part of the Gulf of Carpentaria drainage division (Pusey *et al.* 2004), which extends from the tip of Cape York west to Gove, NT. From around 40,000 to 12,000 years ago the Gulf of Carpentaria was isolated from the ocean and contained Lake Carpentaria, a large freshwater lake into which flowed all the river systems which now draining to the Gulf of Carpentaria (Reeves *et al.* 2008, Torgersen *et al.* 1983). Between 12,000 and 7,000 years ago sea level rise inundated Lake Carpentaria and eventually formed Torres Strait and the present Gulf shoreline (Reeves *et al.* 2008, Torgersen *et al.* 1983). This resulted in the functional isolation of the formerly contiguous freshwater biota within the river systems draining to the Gulf and reduced the opportunity for the movement and exchange of freshwater biota between them. Where a species has become locally extinct it has remained so within that catchment, unless it has been able to re-colonise from another catchment. The relatively drier conditions of the southern Gulf rivers have exacerbated this, resulting in disjunct distributions of a number of species, with populations in western Cape York and the eastern Northern Territory, but no extant populations in the southern Gulf rivers in between (Hydrobiology 2005).

Examples of species with disjunct and restricted distributions, including the Project area, are Spotted Blue-eye and Black-banded Rainbowfish. Spotted Blue-eye persists as five isolated populations in Australia, including the northern Cape York population which extends from the Project area to the Jardine River system. The nearest populations are on Arnhem Land/Groote Eylandt, the Tully–Murray floodplain and the Trans–Fly system in Papua New Guinea. While locally abundant in the Project area, Spotted Blue-eye tends to be restricted to shallow marginal habitats that are among the more vulnerable to water availability alterations. Black-banded Rainbowfish persists as three geographically separated populations in the eastern Kimberley Region, the northernmost part of the Northern Territory and Groote Eylandt, and northern Cape York/Prince of Wales Island. However, these three populations are locally abundant and spread across a number of habitat types.

The broader fish communities present in the Project area reflect the Gulf's geological history. Each drainage system has a fish assemblage that is a different subset of the species that are otherwise widespread across the broader western Cape York region. The relative isolation of each catchment is demonstrated by the local distribution of Northern Trout Gudgeon. It is absent from the Norman and Triluck–Winda Winda Creeks catchments, and was only recorded at Site 14 in Coconut Creek, despite being prolific in bauxite catchments with equivalent habitat availability to the north of Weipa. It appears local conditions in the catchments of the Project area at some time have been unfavourable for the species' survival, except in Coconut Creek. Similarly, while two species of eel-tailed catfishes were widespread in the creek systems of the Project area (Hyrtl's Tandan and Black Catfish) they have not been recorded in equivalent isolated coastal bauxite catchments of the Pine River catchment to the north.

The distributions of these species indicate that historic events in these small catchments have had a large influence on where individual species now occur. The small size of the local catchments, and their isolation from each other by topographic divides on land and the coastal seawater barrier, means that maintenance of all species within each catchment over millennial timescales is not possible in such a seasonal and inter-annually variable landscape. Chance extinction and re-colonisation events will have contributed to the current variable species distribution patterns.

Norman Creek and Coconut Creek had Poreless Gudgeons and Black-striped Rainbowfish whereas these species were not found in the Triluck – Winda Winda catchment. Several species recorded in the Ward River catchment were not recorded in the Norman Creek catchment including Shovel-nosed Catfish, Longtom and Northern Trout Gudgeon. These differences can be partially explained in terms of the particular habitat and connectivity requirements of species, habitat availability, perenniality and connectivity to larger river systems.

Winda Winda Creek has a more seasonal flow regime than Norman Creek and hence lacks species such as Black-striped Rainbowfish. The more open lagoonal habitats and greater abundance of aquatic macrophytes in Winda Winda and Coconut Creeks support the sustained presence of macrophyte dependent species such as Sailfin Glassfish, which are largely absent from all but the lowermost reaches of Norman Creek. Freshwater Longtom is primarily a species of floodplain habitats. Their occurrence in the Project area is limited to the larger Ward River system that has more extensive floodplain wetlands, has seasonal development of freshwater macrophyte beds in the estuarine zone, and is hydrologically linked to the even more extensive floodplain habitats of the Archer and Watson River systems.

Some floodplain specialists present in adjoining river basins (e.g. Saratoga) were not recorded from the study area. The generally higher site diversity recorded for Coconut Creek / Ward River freshwater sites including larger predatory Ariidae Catfish, Barramundi and floodplain specialists such as Longtom can be related to it being a larger river system, which has a more diverse range of available habitats, more substantial areas of dry season aquatic refugia and a common estuary with the still larger Watson and Archer River systems, the latter of which has one of the most diverse freshwater fish faunas in Australia.

The families and species of freshwater fish recorded from the adjoining Wenlock, Embley and Archer Rivers basins and from within the Project area are presented in **Table 8-11.** Marine or estuarine associated species (Sharks, Sawfish, Stingrays, Soles) that only enter fresh waters periodically and/or are recently derived from predominantly marine ancestors are largely absent from the Project area streams. It is postulated that these species are unlikely to occur above the proposed Dam C location on a freshwater tributary of Norman Creek. This is because of lack of suitable habitat and the very low conductivity water, which would impose a high osmoregulation cost and associated physiological stress. Further discussion on the potential for the Freshwater Sawfish and Speartooth Shark, listed under the *Environment Protection and Biodiversity Conservation Act 1999* (EPBC Act) (Cwlth), to inhabit the freshwater tributary of Norman Creek upstream of Dam C footprint is provided in **Table 8-14** and **Section 8.17**. Similar information on the EPBC Act listed Green and Dwarf Sawfishes is summarised in **Table 8-14**, **Section 6.6.4** and **Section 6.9.5**.

Freshwater fishes that are present in the larger adjoining Archer, Embley and Wenlock Rivers basins but are absent within freshwater habitats of the Project area include the Goby family (Gobiidae), the Grunter family (Terapontidae), Banded Rainbowfish *Melanotaenia trifasciata*, and Threadfin Rainbowfish *Iriatherina werneri.* Gobiide and Terapontidae are generally ubiquitous in tropical Australian River basins. However, the recorded distribution of Banded Rainbowfish and Threadfin Rainbowfish in western Cape York catchments is more variable. In addition to being absent from the Project area, these species have not been recorded in some Wenlock River sub-catchments such as Cox Creek, Arthur Creek and Nimrod Creek. These species and the Gobiidae and Terapontidae families have also not been recorded from other equivalently isolated bauxite dominated coastal catchments of the Pine River catchment in the Andoom area north of Weipa. However, some Gobies and Grunters have been recorded from Tentpole Creek, a Wenlock River sub-catchment that includes a significant area of bauxite.

Factors such as perenniality, connectivity, habitat availability and chance extinction/recruitment events appear to play a role in species distribution within the region and may limit the extent of some species. In addition, the absence of certain generally ubiquitous freshwater fish from bauxite catchments in the Project area, and the Pine River catchment, may also be related to aspects of water quality. A potential causative factor may be aluminium bioavailability and associated avoidance of, or exclusion from, these catchments. Aluminium was the only metal for which the measured concentrations in the surface waters of the Project area regularly exceeded the default ANZECC/ARMCANZ (2000) water quality trigger value of 0.8µg/L. This default trigger value is a conservative figure (refer **Section 8.5.1** and is applicable to waters with pH <6.5). The median aluminium concentrations in the Ward River and Norman Creek were 11µg/L and 22µg/L, respectively (refer **Section 5.1.4**). The median concentration of the aggregated Project area freshwater samples was 18 µg/L. Aluminium concentrations from the Wenlock, Archer and Embley Rivers are not available to enable a comparison between bauxite and non-bauxite catchments. The tolerance of aluminium by the fishes of the area and under the geochemical conditions of the surface waters of the Project area's bauxite streams is not known, and cannot be extrapolated from existing ecotoxicity databases. To determine if certain species may be exhibiting avoidance behaviour, more regional data on stream water chemistry and aluminium concentrations would be required, along with ecotoxicity data derived from regional species.

When considering the biogeographic constraints on the distribution and maintenance of fish communities within the study area and across the broader western Cape York region, it is important to recognise that these same controlling factors also operate on much smaller spatial and temporal scales in determining the distribution and maintenance of fish species within a catchment from year to year. The magnitude of wet seasons affects the perenniality of stream reaches and tree swamps and the connectivity established between them on an annual basis varies with the size of the wet season and affects species compositions between years. The relationship between bauxite plateau fish community composition, species distribution and annual hydrological events means that a mining development driven change in sub-catchment hydrology could potentially affect fish assemblages.

Table 8-11 Freshwater Fish Species Recorded from SoE Catchments and Adjoining River Basins

Family	Species	Common name	Archer River	Wenlock River	Embley River	SoE Catchments
Ambassidae	*Ambassis elongatus*	Elongate Glassfish		x	x	
	Ambassis interruptus	Long-spined Glassfish		x		
	Ambassis macleayi	Macleay's Glassfish	x	x	x	
	Denariusa bandata	Pennyfish	x	x		
	Ambassis agrammus	Sailfin Glassfish	x	x	x	x
Atherinidae	*Craterocephalus stercusmuscarum*	Fly-specked Hardyhead	x	x		
Carcharhinidae	*Carcharhinus leucas*	River Whaler		x		
Centropomidae	*Lates calcarifer*	Barramundi	x	x	x	x
Clupeidae	*Nematalosa erebi*	Bony Bream	x	x	x	x

Eleotridae	*Butis butis*	Crimson-tipped Gudgeon		x		
	Ophieleotris aporos	Snakehead Gudgeon		x	x	
	Ophiocara porocephala	Spangled Gudgeon			x	
	Oxyeleotris aruensis	Aru Gudgeon		x		
	Oxyeleotris fimbriata	Fimbriate Gudgeon	x	x		
	Oxyeleotris lineolatus	Sleepy Cod	x	x	x	
	Oxyeleotris selheimi	Giant Gudgeon	x	x		
	Mogurnda mogurnda	Northern Trout Gudgeon	x	x	x	x
	Oxyeleotris nullipora	Poreless Gudgeon	x	x	x	x
	Hypseleotris compressa	Empire Gudgeon		x	x	x
Engraulidae	*Thryssa scratchleyi*	Freshwater Anchovy	x			
Gobiidae	*Awaous acritosus*	Roman Nose Goby		x		
	Glossogobius circumspectus	Circumspect Goby			x	
	Glossogobius concavifrons	Concave Goby		x		

Family	Species	Common name	Archer River	Wenlock River	Embley River	SoE Catchments
	Glossogobius giurus	Flathead Goby	x			
	Glossogobius aureus	Golden Goby		x		
	Glossogobius sp. 1	False Celebes Goby		x	x	
	Glossogobius sp. 2	Munro's Goby		x		
	Glossogobius sp. 3	Dwarf Goby		x		
	Psammogobius biocellatus	Mangrove Goby			x	
Hemiramphidae	*Arramphus sclerolepis.*	Snub-nosed Garfish		x	x	
	Zenarchopterus novaeguineae	Fly River Garfish		x		
Lutjanidae	*Lutjanus argentimaculatus*	Mangrove Jack			x	x
Melanotaenidae	*Melanotaenia nigrans.*	Black-banded Rainbowfish	x	x	x	X
	Melanotaenia splendida inornata	Chequered Rainbowfish	x	x	x	x
	Iriatherina werneri	Threadfin Rainbowfish	x	x	x	
	Melanotaenia trifasciata	Banded Rainbowfish	x	x	x	
Megalopidae	*Megalops cyprinoides*	Tarpon	x	x	x	x
Osteoglossidae	*Scleropages jardini*	Northern Saratoga	x	x	x	
Plotosidae	*Anodontiglanis dahli*	Toothless Catfish	x			
	Porochilus obbesi	Obbes' Catfish		x		
	Porochilus rendahli	Rendahl's Catfish	x	x		
	Neosilurus ater	Black Catfish	x	x	x	x
	Neosilurus hyrtlii	Hyrtl's Tandan	x	x	x	x
Pristidae	*Pristis microdon*	Freshwater Sawfish	x	x		
Pseudomugilidae	*Pseudomugil gertrudae*	Spotted Blue-eye				
Scatophagidae	*Selenotoca multifasciata*	Banded Scat			x	x
	Selenotoca argus	Spotted Scat	x	x	x	x
Soleidae	*Brachirus salinarum*	Saltpan Sole		x		

Family	Species	Common name	Archer River	Wenlock River	Embley River	SoE Catchments
	Brachirus selheimi	Selheim's Sole		x		
Synbranchidae	*Ophisternon bengalense*	Swamp Eel	x	x	x	x
Terapontidae	*Amniataba percoides*	Barred Grunter	x	x	x	
	Hephaestus carbo	Coal Grunter	x	x	x	
	Hephaestus fuliginosus	Sooty Grunter	x	x		
	Leiopotherapon unicolor	Spangled Perch	x	x	x	
	Pingalla lorentzi	Lorentz's Grunter		x		
Toxotidae	*Toxotes jaculatrix*	Banded Archerfish	x			
	Toxotes chatareus	Seven Spot Archerfish	x	x	x	x

Presence reported in Pusey *et al.* (2004) and/or Fish Atlas of North Australia <http://www.jcu.edu.au/vhosts/actfr/Projects/FishAtlas/Index.htm>

8.8 Macroinvertebrates

8.8.1 Freshwater Abundance and Diversity

The macro-crustacea component of the stream macroinvertebrate community has been discussed in the preceding sections. The focus of other stream macroinvertebrate sampling was on qualitative assessment of presence/absence. While low macroinvertebrate abundance and diversity were recorded across all sites (**Figure 8-8**), it should be noted that quantitative assessment of abundance was not the objective of sampling. The objective of the sampling was to apply AusRIVAS methodological protocols to characterise baseline aquatic macroinvertebrate communities on the basis of the presence or absence of macro invertebrate family taxa, and in terms of ecological functioning as indicated by the proportional representation of functional feeding guilds. Macroinvertebrate community predictive and classification components of the AusRIVAS protocol were not applied as appropriate reference sites and predictive models have not been established for the Cape York region (DNRM 2001), particularly for the distinctive aquatic environments that are representative of bauxite plateau landscapes.

Site 22 (Coconut Creek tree swamp) and Site 5A (Norman Creek) recorded the lowest diversity with nine and eight taxa, respectively. The depauperate macroinvertebrate fauna reflects the very low conductivity and hardness recorded in waterbodies throughout the Project area and possibly natural mineralisation effects (refer **Section 8.15.1**). Low in-stream productivity is also influenced by the high proportion of riparian closed canopy vegetation limiting light penetration, although aquatic productivity and nutrient concentrations were moderate in tree swamp habitats such as Site 22. Riparian shading further reduces habitat availability through limited in-stream macrophyte growth. The simple substrate structure, comprising mobile sandy/gravel beds at most sites, is also likely to contribute to a reduced macroinvertebrate assemblage.

Molluscs including mussels (bivalves) and snails (gastropods) were completely absent from the Project area's freshwaters, which is likely a result of the lack of available calcium for secretion of calcium carbonate shell structures.

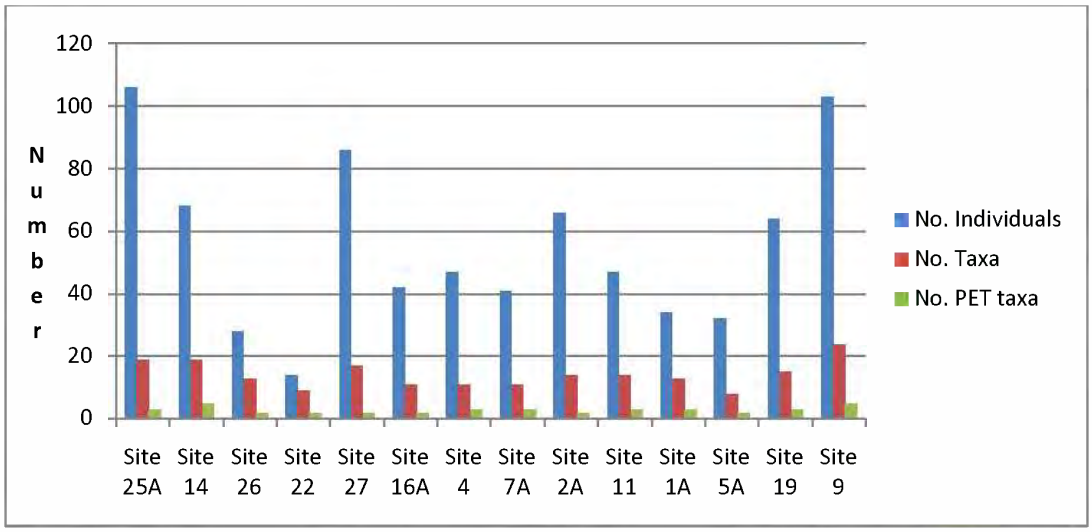

Figure 8-8 Summary of Macroinvertebrate Abundance and Family Richness and PET Taxa Richness

Taxa with external gill filaments, such as Plecoptera (Stoneflies), Ephemeroptera (Mayflies) and Trichoptera (Caddisflies) (collectively referred to as PET taxa) are sensitive to a range of pollutants. PET taxa richness generally ranged between two and three for all sites, with the

exception of Site 9 (Winda Winda Creek) and Site 14 (Coconut Creek), which each recorded five. This low PET taxa richness is also reflective of the above mentioned generally low macroinvertebrate diversity, but it is not clear which potential stressor might be the cause.

Stream Invertebrate Grade Number – Average Level (SIGNAL) is a useful method of assessing the tolerance of macroinvertebrates to pollution. However, this method was originally developed for temperate streams in south-eastern Australia to assess the impacts of sewage effluent on macroinvertebrate communities. While the method has been tested elsewhere in north-eastern Australia, it may not be directly applicable for the naturally depauperate streams that characterise the highly seasonal aquatic habitats in this region. However, the AusRIVAS-compatible data collected by this study indicated some potential disturbance sensitivity within the macro invertebrate community, particularly within seasonal stream habitats, which could have application for future catchment impact monitoring. Given the naturally low freshwater macroinvertebrate diversity and abundance in the study area, abundance weighted SIGNAL scores were calculated according to the methods described in the National River Health Manual (Chessman 2003) (**Figure 8-9**).

The scoring system developed for SIGNAL is based on ranges of impact, whereby scores >6 equate to a healthy habitat, 5–6 mild pollution, 4–5 moderate pollution, and <4 severe pollution. The streams within the Project area are in a relatively pristine state, so it is not appropriate to categorise sites based on levels of impact. Rather, sites have been categorised based on "sensitivity" to pollution, with scores >5 being very sensitive, 4–5 moderately sensitive and <4 moderately tolerant. Abundance weighted scores indicate that streams within the Project area are generally very sensitive to pollution. Sites 26 and 16A are moderately sensitive and Site 22 is moderately tolerant. The lower sensitivity at these sites is consistent with the low diversity, low PET richness (**Figure 8-7**) and high proportion of pollution tolerant predator species (**Figure 8-9**).

In terms of habitat characterisation, the moderately tolerant site (22) was an intermittent (albeit clear, seasonally spring fed) tree swamp, the moderately sensitive sites (26, 16A) were a highly seasonal stream channel and a coastal lagoon, and the very sensitive sites were stream channel and tree swamp sites with more permanent flows and water levels.

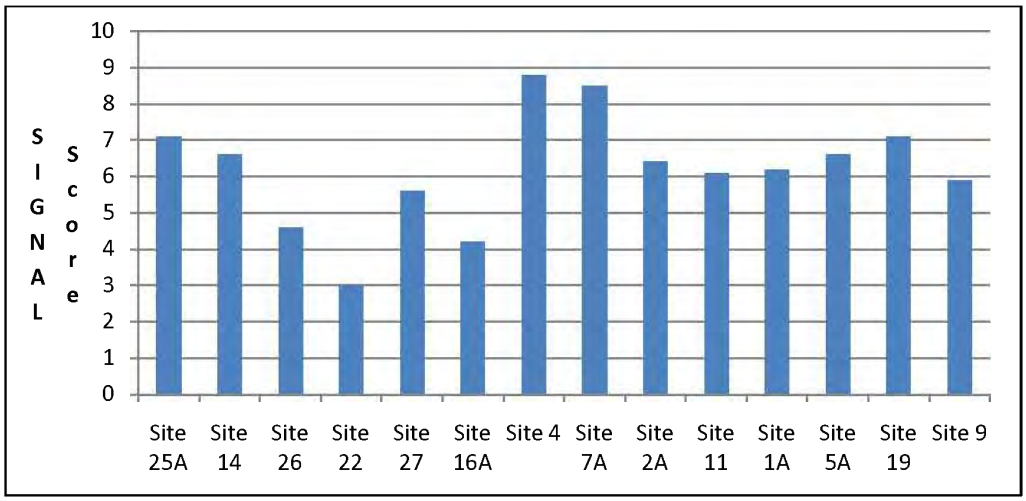

Figure 8-9 Macro Invertebrate Abundance Weighted SIGNAL Scores

8.8.2 Freshwater Macroinvertebrate Feeding Guild Composition

The composition of macroinvertebrate functional feeding groups recorded in May 2008 is provided in **Figure 8-10**. Predators were found to be the dominant feeding taxa in fast flowing

streams in the Coconut and Ina Creek Catchments (Sites 25A, 14A and 26) and the tree swamps and coastal lagoons within the mining lease (Sites 22, 27 and 16A).

Feeding group structure in Norman and Triluck Creeks varied depending on a range of factors such as stream type, flow and habitat/food availability. Predators were found to dominate the feeding group structure in deep, fast flowing and incised streams (Site 1A, Site 5A and Site 9). Filter feeders were dominant in sites characterised by broad drainage depressions with less defined channels (i.e. Site 4, Site 11 and Site 19). This indicates that the ecological processes in these sites are potentially sensitive to sediment inputs, as their ambient water quality is partially determined by filtration and attenuation of suspended sediments by emergent and submerged vegetation.

Shredders dominated the feeding group structure at Site 2A in the Norman Creek catchment and were also well represented in the Coconut and Ina Creek catchments, indicating good availability of Coarse Particulate Organic Matter (CPOM) at these sites. Shredders rely on the input of allochthonous material. The stream reach subject to inundation by the proposed dam is likely to initially experience a loss of fringing riparian vegetation and a shift in macroinvertebrate community structure, including a reduced complement of shredders. However, experience from other water storage dams in bauxite plateau streams suggest that swamp forest tree species (*Melaleuca spp.* and *Lophostemon suaveolons*) present in contributing catchments have the ability to colonise the variable "riparian" zone defined by fluctuating water levels in water storages. These species ultimately establish riparian forest margins capable of supporting shredder macroinvertebrates at least during periods of higher supply water levels when such riparian forest provides an overstorey to water margins.

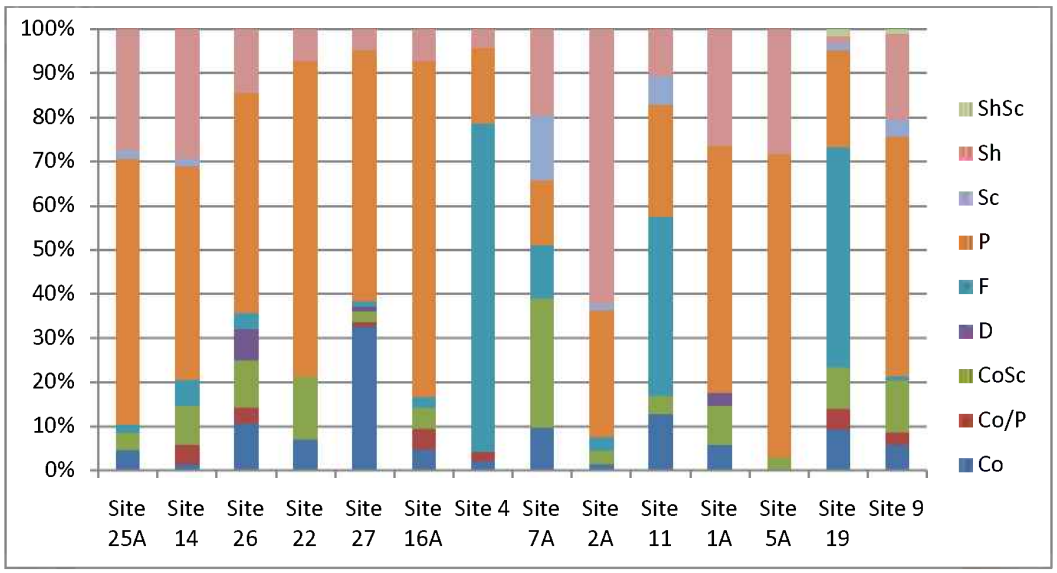

Figure 8-10 Macroinvertebrate Functional Feeding Group Composition

Key: ShSc – Shredder Scrapers, Sh – Shredders , Sc – Scrapers , P – Predators, F – Filter Feeders, D– Deposit Feeder , CoSc – Collector Scrapers , Co/P – Collector Predators , Co – Collectors)

Collector-Scraper taxa were the dominant functional feeding group at Site 7A in the Norman Creek catchment, indicating some importance of algal/detrital in-stream food resources and sensitivity to sediment inputs at this site. These taxa are typical of shallow, rocky bottom streams with good light penetration. Site 7A is the most perennial of all surveyed stream sites and due to its non-alluvial upper catchment setting has only a narrow band of riparian vegetation which facilitates in-stream light penetration. Benthic algal processes or cycling of terrestrial vegetative material through the aquatic ecosystem is likely to represent an important

basis to ecological functioning at this site. The low proportions of Scraper taxa found at other sites throughout the study area are likely due to a combination of habitat availability (i.e. riparian shading restricting algal production) and the sampling method employed (i.e. edge sweep sampling only). The substrate is more likely to have formed part of the sampled habitat in the narrow and shallow stream channel at Site 7A.

8.8.3 Estuarine Benthic Macroinvertebrates

The macro-crustacea component of the estuarine macroinvertebrate community has been discussed in preceding sections. The focus of estuarine benthic macroinvertebrate sampling was on characterising the composition of the benthic community between estuaries and between sites along the salinity gradient within an estuary with a qualitative assessment of taxa presence/absence at the family level. Grab sampling was conducted at upper, mid and lower estuarine sampling sites within the Ward River estuary (Site 28, Site 29 and Site 30) and at the lower estuarine sampling site (Site 12) in the Norman Creek estuary.

Sampling was conducted in May 2009 at a time when the estuary was dominated by freshwater inflows. Further sampling would be required to characterise benthic invertebrate communities during the dry season saline phase of the estuary. Given the dry season changes observed in estuarine salinity, water chemistry and other benthic habitat characters such as seagrass species composition and extent, changes in the benthic invertebrate community could also be expected to occur.

Three replicate grab samples were collected from littoral margins, channel edge, mid channel and, where present, sand bars and beds. However, only samples from littoral margins were chosen as a standardised habitat present across all sites for processing (binocular microscope identification and counting of specimens) for reporting. Observations on other samples that have been archived are also reported.

While generally low benthic macroinvertebrate abundance and diversity were recorded for all reported sites (**Table 8-12**), it should be noted that quantitative assessment of abundance was not the objective of sampling. The objective of the sampling was to characterise baseline aquatic macroinvertebrate community on the basis of the presence or absence of macro invertebrate family taxa and in terms of its ecological functioning indicated by the proportional representation of functional feeding guilds.

The low abundance of fauna is indicative of an oligotrophic (low nutrient, low primary productivity) estuary, which would be expected given the low nutrient status of freshwater inputs derived from groundwater sources. It is also likely to reflect the dominance of freshwater inflows within the estuaries at the time they were sampled, particularly the upper and mid estuary sites on the Ward River. Estuarine benthic invertebrate communities are recognised to be more depauperate in low salinity / brackish and upper estuary environments.

Littoral sampling sites were amongst mangrove roots, commonly characterized by accumulated leaf litter from overstorey mangroves and had fine organic mud or silty sand substrates. These sites appeared to be anoxic environments, based on odours released by sample grabs and anaerobic sulphitic bacteria observed at some sites. Few invertebrate specimens visible to the naked eye were apparent during sieving of littoral grab samples.

Table 8-12 Number of Specimens of Estuarine Benthic Macroinvertebrate Families Recorded in Grab Sample Replicates

			Norman Creek lower (Site 12)			Ward River lower (Site 30)			Ward River mid (Site 29)			Ward River upper (Site 28)			Total

The greatest abundance and diversity of benthic macroinvertebrates recorded from processed littoral samples was in the lower estuary sites of both the Ward River and Norman Creek. The lower Norman Creek samples were dominated by marine worms (Polychaetes) and a few individual crustaceans and molluscs. The lower Ward River samples had a few individual marine worms, no molluscs and were dominated by crustaceans, primarily Amphipods. Upper catchment littoral sites had a lower diversity and abundance of invertebrates and a greater representation of classes and families (i.e. Arthropods, Insecta) more typical of freshwater fauna, reflecting the influence of freshwater inflows at these sites. Freshwater Charophyte algae *Chara spp.* were commonly recorded in channel grab samples from the mid and upper estuary sites of the Ward River.

Within lower estuary sites, visual observations made during sample sieving suggested a greater abundance of macroinvertebrates in channel edge and sand bar samples, particularly within seagrass *Halodule pinifolia* beds, where a substantial biomass of marine (Polychaete) worms was observed within the seagrass rooted silty-sand substrate. Deeper and coarser grained sand /shell grit bars and channel sites appeared to support a greater mollusc fauna. Central channel sites commonly had hard scoured clay substrates which were hard to grab sample and lacked obvious invertebrate fauna.

One of the most noteworthy finds from a littoral grab sample in the upper Ward estuary was a single specimen of a Mysid (shrimp) Crustacean tentatively identified by macroinvertebrate taxonomists, including the senior curator of Crustacea at the Queensland Museum and an expert in mysid taxonomy from the Smithsonian, as belonging to the family Lepidomysidae. This family is only known from Italy, India, Cuba and Mexico and has not previously been recorded in Australia. If correctly identified, this specimen is considered to represent a finding of national and international phylogenetic and biogeographic significance (L. Walker, Ecowise, pers. comm.). This Family is also generally known to be stygofauna (groundwater/cave dwelling organisms), although they can occur in brackish water away from caves. Its appearance in a grab sample may suggest the upper estuary sample site was in a groundwater upwelling location, as upwellings are common in the upper estuary, and such an upwelling would be a likely habitat for a stygobiont able to survive in open water.

Direct inflows of groundwater to the Ward estuary in the upper catchment were first recorded by salinity profiling and visual observations in the 2008 (December) dry season. The finding of stygofauna further establishes the significance of groundwater inflows in the upper estuary of the Ward River and highlights a subterranean component to the perennial groundwater aquifer dependent ecosystems.

In summary, the benthic invertebrate community of the study areas estuaries can be characterised as far as practicable by the limited data set as being depauperate, most likely on account of the generally low nutrient status of the estuaries and their broad seasonal fluctuations between fresh wet season and saline dry season phases. Ambient dissolved aluminium concentrations and the bioavailability of aluminium in the soft water chemistry of the catchment (refer **Section 8.15.1**) could also theoretically be a causative factor in low benthic invertebrate abundance and diversity.

8.9 Introduced Species

The only introduced plant or animal species observed in aquatic ecosystems of the Project area was the Cane toad (*Bufo marinus*). Observed densities in seasonal aquatic habitats within Darwin Stringybark (*Eucalyptus tetrodonta*) woodland dominated areas and stream riparian corridors were generally low. However, large aggregations were observed at coastal wetland sites on several occasions, particularly just prior to the wet season although observed densities were not as high as can be encountered on the east coast of Queensland. This species has been established in Cape York for two decades and observed densities probably represent equilibrium populations for the habitat types concerned.

The complete absence of any other introduced aquatic plant or animal species is a key value of the SoE area.

Potential sources of introduction to the area include:

- live bait (fish or crustaceans) brought to the site for recreational fishing purposes;
- intentional stocking of constructed storages with recreational species;
- keeping of exotic aquarium species on site, e.g. in administration offices, and their subsequent accidental or deliberate release into natural waters; and
- via machinery or other equipment that has previously operated in aquatic ecosystems in other areas containing introduced species before coming to site, e.g. salvinia or other macrophytes attached to boats used on water storage dams.

While no exotic aquatic plant or animal species risks have been identified for the Weipa area, which is where most equipment coming to the SoE area is likely to be sourced, there are some risks posed by terrestrial or semi-aquatic species present in the Weipa and adjoining Aurukun areas. These primarily include potential grass weeds of riparian and aquatic habitats, e.g. Gamba Grass *Andropogon gayanus* and Guinea Grass *Panicum maximum* (both present in Weipa and potentially severe weeds of riparian areas), Para Grass *Brachiaria mutica* (present in Aurukun area, a severe weed of wetland habitats) and also Rubber Vine *Cryptostegia grandiflora* (present in Aurukun area, a severe weed of riparian habitats). Other aquatic or semi-aquatic exotic species are known to occur further away, but in areas from which machinery may be sourced, such as the Cairns / Mareeba area.

Recreational activities will be limited in the Project area and the potential for any additional aquatic species to be introduced to the area in association with mining development is unlikely.

The implementation of appropriate machinery and equipment wash down and quarantine protocols should serve to limit the risk of introductions. Weeds will be monitored and controlled through a weed management program (refer **Section 7.10.2**).

8.10 Threatened Aquatic Species

This section identifies the species listed as "matters of national environmental significance" (MNES) under the EPBC Act, and species listed as threatened under the Queensland *Nature Conservation Act 1992* (NCA), that potentially occur in the vicinity of the Project area.

A search of the Department of Sustainability, Environment, Water, Population and Communities (DSEWPaC) (formerly the Department of Environment, Water, Heritage and Arts (DEWHA)) Protected Matters search tool was conducted. The search area is shown in **Figure 7-2** and detailed in **Table 7-1**. **Table 8-13** summarises the search results with respect to aquatic ecosystems and species.

Table 8-13 Summary of Aquatic Ecosystem EPBC Act Protected Matters Search

Matters of National Environmental Significance	Result for aquatic ecosystems
Wetlands of International Significance:(RAMSAR Sites)	None
Threatened Species	3 (3 fish)
Migratory Species	7 (Dugong*, Estuarine Crocodile, 5 wetland birds)

* Dugong may utilise upper estuary habitats.

Three species of threatened fishes were identified in the EPBC Act search as potentially present within the lower freshwater and estuarine habitats considered in this assessment of aquatic ecosystems in the Project area, namely:

- Freshwater Sawfish (*Pristis microdon);*
- Green Sawfish (*Pristis zijsron*); and
- Dwarf Sawfish (*Pristis clavata*).

An additional threatened species listed under the EPBC Act, the Speartooth Shark *(Glyphis* sp A.), has been included in this assessment as a potential inhabitant of the Project area. There is limited knowledge regarding the habitat and requirements of these species; however, available information is summarised in **Table 8-14**.

No EPBC Act listed Threatened aquatic fish species were confirmed as present within the Project area. **Table 8-14** describes both the likelihood of each EPBC Act listed Threatened fish species occurring within the very large Project area, and the likelihood of each occurring within the much smaller aquatic ecosystems potentially disturbed by the proposed Project

The Freshwater Sawfish (*Pristis microdon)*, Dwarf Sawfish *(Pristis clavata),* Green Sawfish (*Pristis zijsron*) and Speartooth Shark *(Glyphis* sp A.) are considered likely to occur in the estuarine and lower brackish reaches of the Project area's main drainage systems due to the suitability of the habitats present and their similarity to where these species have been recorded at sites elsewhere on Cape York (including the Wenlock–Dulcie River system). There are also anecdotal reports from Traditional Owners of Freshwater Sawfish observations in the lower Norman Creek and Ward River systems (H. Marmoss – Kalinda pers. comm.). Estuarine fish sampling conducted in May 2008 and 2009 recorded no elasmobranchs (sharks and rays) of any species from estuarine sites in the Project area.

The Green Sawfish and Dwarf Sawfish are listed as critically endangered, and the Speartooth Shark is listed as endangered, under the International Union for Conservation of Nature and Natural Resources (IUCN) Red List of Threatened Species (IUCN 2008).

Dugongs (*Dugong dugon*) are known to occur in marine habitats in the Project area and are addressed in **Section 6.6.3** and **Section 6.9.4**. The Estuarine Crocodile (*Crocodylus porosus*) was recorded during field surveys. However, this species is largely terrestrial and is addressed in **Section 7.15.5**. One of the five EPBC Act listed migratory wetland bird species (Great Egret (*Ardea alba*)) was recorded during field surveys. All EPBC Act listed migratory bird species identified from the EPBC Act database search, recorded during field surveys, or assessed as potentially occurring based on available habitat, are addressed in **Section 7.15.5**.

Several species listed as threatened under the NCA that may be considered semi-aquatic or dependent upon aquatic ecosystems of the Project area were recorded during field surveys, including the Estuarine Crocodile (*Crocodylus porosus*), Black-necked Stork (*Ephippiorhynchus asiaticus*) and Radjah Shelduck (*Tadorna radjah*); however, these species are also substantially terrestrial and are addressed in **Section 7.15.6**.

Project related disturbance of aquatic ecosystems would be limited to the following:

- Construction and operation of Dam C on a freshwater tributary of Norman Creek; and
- Activities (including dredging and the clearing of 400m^2 of mangrove habitat) associated with the construction and maintenance of the ferry/barge terminals within the estuarine reaches of the Hey and Embley Rivers.

Descriptions of these activities and infrastructure are provided in **Section 2.7.2** and **Section 2.7.3**. A description of the location and size of Dam C on a freshwater tributary of Norman Creek is presented in **Section 5.2.3**.

Table 8-14 Threatened Fish Species Listed under the EPBC Act Potentially Occurring in the Project Area

Common Name	Scientific Name	EPBC Status	Key Requirements	Preferred habitat in the Weipa/Cape York Region	Likelihood of occurrence within the Project Area and Areas of Proposed Disturbance within the Project Area
Freshwater Sawfish	*Pristis microdon*	V	Preferred habitat is mud bottoms of river embayments and estuaries, but they are also found well upstream (Allen 1997). They are usually found in turbid channels of large rivers over soft mud bottoms (Allen 1991) more than 1m deep, but they will move into shallow waters when travelling upstream or while hunting prey (Wilson 1999). Anecdotal evidence suggests that the freshwater sawfish may be found in closed systems (Thorburn *et al.* 2003). Small specimens of this species have also been caught in remote ponds that have been isolated for a number of years (DSEWPaC 2010) Pupping occurs during the wet season, which is also when this species moves into freshwater reaches (DEWHA 2005).	This species occurs in drainages in northern Australia, including the adjoining Archer, Embley and Wenlock – Dulcie River basins, occurring in freshwater and upper estuarine areas.	**Project Area** ***Likely*** This species may occur in estuarine and the lowermost freshwater reaches within the Project area. Suitable habitat present in the brackish reaches of Norman Creek and the Ward River, though generally low abundance of all elasmobranchs species have been observed at these sites. Anecdotal records of sawfish within lower Ward River estuary (which would not be disturbed by Project related activities) and Norman Creek estuary (downstream of Dam C) reported by Traditional Owners may include this species. **Dam C on Norman Creek and Upstream of Dam C** ***Unlikely*** Anecdotal records of sawfish species have only been recorded in the lower reaches of Norman Creek, which is downstream of Dam C. The freshwater tributaries of streams like Norman Creek have extremely low conductivity due to their catchments being highly weathered bauxite landscapes, which do not contribute salts. Recorded conductivity values approach those of distilled water. It is hypothesised that these extremely low conductivity values present an osmoregulation constraint on the freshwater fish community that occur in these systems. This is evidenced by the complete absence of records in the freshwater tributaries of Norman Creek for otherwise ubiquitous families, genera and species of freshwater fishes found throughout tropical Australia, including in adjoining river systems to the Project area. It is suggested that the extremely low conductivities of Norman Creek's freshwater tributaries would present an osmoregulation constraint on the Freshwater Sawfish as it possesses a more primitive osmoregulation capacity than modern ray finned fishes. While the estuarine and possibly lower tidally influenced freshwater reaches of the Norman Creek system do provide potentially suitable habitat for this species, the seasonal freshwater tributaries of Norman Creek, upstream of the proposed Dam C do not. Combined with the abovementioned water quality constraints, the small size and seasonality of Norman Creek would also be a constraint, as the Freshwater Sawfish generally inhabits larger perennial river systems as opposed to small seasonal creeks like Norman Creek. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Possible*** Although this species has not been recorded in either of these rivers, the footprints of the ferry/barge terminals would be within the estuarine reaches of these rivers that this species may traverse. The extent of disturbance within these areas would be minimal in relation to the total estuarine environment available within these rivers. Disturbance would consist of the clearance of 400m^2 of mangroves (0.008% of the associated vegetation community within the Project area) and 2.1ha of riverbed. The dredging in these areas would only be to a depth of -2m LAT.

Common Name	Scientific Name	EPBC Status	Key Requirements	Preferred habitat in the Weipa/Cape York Region	Likelihood of occurrence within the Project Area and Areas of Proposed Disturbance within the Project Area
Green Sawfish	*Pristis zijsron*	V	Across its range, the Green Sawfish has been reported to inhabit marine inshore waters, estuaries, lagoons and less saline environments (though not purely freshwater) occurring in areas with a muddy substrate and frequently in shallow water (Stead 1963). Sawfish may move into marine waters after the wet, and during the wet season enter estuarine or less saline environments (though not freshwater) to breed (Peverell 2005 and DSEWPaC, 2010).	Most records are from marine and estuarine areas (Thorburn *et al.* 2003; Peverell *et al.* 2004). Closest records to the study area are from marine waters of Albatross Bay and Mission River (Blaber *et al.* 1990b, Thorburn *et al.* 2004).	**Project Area** ***Likely*** Most records from northern Australia are from shallow marine inshore waters (c/f estuaries). Adults are known to seasonally frequent inshore waters and rivers during the monsoonal months to pup (Peverell 2007). Records from Albatross Bay adjoining the mouth of the Embley River make occurrence within the northern estuarine section of the Project area likely. **Dam C on Norman Creek and Upstream of Dam C** ***Unlikely*** This species is not found within freshwater environments. Dam C would be located on a freshwater reach of Norman Creek. Therefore this species is unlikely to occur within the footprint of the proposed Dam C or upstream of this dam. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Likely*** Records from Albatross Bay adjoining the mouth of the Embley River make occurrence of this species within the estuarine sections of the Hey and Embley Rivers likely. The extent of Project related disturbance of these areas would be minimal in relation to the total estuarine environment available within these rivers. Disturbance would consist of the clearance of 400m^2 of mangroves (0.008% of the associated vegetation community within the Project area) and 2.1ha of riverbed. The dredging in these areas would only be to a depth of -2m LAT.
Dwarf or Queensland Sawfish	*Pristis clavata*	V	The Dwarf Sawfish usually inhabits shallow (2–3m) coastal waters and estuarine habitats. The species prefers highly turbid environments (DSEWPaC, 2010) and are only usually found in silt sections of an estuary which are completely devoid of instream structure (Thorburn *et al.* 2003). However DSEWPaC (2010) does note that this species may rest either side of high tide in inundated mangrove forests. Restricted to brackish and salt water (Thorburn *et al.* 2007). Juveniles more commonly encountered in coastal foreshores and embayments; adults in marine waters (DEEDI 2009). Estuarine habitats are used as nursery areas by Dwarf Sawfish, with immature juveniles remaining in these areas up until three years of age (Thorburn *et al.* 2007a). Adults are known to seasonally migrate back into inshore waters (Peverell 2007).	Preferred habitat identified on the basis of capture locations include open estuarine channels and silty sand flats lacking structure with fine substrates (mainly silt), high turbidity and often with low dissolved oxygen. This species has been confirmed from the Pine River on the western coast of Cape York Peninsula (DEHWA 2010) which lies 20km to the north of the study area.	**Project Area** ***Likely*** This species may occur in estuarine reaches within the Project area. Suitable habitat is present in near coastal areas and estuaries of Norman Creek the Ward River and Embley River, though generally low abundance of all elasmobranchs species were observed at Norman Creek and Ward River sites. Records for this species exist for an estuarine system (Pine River) 20km to the north, although this system is at least anecdotally thought to have higher turbidity levels. Anecdotal records of sawfish within lower Ward River and Norman Creek estuaries reported by Traditional Owners may include this species. **Dam C on Norman Creek and Upstream of Dam C** ***Unlikely*** This species is not found and does not breed within freshwater environments. Dam C would be located in a freshwater reach of Norman Creek. Therefore this species is unlikely to occur within the proposed footprint of Dam C or upstream of the dam. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Likely*** Suitable habitat for this species is present in near coastal areas and the estuary of the Embley River. Disturbance in the Embley River associated with the Project would be limited to a small amount of dredging activities related to the construction and maintenance of the Hornibrook Ferry Terminal. This species may also utilise as a resting place either side of high tide, the 400m^2 of mangrove forest that would be cleared for the construction of the Hey River ferry/barge terminal. The area of mangroves that would be cleared only represents 0.008% of this mangrove community within the Project area. Therefore there would be sufficient remaining mangrove habitat in the surrounding area which the species would be able to utilise for resting.

Common Name	Scientific Name	EPBC Status	Key Requirements	Preferred habitat in the Weipa/Cape York Region	Likelihood of occurrence within the Project Area and Areas of Proposed Disturbance within the Project Area
Speartooth Shark	*Glyphis sp.* A	CE	Relatively shallow, turbid, upper freshwater, and possibly brackish, reaches of rivers and associated floodplains. Seem to be particularly adapted to low oxygen environments. The potential area of occupancy of *Glyphis* species in creek and river systems is restricted from the mouth of a river to the point where the river ceases to be perennial (Stevens *et al.* 2005). *Glyphis* species do not utilise ephemeral reaches.	This species occurs in freshwater and estuarine areas of northern Australia, including the Wenlock River basin (Peverell 2005).	**Project Area** ***Likely*** This species may occur in estuarine and the lowermost freshwater reaches within the Project area below the perennial extent of the creeks and rivers. Records exist for the Wenlock River and similar habitat is present within the Project area, though generally low abundances of all elasmobranchs species have been observed (Peverell, McPherson, Garrett and Gribble 2006). **Dam C on Norman Creek and Upstream of Dam C** ***Unlikely*** The potential area of occupancy of the Speartooth Shark in creek and river systems is restricted from the mouth of a river to the point where the river ceases to be perennial (Stevens *et al.* 2005). Regional records for the species come from large perennial river systems i.e. the Wenlock River. The species is not known to utilise small seasonal creek reaches. The proposed Dam C would be on an highly seasonal freshwater tributary of Norman Creek, which although perennial dries to small, shallow pools which are isolated except for connecting trickling flows in the dry season. Therefore, it is unlikely that the Speartooth Shark, if present in Norman Creek would require passage past the proposed site of Dam C. The freshwater tributaries of streams like Norman Creek have extremely low conductivity due to their catchments being highly weathered bauxite landscapes, which do not contribute salts. Recorded conductivity values approach those of distilled water. It is hypothesised that these extremely low conductivity values present an osmoregulation constraint on the freshwater fish community that occur in these systems. This is evidenced by the complete absence of records in the freshwater tributaries of Norman Creek for otherwise ubiquitous families, genera and species of freshwater fishes found throughout tropical Australia, including in adjoining river systems to the Project area. It is suggested that the extremely low conductivities of Norman Creek's freshwater tributaries would present an osmoregulation constraint on the Speartooth Shark as it possesses a more primitive osmoregulation capacity than modern ray finned fishes. While the estuarine and possibly lower tidally influenced freshwater reaches of the Norman Creek system do provide potentially suitable habitat for this species, the seasonal freshwater tributaries of Norman Creek, upstream of the proposed Dam C do not. **Ferry/Barge Terminals – Hey and Embley Rivers** ***Unlikely*** Although there has been an unverified report of the presence of the Speartooth Shark in the Embley River in 1985, Stevens et al (2005) notes that ongoing fish surveys over 20 years in the Embley River have not recorded this species. Stevens et al (2005) therefore suggests that this species is restricted to the Wenlock and Ducie Rivers in this region, which are large tropical river systems. From this evidence, it is unlikely that this species would occur in either the Embley or Hey Rivers. However if this species was to occur within these rivers, the extent of disturbance associated with the ferry/barge terminals would be minimal in relation to the total environment available within these rivers.

Key to EPBC Status: CE = Critically Endangered V = Vulnerable

8.11 Fish and Invertebrate Tissue Metals

The concentrations of metals in tissue samples (flesh, hind and gill, cephalothorax, tail and whole body) in representative species of aquatic biota are summarised in **Appendix 8B**. The metal concentrations were compared to the Australian and New Zealand Food Association (FSANZ 2009) Food Standards and generally expected levels (GEL) (FSANZ 2009). These values are presented as an indication of what metal concentrations may be expected or tolerable in a tissue type for human consumption.

The metal concentrations were also compared with the Lowest Observed Effects Concentration (LOEC) for post-larval organisms derived from the database of Jarvinen and Ankely (1999). These concentrations are the lowest metals concentrations found in the body of an organism that were observed to co-occur with a recorded effect – for example, reduced survival, affected behaviour or reduced fecundity.

The majority of metal concentrations were well below the appropriate food standard or GEL. The exceptions are listed in **Table 8-15**. It should be noted that as mining has not commenced, these tissue metal concentration results represent the baseline condition. That is, some tissue types from some specimens naturally exceed the food standards, GELs or LOECs.

Several total arsenic measurements for flesh samples of *Neoarius graeffei* were more than ten times the food standard, but the food standard for arsenic is for inorganic arsenic, not total arsenic. The total arsenic concentration for flesh samples of three other fish species were less than the food standard. Edmonds and Francesconi (1993), in their review of the ratio of inorganic to organic arsenic in marine organisms found that inorganic arsenic proportions above 1% occurred only in low total arsenic concentration samples, for which there was no human health risk. Therefore, although the ratio of inorganic to total arsenic was not measured in any specimens, all recorded values would be below the food standard.

Arsenic is naturally higher in sea water than in fresh waters, and in some instances samples from the two lower estuary sites had higher average arsenic concentrations for flesh and gill samples from *Neoarius graeffei*, gill samples for *Toxotes chatareus* and claw flesh samples for Mud Crabs, *Scylla serrata*, than for the sites further upstream in each catchment.

The differences in concentrations of metals in tissues between sites were examined graphically and statistically (using a stepwise analysis of covariance procedure) to examine the pre-existing patterns of difference. Constituents for which there were statistically significant differences indicating consistent within-catchment or between-catchment differences are discussed below. It is important to note that although several statistically significant differences were identified between sites, all concentrations remained low in terms of risk of adverse impacts to organisms or humans consuming them, and should therefore be treated in that context. Also, as no species was caught consistently across all sites, multiple species comparisons between sites were limited; and, while some other, inconsistent patterns of difference between sites were found, without further sampling events it is not possible to determine their possible relevance to future patterns of metal bioaccumulation.

Tissue from fish collected from Site 14A on Coconut Creek had the highest aluminium concentrations of all fish samples (**Appendix 8B**). However, this does not appear to have been related to aluminium concentration in water as the median concentration of Site 14A was 5µg/L while that of other sites where tissue concentrations are low have higher concentrations of aluminium in water (Site 9 on Triluck Creek is 7.5 µg/L and Site 11 on a tributary of Norman Creek is 35 µg/L). The observation of some higher levels of bioaccumulation at Site 14 may reflect previous exposure to aluminium as fish move around the catchment (Site 14 dries up early in the dry season). Individual Dytiscidae beetles from Sites 4 on Norman Creek and 14A on Coconut Creek had much higher aluminium concentrations than were typically found in specimens from the other sites. These results show natural variability in aluminium bioavailability within and between catchments in the study area.

Table 8-15 Tissue Samples (2008 and May 2009) above Food Standard or Generally Expected Levels

Metal	Samples Above Standard	Samples Above GEL	Samples Above LOEC
Silver	No std	No standard	No std
Aluminium	No std	No standard	No std
Antimony	No std	1 *Cherax sp.1* cephalothorax sample above 0.1mg/kg GEL	No std
Arsenic	Nil	6 *N. graeffei* flesh samples above 20mg/kg GEL	Nil
Cadmium	No std	Nil	Nil
Copper	No std	Nil	8 *L. calcarifer* liver samples above LOEC of 4.3mg/kg 4 *T. chatareus* gill samples above LOEC of 0.64mg/kg
Mercury	3 samples above USFDA Guidance (1.0mg/kg) and 1 above proposed CODEX standard (0.5mg/kg) in *N. midgleyi* liver samples	No standard	No std
Manganese	No std	No standard	No std
Lead	9 *C. quadricarinatus* cephalothorax samples above ANZFA Food Standard (0.5mg/kg) 5 *Cherax sp.1* cephalothorax samples ANZFA Food Standard (0.5mg/kg) 3 *N. midgleyi* liver samples above proposed CODEX standard (0.2mg/kg) 1 *N. graeffei* liver sample above proposed CODEX standard (0.2mg/kg)	No standard	No std
Selenium	Nil	22 *T. chatareus* liver samples 5 *N. midgleyi* liver samples 5 *L. calcarifer* liver samples 9 samples of *N. graeffei* liver samples. Above GEL of 2mg/kg	Nil
Zinc	1 *N. midgleyi* flesh sample above ANZFA Food Standard of 15mg/kg	Nil	Nil

Note: No std. indicates no appropriate standard or GEL available.

Lower than typical average copper concentrations at the other sites were found in samples from Site 1A in Redclaw tail flesh samples and Hyrtl's tandan hind body samples, for Site 16 for Redclaw cephalothorax samples and Sites 16 and 11 for abdomen flesh samples, and Site 4 and Site 16 in whole Dytiscidae beetle samples (refer **Appendix 8B**).

The Project area is currently undeveloped and therefore differences in bioaccumulation of metals between sites, catchments and/or species are not the result of any mining activities. There is natural ecosystem variability in metal bioavailability within the Project area.

As expected, there is some enhanced bioaccumulation of aluminium in an aluminium mineralised area. The baseline metal concentrations in tissue samples were low, and not indicative of any human or animal population health risks.

8.12 Summary of Aquatic Ecosystem Environmental Values

While the Project area has a landscape that is seasonally saturated by wet season rainfall and runoff, it has only self-contained, short surface drainage networks and is not endowed with the more diverse and productive aquatic ecosystems associated with larger Cape York river systems. Nonetheless, its aquatic ecosystems have environmental values of national, state and regional significance that can be summarised by non-exclusive reference to both geographically specific sites and generic ecological values including:

- high value wetland aggregations;
- aquatic refugia in a seasonally dry landscape;
- species listed under conservation legislation;
- a representative bauxite plateau freshwater fish community; and
- species with restricted distributions.

These are described in the following sections.

8.12.1 Larger "Interface" Wetland Aggregations

There are three relatively larger wetland aggregations partially or wholly contained within the Project area, referred to here as "interface" wetlands due to their location at the interface between tidal influence and catchment freshwater discharge. These include lower Winda Winda–Triluck Creeks, lower Norman Creek and lower Ward River. These sites are continuous, complex wetland aggregations (Blackman *et al.* 1992). Each comprises an aggregation of different wetland habitat types including perennial and seasonal stream reaches, perennial channel hosted lagoons, tree swamps, seasonal coastal lakes, spike rush swamps and tidal mangrove forested estuaries. The lower Ward River is included within the Directory of Important Wetlands In Australia listed as QLD056 Archer Bay Aggregation (DEWHA 2004, Blackman *et al.* 1999) which is listed on the basis of meeting five (Criteria 1, 2, 3, 5 and 6) of the six possible criteria used to determine wetlands of national significance (refer **Table 8-16**).

Results of this study indicate that the two other major wetland aggregations identified within the Project area, lower Winda Winda – Triluck Creeks and Norman Creek, would also meet these criteria albeit with smaller sized aggregations. High values associated with these wetland aggregations are discussed in the following sections.

Table 8-16 Criteria for Wetlands of National Significance

Criteria	Basis for Criteria	Description of Criteria
1	Biogeographic Representativeness	The wetland is a good example of a wetland type occurring within a biogeographic region of Australia
2	Functional Importance of Wetland	The wetland plays an important ecological or hydrological role in the natural functioning of a major wetland system/complex
3	Value as an ecological refuge	The wetland is important as the habitat for animal taxa at a vulnerable stage in their life cycles, or provides a refuge when adverse conditions such as drought prevail
4	Value as a population refuge	The wetland supports 1% or more of the national population of any native plant or animal taxa
5	Value as endangered species habitat	The wetland supports native plant or animal taxa or communities which are considered endangered or vulnerable at the national level
6	Human Social Importance	The wetland is of outstanding historical or cultural significance

Shaded rows indicate criteria met by QLD056 Archer Bay Aggregation (DEWHA 2004, Blackman *et al.* 1999)

8.12.1.1 Primary productivity exports to downstream ecosystems.

Within these wetland aggregations sunlit perennial shallow freshwaters supporting macrophyte and algal growth, extensive seasonal spike rush swamps and mangrove forests generate the

carbon biomass that supports the food chain and productivity of downstream aquatic ecosystems within catchments that are otherwise characterised by relatively low nutrient waters and limited in-stream primary productivity. Nutrient concentrations in surface waters associated with wetland complexes were substantially higher than for streams without substantial associated wetland vegetation, demonstrating that in the Project area wetlands are sources of nutrients, not sinks. Tidally influenced seasonal lakes adjoining the Norman Creek estuary contained significant populations of detritivorous prey species including mullet and shrimps. During field investigations aggregations of Barramundi and other marine fish species commonly observed to be feeding on prey species at the discharge confluences of seasonal lakes and spike rush swamps in the upper Ward River, Norman Creek and Winda Winda – Triluck Creek estuaries.

8.12.1.2 Fishery nursery habitat

The seasonal lakes and perennial channel hosted lagoonal habitat that occurs within these wetland aggregations are recognised to be nursery habitat for fish species of importance to commercial, recreational and Indigenous fisheries, particularly Barramundi.

8.12.1.3 Fisheries

In addition to providing fishery nursery areas these wetland aggregations, particularly estuarine and lower freshwater reach main channels, are important areas for recreational and Indigenous fisheries, particularly for Barramundi but also for a host of other estuarine species sought by these fisheries e.g. Mud crabs.

8.12.1.4 Seasonally Important nesting and feeding habitat for waterbirds

The seasonal lakes and *E. dulcis* 'Bulkuru' spike rush swamps within these wetland aggregations are recognised as significant roosting, feeding and breeding areas for the Magpie goose *Anseranas semipalmata* and a host of other waterbird species including flocks of Brolga *Grus rubicundus* and the NCA "near threatened"-listed Black-necked Stork *Ephippiorhynchus asiaticus* (DEWHA 2004, Blackman *et al.* 1999). Observations of large flocks of waterbirds were particularly noted on the seasonal lakes of the lower Ward River and Winda Winda – Triluck Creek estuaries.

8.12.1.5 Aquatic refugia

The lower reaches of freshwater drainages supplying these wetland aggregations include perennial habitats that function as refugia for freshwater aquatic biota during the dry season, most importantly in years of below-average rainfall when freshwater habitats higher in the catchment are less likely to persist through the dry season.

8.12.1.6 Habitat for threatened species

A number of EPBC Act and NCA listed threatened species (discussed in **Section 8.10**) are known or predicted to occur within these wetland aggregations.

8.12.1.7 Cultural significance

Wetlands are often sites of importance to Traditional Owners due to values associated with both hunting and gathering resources and spiritual significance. The lower Ward River wetlands are part of the Archer Bay Aggregation which is cited as having very high cultural significance to Aboriginal clans associated with the Aurukun community (DEWHA 2004). Traditional Owners have also indicated similar significance is associated with the two other identified larger wetland aggregations.

There are four smaller wetland aggregations within the Project area that collectively share the same range of values as the larger aggregations identified above, but do not have the full suite of values within any individual aggregation. These include the Leithen to Franjum Point Aggregation, False Pera Head Aggregation, lower Ina Creek Aggregation and Waterfall Creek Aggregation.

The Leithen to Franjum Point Aggregation includes an estuary associated with Leithen Creek but lacks a significant freshwater catchment or discharge to support the productivity export or

aquatic refugia values associated with the larger wetland aggregations. However, this aggregation does contain areas of freshwater seepage that support small areas of seasonal tree swamps and *E. dulcis* Spike Rush swamps, the latter having associated waterbird habitat values. It also provides suitable habitat for the full suite of threatened species known or predicted to occur within the study area.

The remaining smaller wetland aggregations (i.e. the False Pera Head Aggregation, lower Ina Creek Aggregation and Waterfall Creek Aggregation) have more extensive catchment areas and/or greater freshwater inputs/discharge but lack extensive estuarine habitats due to elevated lateritic outcrop outlets that prevent or limit the capacity for tidal intrusion. Consequently these aggregations have more limited productivity and fishery values associated with their brackish estuarine interfaces and the lower waterbird habitat values associated due to the absence of *E. dulcis* 'Bulkuru' spike rush swamps. However, perennial freshwater habitats within each of these aggregations do have aquatic refugia values, which are essential for providing freshwater fish recruits to seasonal stream habitats within their catchments. These systems have also been specifically identified by Traditional Owner informants as having high spiritual and harvestable resource values (Geraldine McGuire Pers comm.).

8.12.2 Aquatic Refugia

In a seasonally dry environment such as the Project area, the persistence of aquatic biota, such as non-migratory fish, is tied to the perenniality and extent of freshwater habitats and the access and recruitment of biota to them. In this context the most permanent, extensive and connected freshwater habitats are provided by perennial stream reaches, some of the most significant occurrences of which are contained within wetland aggregations described above. Outside of the named wetland aggregations, perennial stream reaches are primarily limited to the mid and lower reaches of the two major tributaries of the Norman Creek system which also contains perennial reaches in some of its more deeply incised eastern upper catchment tributaries. The lower reaches of the Ward River also has aquatic refugia partially maintained by groundwater discharge but these reaches become dominated by tidal ingress and brackish in the late dry season. The lower Winda Winda and Ina Creek systems contain perennial freshwater habitats restricted to channel hosted pools (discussed below). Perennial stream reaches represent the habitat epicentre for obligate freshwater biota survival within the study area.

Other than stream reaches, other forms of perennial freshwater habitats that provide aquatic refugia values for freshwater biota within the SoE study area, include semi-perennial coastal lakes and lagoons, perennial channel hosted lagoons and permanent pools and soaks within tree swamps, coastal swales, drainage depressions and flood runners and within short coastal spring drainages. However, these other habitats do not provide the same level of population security or recruitment/dispersal capacity as that provided by stream reaches. In some instances the relative isolation of these habitats is in itself a refugial value allowing populations of macroinvertebrates to flourish and be maintained in the absence of significant fish predation pressure, e.g. the greater than average densities of Swamp crayfish *Cherax rhynchotus* encountered within the coastal freshwater lagoon at Pera Head.

8.12.3 Species of Conservation Significance

A number of EPBC Act and NCA listed threatened and migratory species (discussed in **Section 8.10**) are known, or possibly occur, within the aquatic ecosystems of the Project area including sites outside of the wetland aggregations described above. All of these species have a statutory underpinning for their protection, which confers an additional environmental value to the ecosystems they occur in, in terms of the opportunities they provide for meeting these species conservation needs.

Although these species are likely to occur within the Project area, the extent of these habitats within the Project area that would be disturbed is limited to a small area. The potential for these species to occur within Project related disturbance areas is summarised in **Table 8.14**. Potential impacts on these species associated with Project related disturbance are discussed in **Section 8.17** for freshwater species, **Section 7.15** for largely terrestrial species (Estuarine

Crocodile and migratory wetland birds), and **Section 6.9.5** for marine species (Dugong, Green Sawfish and Dwarf Sawfish).

8.12.4 Bauxite Plateau Freshwater Fish Assemblages

The Project area freshwater fish community is characterised by catchment-specific assemblages of mostly widespread species, although it is noted the goby and grunter families have not been recorded (refer **Section 8.7**). Species diversity in tropical Australia has been shown to be very strongly correlated with catchment size (Pusey and Kennard 1996). Typically, nature conservation evaluation frameworks emphasise species rarity and diversity and are not as well equipped to identify values associated with naturally occurring species-poor assemblages or low diversity. The low diversity of freshwater fish within the Project area has been attributed to small catchment size, catchment isolation, a limited spatial and temporal extent of perennial freshwater habitat and physiological constraints associated with the very low conductivity of freshwater emanating from the bauxite plateau (**Section 8.5.1** and **Section 8.7.4**). The naturally high bioavailability of aluminium is also a potential limiting factor, although there is currently insufficient evidence to determine the extent of its effects, if any.

Field surveys in small drainage systems of the Project area, and the Pine River basin which drains bauxite plateau landscapes near Weipa, indicate that such low-diversity fish communities are typical of small stream systems within bauxite plateau landscapes and may characterise a definable "Bauxite Plateau Freshwater Fish Assemblage". The retention of representative examples of these fish communities is a legitimate nature conservation aspiration and one that attributes value to such communities.

The catchment-specific species mixes found within the Project area catchments have been attributed to stochastic events determining recruitment success and/or extinction events and to variable connectivity to larger drainage systems and associated larger species pools. As such, each catchment's freshwater fish community provides a snapshot of an active freshwater fish biogeographic laboratory that is of interest to science in terms of improving the understanding of controls and processes underpinning fish biogeography in the seasonal tropics of northern Australia, and biogeographical and evolutionary genetic processes more generally. They represent isolated freshwater "islands" that have been separated from other freshwater systems since the last sea level rise 7,000 to 9,000 years ago. The systems have experienced limited opportunities for recolonisation via overland flows and coastal freshwater lenses in extremely wet years, and occasional severe stress periods and probable local extinction events in extremely dry years. The processes by which these isolated assemblages have been able to maintain themselves and the extent and rate of genetic divergence from their neighbours are of particular potential scientific interest.

The patchwork of species presence in the various catchments suggests that over longer time periods, and certainly since last sea level rise, the persistence of all the currently present species will have been dependent on the availability of perennial habitats among all catchments, and could not have been maintained by persistence of surface waters within any single catchment. Therefore, conservation management of the "Bauxite Plateau Freshwater Fish Assemblage" requires management of habitat availability across a substantial proportion of all the habitats in the broader western Cape York bauxite areas. The Project area catchments are an integral part of this larger assemblage of inter-dependent freshwater "islands". These aquatic ecosystems would need to be managed carefully to maintain their unique ecosystem values, as various large parts of the bauxite landscape in northern Australia are currently being mined or being proposed for mining. The patchy distribution of species across the bauxite catchments means that the catchments cannot be adequately managed in isolation, but rather should be managed as an inter-related set of aquatic ecosystems, dependent upon one another to maintain the full species set that currently inhabits them.

In terms of maintaining ecological sustainability over the timescale of mining development in the Project area, the freshwater fish communities of SoE stream networks represent the most ready source of recovery recruitment for stream reaches that may be potentially impacted by mining operations. This need to maintain the recovery potential of in-stream biota within the Project area also attributes environmental value to the freshwater fish community. In summary,

the freshwater fish community of the Project area has significant nature conservation, scientific and environmental management values.

8.12.5 Species of Restricted Distribution

Several freshwater species found in the Project area are not currently listed in any conservation management lists or legislation, but nonetheless have patchy or restricted distributions that confer conservation value and suggest they are worthy of specific management within the Project area. These include:

- Spotted Blue-eye *Pseudomugil gertrudae*;
- Black-banded Rainbowfish *Melanotaenia nigrans*;
- Swamp Crayfish *Cherax rhynchotus*; and
- Freshwater Crab *Austrothelphusa raceki.*

In addition, a new species of Freshwater Crab, *Austrothelphusa sp. nov.* was collected from Winda Winda Creek (Site 9A) during the May 2008 sampling. Specimens sent to the Queensland Museum for identification confirmed the status of this new species. No formal description of this species has yet been made. Further survey work in 2009 extended the species recorded range beyond the original record site to upstream and downstream locations (Site 33 and Site 34) but not beyond the Winda Winda Creek catchment. *Austrothelpusa sp.* was not located in other catchments within the Project area during aquatic surveys, although it may be more widespread than the three confirmed sites on Winda Winda Creek.

8.13 Aquatic Ecosystems – Overview Potential Impacts

Other than the proposed water supply storage (Dam C Norman Creek catchment), the direct impact footprint of proposed mining and infrastructure development within the Project area, defined in terms of native vegetation clearing, primarily occurs within terrestrial ecosystems (refer **Section 7**). Implementation of an environmental buffer system as outlined in **Section 7.9.2** would ensure that riparian, wetland and estuarine habitats are buffered from direct impacts associated with vegetation clearing other than where they occur within narrow infrastructure and access corridors that cross drainage lines (**Figure 7-8**), or in Dam C**.** Other indirect potential impacts that commonly affect terrestrial as well as riparian, wetland and estuarine vegetation – including altered fire regime, weed invasion and feral animal disturbance – have also been identified along with mitigation measures in **Section 7.10.2.**

The nature and condition of aquatic ecosystems is largely determined by the integrated outcome of catchment functional processes. All of the Project area acts as a catchment for surface and groundwater that underpins aquatic ecosystem sustainability. Therefore all development that alters catchment conditions to the extent that the behaviour or quality of water within the Project area's catchments is modified has some potential to generate indirect impacts on receiving aquatic ecosystems.

The greatest potential for impact to the behaviour and quality of water within the Project area's catchments is associated with:

- 27,290ha of catchment area that is to be progressively subject to a cycle of vegetation clearing, bauxite mining and rehabilitation over a 40-year mine plan;
- the proposed water supply dam with storage capacity of up to 29GL and a cleared footprint area of 700ha on a tributary of Norman Creek, the most perennial drainage system within the Project area; and
- an infrastructure footprint of 1,360ha on non-mining areas including beneficiation plants, ore stockpiles, tailings storage facility, roads and transport and shipping facilities (includes some infrastructure constructed within or across drainage lines, i.e. stream road crossings).

Potential impacts on aquatic ecosystems due to these proposed developments could be realised via:

- changes in catchment hydrology;
- elevated sediment and other contaminant loads in catchment runoff; and
- loss of aquatic habitat connectivity.

These three primary sources of potential impact to aquatic ecosystems in the Project area and mitigations options are discussed below. Potential impacts associated with underwater noise from pile driving activities on marine and aquatic fauna is discussed in **Section 10.5**.

8.14 Potential Impacts and Mitigation Measures – Altered Catchment Hydrology

8.14.1 Potential Impacts

8.14.1.1 Catchment Hydrological Changes due to Mining

Discussion of the potential interaction of mining operations on surface and sub surface hydrology is provided in **Section 5.2.4** and **Section 5.4** respectively. Changes in the partitioning of incident rainfall to catchment discharge volumes within each of the sub-catchments of the Project area was analysed using the AWBM rainfall-runoff model through four stages of mine development:

1. Undisturbed catchment
2. Active mining area
3. Immature mine rehabilitation (<15 years old)
4. Mature mine rehabilitation (>15 years old).

Modelled outputs indicate overall changes to mined catchment discharge volumes will be very small on account of the naturally high infiltration rates for rainfall in the bauxite landscape and the very low percentage (<1%) of rainfall that is discharged as surface runoff, factors largely unaffected by mining-based alteration of surface cover, topography and drainage lines. For undisturbed catchments in the Project area, monitoring and modelling outputs indicate that almost half (~48%) of the rainfall received by a catchment infiltrates and is conveyed via the lateritic profile and discharged to streams as base flow. A slightly smaller proportion (~42%) is lost to evapotranspiration. The remaining ~9% contributes to "deep base flow", or water that moves as saturated flow beneath the level of the stream bed and which may discharge as surface water (including streamflow) at a lower point in the catchment, or as upwelling in estuaries (refer **Section 5.1.1**).

Another key finding from groundwater bore monitoring indicates the potential for mining-related alteration of catchment hydrology within the Project area is limited since fluctuations in groundwater levels, including rises through the wet season, only occasionally reach or exceed planned mine pit floor levels (refer **Figure 5-26 to Figure 5-29, Table 5-23)**. Consequently, the removal of bauxite from the lateritic profile would have limited potential impact on the storage volume and residence time of the seasonal shallow groundwater aquifers that contribute to stream base flow via discharge from the lateritic profile.

The greatest change to catchment hydrological behaviour indicated by modelling of the mining disturbance cycle is during periods with the greatest active mining area footprint (refer **Table 5-21**). Removal of vegetation cover results in reduced in-pit evapotranspiration losses (down to 35.3% from 42.2% for undisturbed) and pit compaction increases surface runoff within the pit, although pit geometry causes runoff to pond and ultimately infiltrate within the pit and contribute to increased base flow in streams (52.0% c/f 48.4% for undisturbed).

Modelled water balance partitioning responses to mine pit rehabilitation indicate catchments return to near pre-mine hydrological behaviour with the regeneration of mature vegetation cover, except:

- the lowered post-mining landscape topography is reflected in reduced direct surface runoff to streams (0.2% c/f 0.6%); and
- deep base flow / recharge is increased by the greater detention of surface runoff in the post-mined landscape (10.9% c/f 8.8%).

Overall changes to mean annual catchment discharge are predicted to be small, ranging from increases of 0.1% to decreases of 0–1.4% per Project area drainage catchment during the maximum footprint of mining development (refer **Table 5-22**). The long-term rehabilitated post-mining landscape is predicted to have reductions of between 0–3.2% per Project area drainage catchment with a mean overall reduction of 1% for the Project area. These reductions in catchment discharge are predicted to be associated with the increased direct accession of ponded runoff to deep base flow / recharge in the lowered post-mine landscape. The proportion of rainfall that will be expressed as stream base flow is also predicted to be less than the undisturbed situation (46% versus 48% pre-mining) due to the increased accessions to deep base flow. However, it should be recognised that at least some of the extra 1.1% deep base flow will be expressed lower in affected catchments as an increased groundwater contribution to surface waters.

While overall post-mining catchment discharge volumes would be largely unaffected by mining, there is some potential for stream flow duration curves to be affected by the increased detention and re-routeing of surface runoff during the active mining phase. The increased within-pit runoff arising from the compacted mine surface flows to the lowest topographical point and is retained in the pit. Overall net infiltration is higher than the undisturbed situation, as indicated by the increased base flow component in streams. To the extent that the topographical low point within a pit is closer to a stream than the centroid of the pit, there would be a shorter transmission path through the in-situ lateritic profile and hence stream base flow would rise more quickly in response to rainfall than it would in the undisturbed situation. At a catchment scale, these effects would be limited by the relatively small active mining area at any one time.

The relative contributions of surface runoff, base flow to streams and deep base flow have been quantified at a catchment scale but not at a reach scale. Reach scale impacts would be determined by factors including:

- the percentage of contributing catchment that is subject to active mining;
- reach elevation relative to land surface, adjacent mine pit floors and seasonal groundwater levels; and
- the pre-mine partitioning of reach flow sources between surface runoff, stream base flow and deep base flow.

In higher elevation reaches or those lacking perennial flow contributions from deeper aquifers, mining may generate one or more of the following impacts:

- reduced surface runoff flow peaks due to surface flow detention in mine pits;
- increased infiltration through the ground potentially generating a greater base flow peak; and/or
- an earlier post rainfall base flow cessation.

Impacts driven by alteration of surface runoff patterns would be limited by the small percentage of rainfall that is conveyed as surface runoff. Earlier cessation of stream base flow would be limited in most catchments by the small extent and volume of the seasonal aquifer intersected by mine pit floors.

In lower catchment reaches receiving a contribution to surface waters from a perennial deeper aquifer (deep base flow), the alteration due to mining may (assuming sufficient aquifer storage

volume) result in increased dry season flows. However, the extent of this increase is likely to be limited and modelling shows the proportion of incident rainfall that ends up as deep base flow would increase from 8.8 to 10.9% on average. This change is unlikely to be sufficient to lead to water quality changes.

These mining-related catchment hydrological alterations could have the following ecosystem consequences at a reach scale:

- The more rapid ("peakier") delivery of the direct groundwater flow component to surface drainage networks during and immediately following wet season rainfall may result in an extended duration of greater depth inundation of wetland basins and "sumps" within the drainage network than previously experienced. This may result in some waterlogging associated riparian tree death and landward wetland ecotone boundary movement in affected wetland systems.
- In reaches not supplied by deep base flow, reduced and potentially shorter duration groundwater contributions to stream base flows may result in truncated post wet season base flow duration in some stream reaches. However, given the limited interception of the seasonal shallow aquifers by mine pits, indicated by groundwater bore monitoring, this impact is likely to be generally negligible for most catchments, though may be more significant in upper catchment reaches and/or sub-catchments where a substantial proportion of the catchment is proposed to be mined (e.g. Ina Creek ~57%). If this hydrological change occurred, impacts could include: loss or downstream movement of perennial aquatic refugia within the stream drainage network, some alteration of the dry season soil moisture regime adjoining drainage lines and the associated extent of fire refugia dependent riparian vegetation, and inland migration of wetland fresh/brackish ecotonal boundaries due to increased tidal intrusion post wet season (but only where the lower catchment of a drainage network is not supplied by deep base flow).
- Changes to small local catchment discharge points due to the modified surface and internal (lateritic layer) drainage associated with mine pit areas, including redirection of water that may have flowed via groundwater conduits from one catchment into another catchment or drainage reach.
- Where lower catchment reaches or ecosystems experience increased stream base flow volume or duration due to increased contributions from deep base flows, there could be seaward shifts of the tidal–freshwater interface ecotone and increased pool water levels and/or reduced rates of water level recession in receiving tree swamps and wetlands may be promoted. Freshwater wetlands may experience outwards shift in the wet–dry ecotonal boundary via waterlogging tree deaths associated with altered inundation patterns and changes in seedling survival and recruitment conditions due to altered dry season soil moisture conditions and associated fire refugia distribution.
- In the lowermost freshwater reaches of the mined catchments with larger, more valuable wetland complexes (i.e. Winda Winda–Triluck Creeks, Lower Norman Creek, lower Ward River) an extended base flow duration is the most likely impact, though only of a magnitude that would promote ecotonal shifts at a rate within the range of the inter-decadal variability experienced naturally by these systems. A small seaward extension of ecotonal boundaries defined by freshwater-associated mangrove communities may occur at some sites not affected by the water storage dam construction.
- The increased detention capacity of the mined landscape is likely to reduce surface runoff flow peaks (experienced after the catchment is "wetted up" by early wet season rainfall) and their associated geomorphic influences on stream channel form and sediment carrying capacity including pool flushing and scouring effects. However, this effect is likely to be small given the small proportion of direct runoff (<1%) and more than partially offset by peakier contributions to stream base flow and, in reaches receiving deep base flow, by increased dry season flow durations. While the

geomorphic outcomes for any specific reach are hard to predict, some minor changes in stream channel form, possibly including changes to the depth of scour pools that function as perennial/refugial aquatic habitats, could be expected.

In summary, mining impacts to catchment surface and groundwater hydrology are unlikely to significantly alter catchment discharge volumes but may alter streamflow durations in either direction, depending on the partitioning of incident rainfall in each individual catchment or reach. Any such bias would be overlain on any natural patterns of variability in rainfall and flows. The net changes are anticipated to be relatively small and neutral in terms of ecological values at the catchment scale, although detectable changes may occur at the reach scale. While the changes may be directional over the life of the mine they are expected to occur at a rate within the range of the inter-decadal variability currently experienced by these systems and to largely rebound following the rehabilitation of mature vegetation cover post mining.

Aquatic ecosystem impacts are expected to be neutral at a catchment scale but may include:

- impacts to existing wetland and riparian vegetation stands due to altered inundation patterns, changes in preferred recruitment conditions and fire regime exposure;
- small boundary shifts in wetland–terrestrial and freshwater–tidal wetland ecotones. These shifts are likely to be of the order of one to tens of metres and at a rate within the range of the inter-decadal variability experienced by these systems;
- redistribution of aquatic habitat and riparian vegetation fire refugia potentially including both decreases in upper reaches and increases in lower reaches; and
- altered seasonal/inter-annual aquatic biotic community composition associated with localised reach scale losses of species or reduction in access to aquatic refugia or, alternatively, increased persistence/perenniality of freshwater habitats.

Management and mitigation measures to minimise the extent of such hydrological disturbances to aquatic ecosystems over the life of mining development and beyond are discussed below.

8.14.1.2 Catchment Hydrological Changes from Dam C

Infrastructure proposed within the Project area includes a water supply dam on a freshwater tributary of Norman Creek (Dam C). The location and hydrological performance of this proposed storage is described in **Section 5.2.3**. Summary dimensions and flow impacts of the proposed storage is presented in **Table 8-17** (below). The potential aquatic ecosystem impacts associated with the construction and operation of this water storage dam would include:

- clearing and inundation of riparian/wetland vegetation (discussed in **Section 7.9**);
- altered connectivity in riparian (discussed in **Section 7.9**) and aquatic (discussed below in **Section 8.16**) habitats;
- changes to the flow regime and associated water quality, physical habitat and ecological conditions in the receiving reach and estuary downstream of the water storage dam; and
- creation of a large perennial lake habitat above the water storage dam wall.

The potential of the proposed water storage dam to generate altered catchment hydrology associated impacts in downstream reaches would vary with the storage volume and utilisation levels proposed for each development stage.

"Impact benchmarking" methods that assess levels of change from modelled or measured predevelopment annual flow statistics have been used to consider risk to flow-dependent ecological assets including estuaries in subtropical Queensland (Brizga *et al.* 2000, Hydrobiology 2008). These methods considered changes of >20% in mean annual flow and other annual flow statistics as having the potential for "class 2" impacts on flow-dependent ecological assets, i.e. they represent "values above which assessed sites are more likely to have major / very major impacts of water resource development on geomorphological and/or ecological conditions" (Brizga *et al.* 2000). The relevance of this benchmarking method to tropical aquatic ecosystems

in the Project area has not been demonstrated but, in the absence of more specific science, it may be considered indicative.

Dam C would have a maximum storage capacity of 29GL and could be constructed in either in two stages or a single stage. If constructed in two stages, the first stage would provide 10.9GL storage capacity and, later, the wall would be raised to provide 29GL storage capacity. The dam would be constructed in a single stage (29GL storage capacity) should expansion of production above 15Mdptpa be anticipated to occur quickly, or should an initial production capacity of 22.5Mdptpa be adopted. This is the subject of ongoing feasibility studies. This EIS has assessed the impact of the dam at minimum, intermediate and maximum production rates of 15Mdptpa, 30Mdptpa and 50Mdptpa.

The 10.9GL dam would have an 8m wall (at spillway level) and capture approximately a third of the catchment area on the most perennial tributary stem of the creek system (refer **Table 8-17**). At 15Mdptpa, annual mean flows immediately downstream of the dam wall would be reduced by 23.7% and reduced by 6.5% to the estuary under a 15Mdptpa production scenario. The 29GL dam would have a wall height of 12m (at spillway level). At 30Mdptpa, annual mean flows downstream of the dam wall would be reduced by 32.9% and by 9.8% to the estuary. At the 50Mdptpa production rate, annual mean flow downstream of the dam wall would be reduced by 50.5% and mean flow to the estuary reduced by 15.1%.

Annual mean flow volume reductions would also be reflected in reductions of individual and seasonal flow magnitudes with the greatest changes occurring in the wet season onset period when the dam is filling and in the early dry season when spillway overflows decline and base flows would be reduced by diversion for mine use. A summary analysis of the hydrological performance of the water storage dam (refer **Table 5-17)** indicates that modelled annual 10^{th} percentile, median and 90^{th} percentile flows downstream of the dam wall would be reduced under the 15Mdptpa production scenario to 66.7%, 77.3% and 83.3% of pre-dam flows respectively. The corresponding reductions for the 30Mdptpa production scenario are 43.9%, 63.7% and 80.4% of pre-dam flows. For the 50Mdptpa production scenario, reductions are 19.2%, 46.9% and 63.6% of pre-dam flows respectively.

Modelled annual 10^{th} percentile, median and 90^{th} percentile flows to the estuary would also be reduced but to a much smaller extent. Under the 15Mdptpa scenario they would be reduced to 90.1%, 93.5% and 95.0% of pre-dam flow conditions respectively. Under the 30Mdptpa production scenario flow is reduced to 83.1%, 89.2% and 90.2% of pre-dam flow conditions respectively and at 50Mdptpa production to 75.9%, 84.1% and 89.1% of pre-dam flows respectively.

Table 8-17 Summary Dimensions and Flow Impacts

	Dam C	
Norman Creek System	**At 10.9GL capacity**	**At 29GL capacity**
Norman Creek system catchment (to estuary) area (km^2)	259	259
Dam C catchment area (km^2)	77.3	77.3
Dam catchment as % of Total catchment	29.8%	29.8%
Maximum Dam Volume (GL) (at spillway)	10.9	29
Clearing area (km^2) (at clearing limit mRL)	4 (14.5)	7 (18.5)
Dam wall height (m) (at spillway)	8.0	12.0
Downstream of dam wall flows (annual mean) as % of inflows 15Mtdptpa	78.3%	
Downstream of dam wall flows (annual mean) as % of inflows 30Mtdptpa		67.2%
Downstream of dam wall flows (annual mean) as % of inflows 50Mtdpata		49.5%
Estuary flow input (annual mean) as % of pre-mine 15Mtdptpa	93.5%	
Estuary flow input (annual mean) as % of pre-mine 30Mdptpa		90.2%
Estuary flow input (annual mean) as % of pre-mine 50Mdptpa		84.9%

The post-dam impact on mean monthly flows relative to pre-dam conditions under the three development stage scenarios is illustrated in **Figures 5-12** to **5-14.**

Currently the predictive capacity for potential impacts is not sufficient to make clear distinctions between those that would be associated with the 10.9GL dam and 15Mdptpa production scenario as opposed to the proposed 29GL dam and a 30Mdptpa and subsequent 50Mdptpa production scenario. However, application of the >20% change threshold for mean annual flow and other annual flow statistics used for impact benchmarking in studies of subtropical flow dependent ecological assets including estuaries (Brizga *et al.* 2000, Hydrobiology 2008) is indicative of the greater potential for more substantial changes to ecological and geomorphological conditions with the 29GL dam scenarios. A general conclusion is that the water resource demands at 15Mdptpa production would produce impacts that are measurable within the receiving reach but not the estuary, while the 29GL dam and 30Mdptpa production rate would generate more pronounced changes in the receiving reach, but still probably undetectable change to the estuary. The 29GL dam at a 50Mdptpa production rate is likely to cause significant change to the receiving reach and lead to measurable change in the estuary.

In effect, each subsequent water resource development stage would accentuate the aquatic ecological impact of the annual dry season via earlier cessation of dry season flow, later onset of larger early wet season freshwater flows and seasonally reduced freshwater flow volumes to the affected receiving reach.

In the absence of specific flow-linked ecological or physical habitat response data, a monthly flow volume of 1GL is useful for illustrating relativities between water resource development stage scenarios. Under pre-dam conditions, mean monthly flow volumes at the dam site of less than 1GL are only associated with the four months of the latter dry season (Aug–Nov). Under the 10.9GL dam scenario this increases to five months (Jul–Nov), under the 29GL dam and 30Mdptpa production rate scenario it increases to six months (Jun–Nov) and under the 29GL dam and 50Mdptpa production rate scenario it increases to seven months (Jun–Dec).

Each subsequent water resource development stage would also reduce the aquatic ecological impact of the annual wet season within the receiving reach, effectively emulating a smaller wet season with reduced frequency and duration of larger monthly flows and an overall reduction in seasonal flow volume. A threshold monthly flow volume of 2GL is useful for illustrating relativities between water resource development stage scenarios. Under pre-dam conditions, mean monthly flow volumes at the dam site of greater than 2GL occur from the onset of the wet season in January through a post wet season flow recession period extending to June (six months), reaching a monthly peak of 18.1GL in March (refer **Figure 5-12**). Under the 10.9GL dam scenario this decreases to five months (January–May) with a monthly peak of 17GL in March. Under the 29GL dam and 30Mdptpa production rate scenario it decreases to four months (February–May) with a monthly peak of 16.02GL in March, and under the 50Mdptpa production scenario it remains at four months (February–May) but has a more substantially reduced monthly peak of 12.9GL in March.

Considering the magnitude and seasonal distribution of modelled flow regime changes the following two broad groupings of impact would be predicted for the downstream stream reaches and the receiving Norman Creek estuary.

1. *Habitat modification in the receiving tributary stem to the confluence with the Norman Creek estuary.*

The extent of reduction of mean annual flow volume and individual flow magnitude and frequency downstream of Dam C indicated by the flow modelling will potentially generate a range of habitat responses in the ~5km of stream reach that extends from the proposed dam wall to the confluence with a tributary stem of the Norman Creek estuary. The lower half of this receiving reach is tidally influenced and mangrove lined while the upper half has a relatively steep gradient that, when field inspected in May 2009, hosted a range of flowing freshwater habitats including riffles and runs. Downstream of the proposed dam wall the reach comprises: incised flowing channel through open woodland, braided channel through swamp forest, riffle

and run sequences through outcropping lateritic bedrock and riparian forest / woodland, broader channel hosted lagoons within swamp forest, and narrow shallow flowing channel through open claypan "interface" swamp with isolated mangroves. No significant tributary catchment channel joins the main channel of the affected reach until approximately 3.4km downstream of the proposed dam wall, so flow reductions in the freshwater reach below the dam would not be significantly mitigated by tributary flow contributions. Subject to the magnitude of pre and post dam contributions of deep base flow to the receiving reach, the adopted environmental flow regime, spillway overflows, and the extent of dam seepage that could occur through or around the dam wall foundation, the following habitat changes could potentially occur:

- Changes in receiving reach channel geomorphology: Current hydrological modelling and geomorphological understanding limits the accuracy of potential impact predictions. Changes are likely to include deepening and armouring of the stream channel immediately below the dam wall due to reduced sediment supply from above the storage. The extent to which such changes would extend further downstream would depend on the degree to which the loss of sediment supply (mainly bed load) from above the storage is compensated by local catchment supply, potentially increased ingress of estuarine sediment with tidal inflows in lower reaches and the unknown potential of large flow events to deliver sediment from the water supply dam over the spillway. Incised run-in channels in the stream bank and dendritic drainage networks within the interface swamp mid section of the affected reach suggest local sediment inputs may be consequential despite the generally very low suspended solids loads of Norman Creek upstream of the proposed dam site. Reduced total flow volumes and individual flow magnitude, particularly in the early summer (December–January) and winter (June–July) periods, could lead to some shallowing and narrowing of the lower stream channel due to reduced sediment transport capacity and increased riparian vegetation growth, particularly paperbarks *Melaleuca spp*. and/or mangroves (in lower tidally influenced reach sections) into the stream channel. The maintenance of near pre-dam magnitude peak individual flows and monthly flow volumes in late summer – early autumn (February–April) following the filling of the water supply dam under most development stage scenarios would still provide significant "re-setting" of the receiving reach channel and would serve to mitigate geomorphological impact potential associated with overall reductions in wet season flow volume and duration. Geomorphic impact potential would be greatest with the 29GL dam and 50Mdptpa production rate scenario, given the near 50% reduction in annual mean and median flows, 80% reduction in 10^{th} percentile and 37% reduction in 90^{th} percentile flows. It is predicted that receiving reach channel narrowing, shallowing and occlusion by riparian vegetation encroachment are likely to be an apparent habitat change under this development scenario;
- Greater seasonality variability in channel hosted lagoon/pool water levels including potentially greater recession earlier in the dry season;
- A reduced surface freshwater lens in the upper estuary with reduced freshwater hydraulic damming of tidal inflows, the extent of which would be proportional to the reduction in freshwater inflows throughout the year. In contrast, there may be enhanced groundwater discharge into the bottom of the water column (associated with mining increasing deep baseflow). Resultant changes within the receiving reach would include greater seasonal variability and increased maximum salinity levels in the lower section of the affected reach in the early and late dry season with concomitant impacts on freshwater associated mangrove and *Melaleuca* species. The more significant expression of this type of impact would be associated with the 29GL dam, particularly at the 50Mdptpa production rate, and potentially include dieback of some riparian vegetation as ecotonal boundaries defined by salinity regimes shift;
- Decreased abundance of freshwater macrophyte communities in the lower mid-section of the affected reach and reduced occurrence of flow-associated freshwater macrophytes;

- Increased colonisation of the mid-section of the affected reach by mangroves (compared to freshwater associated riparian vegetation i.e. paperbarks) and upstream movement / increased domination by lower estuary associated mangrove species and compression of the freshwater associated mangrove community zones; and
- Potential water quality impacts associated with dam seepage if it occurs and/or elevated dissolved aluminium concentrations in the upper estuary associated with increased proportion of groundwater inflow compared to surface water inflow (both discussed further below).

The extent of some of these potential impacts can be mitigated by environmental flow strategies (refer below), although the mitigation capacity of environmental flows would be ultimately limited by engineering and water resource utilization constraints. Some changes (i.e. salinity regime) would occur immediately following dam construction while other vegetation community and channel geomorphic changes would generally develop over a decadal time scale. Other than the potential water quality impacts that could result from dam seepage, modified habitats would be expected to be healthy and functional and to fall within the range of variability encountered in the existing estuarine habitat aggregation and to continue hosting the range of existing faunal communities albeit with some redistribution of their preferred habitat niches and a reduction within the affected reach of flow and freshwater associated communities under the more intensive development scenario.

2. Alteration of magnitude and timing of wet season flow to the Norman Creek estuary

Under pre-dam conditions the onset of wet season flows to the Norman Creek estuary is experienced in the December–January period, though peak wet season flows don't occur until the bauxite catchment has been "wetted up" usually in March with a symmetrical rising and recessionary flow hydrograph through February and April (refer **Figure 5-12**). Under the modelled post-dam flow regimes, the onset of surface freshwater flows greater than 2GL/month in the estuarine tributary stem below Dam C is effectively delayed by three weeks at 15Mdptpa production, four weeks at 30Mdptpa production and five weeks at 50Mdptpa production (refer **Figure 5-12, 5-13** and **5-14** respectively). However, deep base flow contributions to this reach are predicted to increase as a consequence of mining. Impacts associated with changes in the seasonal timing and volume reductions of surface freshwater flows below the dam would be most felt in the 3.4km of reach downstream of the dam before its confluence with the next major tributary.

While specific causal mechanisms are variable between fisheries, estuaries and regions, the timing and magnitude of freshwater flows into tropical Australian estuaries has generally been demonstrated to correlate strongly with coastal fisheries production (Robins *et al.* 2005, 2006, Halliday *et al.* 2007). Likely causal mechanisms in terms of potential fisheries productivity impacts include delayed and reduced inputs of nutrients, delayed inundation and reduced extent of prey and nursery wetlands and reduced downstream displacement of freshwater prey species and/or competing adults (Robins *et al.* 2005).

Considering the magnitude of flow timing deferrals and volume reductions within the dammed Norman Creek estuary tributary stem, there is some potential for these types of impacts downstream of Dam C. However, catchment hydrological behaviour characteristics would serve to mitigate the potential for impact. The bauxite-dominated Norman Creek catchment exports very little stream flow until the lateritic profile is "wetted up", at which time the base flow increases gradually to a peak, generally in March. This contrasts with "hard" catchments in which onset of wet season rainfall events translate as flow pulses to receiving estuaries, usually with significant associated ecological responses. Consequently the diversion of early wet season flows to the filling of Dam C would not alter the nature of the main freshwater flow pulse experienced by the estuary though it would defer the onset of wet season freshwater flows and increase late dry season salinity levels within the affected estuary stem. These potential impacts would be mitigated to some extent by environmental flow releases, increased deep base flow and, potentially, dam seepage.

Modelling of peak flow behaviour pre and post dam construction indicates that the deferral of pre-dam bank-full flow (associated with back levee wetland inundation events) timing in February (Day 52 i.e. 21 February) would on average be only one day under the 15Mdptpa production scenario, six days under the 30Mdptpa production scenario and nine days under the 50Mdptpa production scenario (refer **Figures 5-16 to 5-18**). This is because the dam is full and overflowing up to a month, on average, before bank-full flow volumes are reached and hence presence of the dam has a limited impact on when bank-full flow first occurs. Peak catchment discharge at Dam C for March is predicted to decline from 18.1GL to 17.0GL under the 10.9GL dam and 15Mdptpa production scenario, to 16.0GL under the 29GL dam and 30Mdptpa production scenario and to 12.9GL under the 50Mdptpa production scenario. Consequently there is some potential for impacts to downstream wetland primary productivity and fishery nursery and recruitment values associated with higher late dry season salinities, delayed and reduced inputs of nutrients and delayed floodplain / back levee wetland inundation, particularly under the more intensive development scenario. The significance of bank-full flow deferral for back levee wetland inundation timing would be mitigated by catchment run in downstream of the water supply dam which would be unaffected.

The implications of impact within the dammed freshwater tributary stem to the broader Norman Creek estuarine ecosystem would depend upon the impact of Dam C on the flow regime experienced by the broader estuary and the maintenance of geomorphic, wetland productivity and fishery recruitment processes throughout the broader estuary. The use of flow statistics to predict estuarine ecology and fisheries production impacts is in its infancy in tropical Australia (Robins *et al.* 2005). The relevance of impact benchmarking methods (i.e. Brizga *et al.* 2000, Hydrobiology 2008) that have used changes of mean annual flow and other flow statistics to indicate the potential impacts on geomorphological and ecological conditions in sub-tropical estuaries to tropical estuaries, particularly oligotrophic ones such as those in the Project area, has not been demonstrated but in the absence of more specific science it may be considered indicative. These methods use changes of >16% in mean annual flow and other flow statistics to indicate the potential for "class 1" (no/minor) impacts and changes of >20% in annual flow statistics to indicate the potential for "class 2" (major / very major) impacts. Flow conditions immediately downstream of Dam C and flows to the whole Norman Creek estuary have been modelled under 15Mdptpa, 30Mdptpa and 50Mdptpa production scenarios (refer to **Tables 5-17 to 5-19**). Modelling for the 15Mdptpa, 30Mdptpa and 50Mdptpa production rates show mean annual flow to the whole Norman Creek estuary declining by 6.5%, 9.8%, and 15.1%, respectively. Only the latter annual mean flow reduction of 15.1% approaches the indicative threshold (16%) for "class 1" (no/minor) impacts to downstream ecological and geomorphological conditions used by Brizga *et al.* (2000).

To examine the nature of flow impacts further it is also useful to identify the distribution of changes across the duration of the wet season (**Tables 5-17 to 5-19**). During months of higher flow (>1000L/s, January to June) residual monthly 10^{th} percentile, median and 90^{th} percentile flows to the estuary do not drop below 80% of pre-dam flow conditions under the 15Mdptpa production scenario, other than the monthly 10^{th} percentile (71.6%) and median (74.1%) flow for January and 10^{th} percentile flow for June (72%). During the January to June period of higher flow at 30Mdptpa production, the residual 10^{th} percentile flow falls below 80% of pre-dam flow in January, February, May and June (in the range ~71 to 76%). Residual median monthly flows are also below 80% of pre-dam flows in January (71.6%) and June (72.8%). At the 50Mdptpa production rate, the residual 10^{th} percentile flow falls below 80% for all months of higher flow other than April (in the range 71.6 to 73.5%). Residual median monthly flows are also below 80% of pre-dam flows (in the range 71.6 to 77%) for all months other than March and April and the 90^{th} percentile flow also drops below 80% for January (72.1%) and June (73.2%).

Where there are reductions of >20% magnitude for annual flow statistics for total flows to the estuary for the months prior to the March flow peak, there is an increased likelihood of some impact to wet season primary productivity and fisheries recruitment within the Norman Creek estuary. Mechanisms could include detention of upper catchment organic load inputs, reduced nutrient exports from the affected tributary stem, reduced displacement of prey populations to

the downstream estuary and higher salinity constraints on prey or larval recruitment or freshwater macrophyte habitats. "Late" wet seasons are associated with significantly reduced recruitment in some estuarine fisheries, particularly Barramundi (Robins *et al* 2006).

However, given the timing and relative magnitude of the March peak flow event is maintained despite the presence of the dam, and that mean monthly flows to the receiving estuary are generally maintained above 80% of pre-impact flows for the core wet season period, such impacts to fishery productivity, if they occur, are predicted to be small.

In wetter years it is likely that the impact of any reduced primary productivity and fisheries recruitment associated with reduced flows from the affected estuary stem would be swamped and masked by the productive potential of the broader estuary ecosystem. The magnitude of impact experienced by the broader estuary would be expected to be within the range of variation naturally experienced during annual wet seasons due to El Niño – La Niña rainfall cycles, and variable monsoonal trough and cyclonic rain depression formation; however, these impacts would be directional over the longer term and are likely to be measurable under the 50Mdptpa development scenario.

Dam Seepage

The lateritic landscape of the Project area has relatively high levels of permeability as demonstrated by observed rates of rainfall infiltration and the commonly observed contributions of groundwater to streamflow via multiple macro pores within and on the margins of drainage channels. Water storage impoundments constructed in this landscape give rise to elevated head pressure and have the potential to cause seepage to shallow groundwater aquifers hosted in the lateritic profile of the host material in which the dams are constructed. If such seepage moved under or around the dam wall cut-off trench and extends to topographic lows on the downstream side of the water storage dam there is a high likelihood that it may express as groundwater discharge to receiving stream reaches downstream, potentially at a level of contribution that may exceed surface flow inputs. Experience gained from water quality monitoring in bauxite landscapes north of Weipa indicates that when groundwater inputs are the dominant component of stream flows, low dissolved oxygen concentrations and elevated iron concentrations often occur and can result in an up to one unit decrease in surface water pH when the iron oxidises. Such anoxic and low pH conditions can drive significant changes in habitat and aquatic community composition. The dominance of groundwater flows also increases the bioavailability of manganese, as evidenced by increased bioaccumulation of manganese in aquatic organisms downstream of such groundwater inputs. Where these influences of dominant groundwater inflows have been observed in other bauxite catchments (Pine River), observed water quality and habitat changes have been limited to relatively restricted (<1km) extents of the receiving stream reach and conditions beyond that point are indistinguishable from other surface flow dominated reaches. The potential for water quality and habitat impacts associated with dam seepage to occur at Dam C would depend upon the suitability of host basement rock from a permeability and structural engineering perspective to prevent downstream seepage. If dam seepage emerges as a likely risk during geotechnical investigations for water storage dam construction, specific environmental flow release strategies would need to be devised to mitigate potential water quality and habitat impacts.

Released Dam Flows Water Quality

Flow releases from Dam C are a potential source of water quality impact to receiving downstream ecosystems. If the water storage dam is stratified, deeper water layers may be significantly cooler than the surface and be low in dissolved oxygen and high in dissolved nutrients and metals (Fe, Mn). The risk of impact to water quality is usually greatest following the initial inundation period post construction when submerged vegetation and organic material decomposes and provides a source of biological oxygen demand that can create anoxic bottom layers that may "roll over" during cool weather events or possibly in response to cooler temperature inflows. This risk would be mitigated by clearing and burning of vegetation prior to dam inundation. Water quality monitoring results in a 12m deep water storage dam constructed in a bauxite catchment north of Weipa (Ely Dam, Pine River catchment) indicate that the clear water conditions associated with an established water storage dam in a bauxite catchment

promotes mixing throughout the 12m water column and limits opportunities for thermal and water quality stratification. Outlet works design, water quality monitoring and environmental flow strategies provide mitigation opportunities to manage potential impacts to water quality associated with flow releases from Dam C.

Artificial lakes

From a habitat perspective one of the potentially positive ecological impacts of the water storage dam construction would be the creation of perennial lake habitat that would increase the extent of perennial freshwater habitat available within the impounded catchment. This would act as aquatic refugia for obligate freshwater biota that may be exposed to increased habitat stresses elsewhere in the developed catchment. Maintenance of aquatic habitat connectivity with downstream reaches (**Section 8.16**) is prerequisite for the realisation of the full productive potential of such artificial habitats which would still be limited by water resource utilisation needs and associated water level fluctuations. Experience gained from other water storage dams constructed in bauxite catchments in the Weipa area indicates that their ecological function is comparable to natural lagoons in the area, due in part to the natural affinity of the local aquatic fauna and flora to seasonal tree swamp and lake conditions.

8.14.1.3 Catchment Hydrological Changes From Ward River Pumping

To supplement the water supply provided by Dam C on a freshwater tributary of Norman Creek under the 30Mdpatpa and 50Mdptpa production scenarios, it is proposed that a pumping station be established on the lower Ward River, above the tidal influence (see **Figure 1-3**). The pumping would be subject to the following constraints:

- pumping would only occur when river flow is above 1000L/s;
- extraction rate not to exceed 20% of river flow at any time;
- maximum extraction rate not to exceed 1200 L/s; and
- overall annual extraction not to exceed 1% of mean annual flow (2.67GL) at pump location.

The daily water balance model was used to model the change to downstream flow at the 30Mdptpa and 50Mdptpa production rates (see **Section 5.2.3**). The changes to flow under both production rates are very similar and the results at 50Mdptpa are summarised in **Table 5-20.**

The modelling shows that the annual extraction from the Ward River at maximum production comprises no more than 1% of the mean, median or 90th percentile flow volume and no more than 1.4% of the 10th percentile flow. Flow to the whole Ward estuary would be reduced by no more than 0.6% of mean, median, 10th and 90th percentile flow. This level of extraction is considered to present no potential for observable impact to the Ward River estuary.

The volume of water extracted varies throughout the year with 88% (2.21GL) of the annual total being pumped on average from December to July. Water would be pumped in the drier months only if the preceding wet season was well above average and sufficiently wet to maintain a minimum 1000L/s flow in the river. Mean monthly extraction does not exceed 5.3% of mean monthly river flow in any month except July (16.6%). Mean monthly flow to the whole Ward estuary is not reduced by more than 2.5% in any month except July (7.8%).

The potential for downstream impact due to the peak extraction in July is mitigated by four factors:

- the small change in the months before and after July (i.e. the change is short-term);
- the decline is well within normal seasonal variation (e.g. the 10th percentile natural July flow is 80% less than the mean July flow);
- there is no pumping when river flow is <1,000L/s; and
- there is only a short downstream freshwater reach below the pump station

The only potential impact that could occur may be an upstream retraction of the freshwater–mangrove riparian vegetation community ecotone in the longer term. Such impact, if it did emerge, is likely to fall within the range of inter-decadal variation naturally experienced during annual wet seasons due to El Niño – La Niña rainfall cycles, and variable monsoonal trough and cyclonic rain depression formation. RTA would monitor river flow at the pump station using flow meter as described in **Section 5.5.1** and the position of the freshwater–mangrove ecotonal boundary by using aerial photography as described in **Section 8.14.2.1**.

8.14.2 Mitigation Measures

8.14.2.1 Catchment Hydrological Changes due to Mining

Progressive mining and rehabilitation of 27,290ha of the Project area over a 40-year mine plan represents a significant disturbance to the catchments hosting the Project area's aquatic ecosystems. The extent to which this catchment disturbance generates downstream hydrological impacts would be mitigated by commitment to mine development and rehabilitation approaches that are informed by the hydrological behaviour and requirements of the catchment's surface and groundwater systems. The principal mitigation commitment is to mining operations and post-mine rehabilitation strategies that ensure developed catchments still effectively deliver the groundwater recharge and surface runoff needed to sustain downstream aquatic ecosystems.

Pre-mining Definition of Sub-catchment Hydrology

The ability to define potential hydrological impacts at a reach or sub-catchment scale is currently limited by the resolution of surface and groundwater hydrological data for the Project area. To improve the understanding of the Project area's hydrology and the capacity for adaptive management responses, the establishment of baseline hydrological data for representative sub-catchments draining proposed mining blocks would form part of the environmental monitoring regime adopted for mining development. These hydrological investigations would effectively establish the pattern of surface drainage, seasonal groundwater profiles, partitioning of surface runoff and groundwater base flow, and seasonality of downstream flow hydrograph and perenniality / aquatic refugia within receiving surface drainage systems.

Mine Pit Drainage and Detention Management

Active mining pits represent the maximum hydrological disturbance footprint of the proposed mining development cycle in terms of the potential alteration of the downstream flow duration curve and of the relative contribution and partitioning of surface and groundwater flows to the catchment. Hydrological impact mitigation options during this stage of catchment development are primarily limited to the layout of mine drainage systems. As far as practicable drainage would be routed to match the discharge characteristics of the pre-mine surface drainage networks at the overall sub-catchment scale in order to emulate the pre-mining hydrograph and runoff flow characteristics.

Hydrologically Informed Post-Mining Rehabilitation

Emulating the pre-mining runoff flow characteristics and flow duration curve at the sub-catchment scale would be an aspirational objective of post-mining landscape rehabilitation strategies. Specific measures would include: ripping of compacted pit floors to facilitate infiltration to groundwater, contouring of mine pit and final land surfaces to route surface runoff to match pre-mining drainage networks where possible and the incorporation of seasonal wetland basin detention areas (revegetated with appropriate wetland species) where required in the post-mining landscape. Hydrological data from control sub-catchments (described above) would be used to assess the performance of post-mining landscape rehabilitation techniques and to support adaptive management improvements in subsequent cycles of mine block development.

Monitoring and Assessment of Hydrological Performance

Specific ecological monitoring activities would be implemented over the life of the mine to assess the performance of hydrological impact mitigation strategies and to inform ongoing and future mine development. Detailed (~1:10,000 scale) mapping of vegetation ecotonal boundaries including: terrestrial–freshwater, freshwater–tidal, and sclerophyll–fire sensitive interfaces in mined sub-catchments would be mapped from aerial photographs (with ground-truthing) and input to a Geographic Information System (GIS) and monitored and remapped on a decadal (10-year) frequency. This data would provide an ability to assess the relative contribution of both natural and mining-induced changes to catchment hydrological conditions to vegetation boundary movements that emerge over longer-term (decadal) time scales. Dry season monitoring surveys of freshwater aquatic refugia extent and distribution within mined sub-catchments and the aquatic organism communities they contain would also be used on a 3–5 yearly frequency to provide ongoing assessment of catchment hydrological impact mitigation effectiveness.

8.14.2.2 Catchment Hydrological Changes Generated by Dam C and Ward River Pumping

Four groups of mitigation measures can be identified for the potential impacts associated with catchment hydrological changes generated by the construction and operation of proposed water infrastructure.

Dam Wall Construction

Thorough geotechnical investigations and construction methods that ensure as far as practicable that the constructed dam wall is keyed into impermeable basement and batter foundations would provide the best opportunity to mitigate the water quality and hydrological impacts that could be associated with dam seepage to downstream reaches. If geotechnical investigations indicate that dam seepage would be a significant issue for water storage dam management, specific environmental flow strategies would be needed to mitigate potential water quality impacts. The reach downstream of the proposed dam wall site includes riffle and run features that would serve to re-oxygenate dominant groundwater inflows if they develop and would effectively limit the downstream reach of potential water quality impacts and the volume of environmental flow release required to counter groundwater inflow dominance.

Design of Outlet Works

Experience with other water storage dams in bauxite dominated catchment in the region (Ely Dam, Pine River Basin) suggests that impoundment stratification is not a significant management issue for dams up to 12m deep. However, the behaviour of the proposed water storage dam in the Project area cannot be predicted confidently enough to entirely dismiss the potential for stratification. While the proposed off-take from the dam is a low level one, the design would allow for the future retro-fitting of a variable higher level off-take should dam stratification emerge to be a significant management issue.

RTA proposes that the outlet works will be designed to accommodate a release flow rate of up to 1000L/s.

Environmental Flow Strategies

Dedicated environmental flow releases in addition to spillway overflows have been identified as a mitigation measure for a range of potential impacts associated with the proposed water supply dam including:

- maintenance of some downstream flow while there are still upstream inflows into the dam;
- allowance for some early "onset of wet" season flows otherwise delayed by dam filling;
- maintenance of seasonal salinity regimes within natural ranges in upper estuarine / tidally influenced freshwater reaches;
- maintenance of geomorphic features associated with post wet season base flows; and

- dilution of groundwater dominance and associated water quality impacts where dam seepage (or enhanced groundwater recharge/discharge associated with mined catchments) generates increased groundwater inputs to reaches downstream of the dam.

There is currently insufficient system understanding to detail all operational characteristics of environmental flow regimes that could deliver the impact mitigation aspirations listed above or whether certain mitigations might be needed at all. Monitoring and adaptive management responses (below) would be a prerequisite for the ongoing assessment of effectiveness and development of such mitigation capacity. RTA proposes that Dam C would be fitted with a low level outlet pipe which would permit the controlled release of environmental flows (up to a maximum of 1,000L/s) when required. Continuous streamflow gauging stations would be installed upstream and downstream of the dam in order to assess the impact of the dam on flow and allow information on inflows to inform decisions on environmental flow releases.

RTA proposes the following initial operating criteria for dry season environmental flow releases:

- sufficient water in each dam would be reserved for environmental flows to enable releases of up to 25% of inflows during the mid to late dry season (August–October) and 5% of inflows at other times; and
- when dam inflows cease, environmental flow releases would cease.

The above criteria would be subject to change based on operating experience and the results of monitoring.

Modelling shows that once the dam is full following the onset of the wet season, the spillway would typically overflow continuously throughout the rest of the wet season. Environmental flow releases are unlikely to be necessary during this period and, if they are, they are likely to be infrequent.

It is necessary for the maintenance of the reliability of the Project water supply that the dam fills quickly at the start of each wet season. This mitigates releasing significant volumes of water during the dam filling period (which would typically take four to eight weeks depending on the residual water level and climatic conditions). The dam has been sized to allow for environmental flow releases equal to 5% of dam inflows during the dam filling period. If larger volumes were to be released, the dam wall would have to be raised to maintain the same reliability of supply, with consequential increases in the surface area of inundation. However, the release of up to 25% of inflows during the mid to late dry season (August–October) is proposed in order to mitigate the potential development of ecologically critical salinity levels in the receiving estuary stem during this period.

With regard to pumping from the Ward River, potential impacts associated with extraction of streamflows would be effectively mitigated by restricting pumping to (a) 1% of mean annual flow in any one year, (b) less than 20% of river flow at any time, and (c) times when flow is >1,000L/s. The primary focus of this pumping regime is to ensure maintenance of seasonal salinity regimes in upper estuarine / tidally influenced freshwater reaches.

Monitoring and Adaptive Management

Further monitoring and characterisation of the receiving reaches downstream of the proposed water supply dam is recommended to support a responsive, adaptive management capacity for potential impacts. Continuous streamflow gauging stations would be installed upstream and downstream of the dam in order to assess the impact of the dam on flow. Key areas for further investigation include:

- magnitude and temporal patterns of post wet season extended base flows (monitor and characterise up to dam construction);
- seasonal salinity regimes in upper estuarine reaches and their relationship to surface base flows, groundwater inflows and reach habitats (quarterly vertical salinity profiling and macrophyte community monitoring at upper estuary water quality sampling sites);

- existing groundwater inflow rates in receiving reaches and their relationship to ambient dissolved oxygen levels, soluble aluminium, iron and manganese concentrations (at least quarterly water quality monitoring);
- measurement of water table levels in vicinity of Dam C (at least quarterly);
- maintenance of aquatic faunal communities in receiving reaches (fish and other aquatic fauna surveys on a 3–5 yearly frequency); and
- mapping of fine scale zonation of freshwater dependent riparian and wetland vegetation communities in tidally influenced lower freshwater reaches (aerial photography interpretation, mapping and GIS input on a decadal frequency).

It is proposed that such monitoring activities be established and maintained on the tributary stem to be affected by Dam C.

The following monitoring is proposed in relation to the Ward River pumping station:

- Continuous flow monitoring of the river and monitoring of pumped volumes.
- Mapping of fine scale zonation of freshwater dependent riparian and wetland vegetation communities in tidally influenced lower freshwater reaches (aerial photography interpretation, mapping and GIS input on a decadal frequency).

8.15 Potential Impacts and Mitigation measures – Elevated Sediment and Contaminant Loads

8.15.1 Potential Impacts

8.15.1.1 Elevated catchment sediment loads

Clearing vegetation cover for mining and infrastructure development, including road corridors, in a seasonal tropical environment subject to monsoonal and cyclonic rainfall events may result in elevated sediment loads in catchment runoff from the Project area at some stages of the development cycle, albeit a minor consideration given that direct surface runoff is less than 1% of incident rainfall.

Sediment can act as a stressor in aquatic systems both in suspension (turbidity/total suspended solids) and when it settles out (sedimentation). Impacts associated with long-term elevation in turbidity on stream flora and fauna typically include:

- loss of faunal diversity on a local, and perhaps more widespread, scale, as many species are intolerant of elevated turbidity;
- migration impediment or prevention for sediment intolerant fauna;
- loss of aquatic macrophytes and algae due to smothering by sediment and/or loss of instream primary production due to light attenuation and scouring; and
- loss of benthic habitat due to smothering and infilling by sediment.

The mechanisms of action of TSS are typically indirect and, therefore, may be very complex in their details. Consequently, the responses of different aquatic species to different types of solids are highly variable. The streams of the Project area generally have very low turbidity. This is due in part to (a) the very small proportion of direct surface runoff, (b) the filtering effect of water passage through the lateritic groundwater aquifers to streams, and (c) the charged surface structure of the alumino-silicate matrix of most particles enhancing flocculation and settlement rates. In some circumstances these drivers of surface water clarity can be over-ridden for short periods by the high intensities of local rainfall.

The tolerance of the local ecosystems to suspended sediment is unknown. Many species present in the Project area are widespread in the Western Cape region and occur in other, more turbid, catchments. However, as is noted above, the Project area assemblages include species that favour clearwater conditions. The aquatic floras are likely to be highly dependent on the

current water clarity. Given the habitats and biology of the fish, plant and macroinvertebrate communities, they are assumed to be intolerant of long exposure to elevated suspended sediment concentrations and sedimentation. The following points summarise the sensitivities of the local aquatic communities:

- A number of the fishes in the Project area are visual predators susceptible to elevated turbidity reducing the effective visual range.
- Many macroinvertebrates feed by shredding, scraping or collecting plant matter or by filtering organic matter from the water. These organisms are susceptible to abrasion and clogging of delicate feeding and breathing apparatus. They are also susceptible to alterations in the organic content of bed sediments. The most sensitive macroinvertebrates are those that are adapted to feed on fine food particles in clear water. These species are present in higher numbers in the catchments in the Project area than is typical for stream systems, suggesting a strong dependency on the current low TSS conditions.
- Aquatic macrophytes and algae are photosynthetic organisms that are susceptible to alterations in the light levels reaching the creek surface and light levels penetrating through the water column. Plants and algae are also susceptible to sedimentation and scouring. Macrophytes are important habitats for many faunal species and the high taxonomic proportion of scrapers among the macroinvertebrates testifies the importance of algae to aquatic food chains in the Project area.
- Deep pools are important perennial refugia and the infilling of pools due to potentially increased sediment loads could be highly detrimental.
- Benthic macroinvertebrates also have specific fine-scale habitat requirements and are susceptible to alterations in interstitial space abundance and sizes and coatings of bed surfaces due to sedimentation.
- Some of the fish species recorded from the Project area are very brightly coloured and colour displays can play an important role in their breeding behaviour. Elevated turbidity may adversely affect the ability of fishes to sense these visual displays and, therefore, the success of breeding.
- Some fish species are known to spawn in gravel/sand beds. These species would be expected to be susceptible to alterations in creek-bed substrate grain size and composition that may arise due to potential sedimentation. Other species lay adhesive eggs on creek-side vegetation, aquatic macrophytes or hard substrata. These spawning modes are susceptible to impacts from habitat smothering or dieback of macrophytes.

The above characteristics, in the absence of established measures of sediment tolerance, indicate that the local aquatic ecosystems are likely to be highly sensitive to elevated sediment inputs underpinning the required commitment to effective sediment runoff mitigation measures (**Section 8.15.2**). Exposed soil and subsoil surfaces created after vegetation clearing during the mine development phase are at risk of contributing to rainfall-derived sediment load spikes, including from haul road crossings of drainage lines. Mining pits retain overland flow due to their lower topographical position in relation to the relatively flat surrounding landscape. Clearing and soil stripping is scheduled in the dry season so that pit development is underway by the onset of the wet season, thus minimising the risk of runoff from disturbed areas entering creeks. The experience gained at existing operations in managing sediment runoff risks posed by mining operations in this environment (e.g. the use of internally draining mine pits) would serve in mitigating the potential impacts associated with possible elevated sediment loads.

In the absence of established measures of sediment tolerance the local aquatic ecosystems are likely to be highly sensitive to elevated sediment inputs underpinning the required commitment to effective sediment runoff mitigation measures (**Section 8.15.2**).

8.15.1.2 Contaminants derived from Mining, Processing and Handling Operations

Metalliferous mining necessarily occurs in mineralised catchments. The mineralisation is natural and the local aquatic ecosystems must be adapted to the natural levels of exposure to the constituents of that mineralisation. However, mining has the potential to enhance the inputs of metals into ecosystems as a result of increasing the exposure of the mineralisation to the air and rainfall.

There may be the potential for increased dissolved metal concentrations in recycled process water from the beneficiation plant including tailings liquid, in runoff from mine workings and possibly in runoff from ore stockpiles. Mining and beneficiation of ore would expose new surfaces that have not necessarily been as exposed to leaching in-situ as is otherwise typical of the lateritic deposits. Subsequent washing in the beneficiation plant or exposure to rainfall in the stockpiles may mobilise metals from those fresh surfaces into solution.

The following has been considered in terms of potential impacts on aquatic ecosystems as a result of altered metals concentrations that could occur from mine development:

- There may be a risk of further increasing the exposure of organisms to aluminium due to construction and, to a lesser extent, operation activities mobilising additional sediment to waterways or altering groundwater – surface water interactions.
- Toxicity and environmental tolerance in fishes is a "concentration × duration" relationship that is non-linear. That is, the biological response to metal concentrations does not increase in a consistent fashion with increasing concentrations; rather, once a tolerable threshold value has been reached, small additional increments in metal concentrations can result in greatly increased detrimental responses. The concentrations that can be tolerated in short-term exposures tend to be much greater than the concentrations that can be tolerated in the long term. Under baseline conditions, organisms may be exposed to short periods of elevated aluminium concentrations, particularly in the late dry season and wet season. However, the key point is that there are periods of reduced aluminium concentration ("recovery" periods). The toxicity risk to aquatic organisms has the potential to be increased by altering the "concentration" or the "duration" component of their exposure; by altering both, the risk increases substantially.

Background dissolved aluminium concentrations in the surface waters are naturally above default ecosystem protection guidelines and should, in a precautionary framework, be regarded as potentially imposing some natural toxicity to aquatic organisms.

The natural aluminium concentrations in freshwaters were generally substantially higher than estuarine waters. The median for freshwater streams was 18µg/L and that of tree swamps 40µg/L, compared with 2.5 to 4µg/L for estuarine and marine waters, respectively. The percentage of taxa that might be at risk under natural conditions in freshwaters may be greater than for estuarine waters, and the potential implication of an increase in median aluminium concentration to the 80th percentile concentration could also be substantially greater.

Bauxite is an oxidised and leached material, not prone to acid generation and thus acid drainage. However, the nature of the aluminosilicate structure of bauxite is such that it will tend to scrub ions from solution in waters passing through the laterite layers; hence, the freshwaters of the Project area have been found to have very low hardness, a characteristic that can enhance the toxicity of some metals (ANZECC/ARMCANZ 2000, Markich *et al.* 2001, Waller *et al.* 2005, Markich and Camilleri 1997).

Crude ore from the Project area, and ore and tailings solids from existing Andoom and East Weipa operations, have been analysed for metals (Rio Tinto 2009b). In addition, tailings liquid, water from tailings recovery slots, shallow aquifer groundwater, and runoff from existing product stockpiles were also analysed. The results and implications are summarised below.

- Aluminium concentrations in runoff from the Lorim Point bauxite stockpile indicated a relatively low (compared with Project area surface water samples) filterable aluminium concentration of 7µg/L.

- The tailings liquid for East Weipa had a mean aluminium concentration of 25µg/L, within the background SoE Project range for surface waters (the median for freshwater streams was 18µg/L and that of tree swamps 40µg/L). The Andoom tailings liquid had a mean aluminium concentration of 216µg/L owing to the increased use of artesian water, which is above the 80th percentile calculated for any freshwater site in the Project area but within the range found in late dry season sampling of site waters (refer **Table 5-9**).
- The concentration of aluminium in recovery slot water is less than or similar to that of the tailings liquid.
- The results, while a limited dataset, suggest that bauxite stockpiles may not be a significant contributor of aluminium to surface water ecosystems via runoff, but that tailings liquid and some tailings seepage waters may contain aluminium concentrations of potential environmental significance.
- The following metals were not detected in tailings liquid at concentrations greater than the reporting limit: arsenic, boron, cobalt, copper, lead, nickel, selenium, zinc and mercury. This, combined with the lack of enrichment in the ore, indicates these elements are not considered potential constituents of concern for the Project area.
- Tailings solid and ore samples were collected for leach analyses using two analytical methods. A de-ionised water bottle leach procedure was completed (AS4439.3) over a period of 18 hours and a 1:5 solid/water dilution leach test using deionised water over a 1-hour period. The bottle leach procedure presents a more conservative result. Results of both methods are presented in **Table 8-18** and **Table 8-19** respectively. The concentration of aluminium in tailings leachate was 10µg/L as a result of method AS4439.3, less than the median of Project freshwater streams (18µg/L); the concentration of aluminium in ore leachate was less than the laboratory limit of reporting and the 80th percentile (40µg/L). Based on these results, leaching from ore is not anticipated to have an adverse effect on surface or groundwaters.

Aluminium, iron and manganese would be monitored and results compared to the Project trigger values (refer **Section 5.5.1**).

8.15.1.3 Estuarine Water Quality

The higher water use scenarios planned for Stage 2 development for production rates of 30Mdpta and above are estimated to reduce mean annual flow to Norman Creek estuary by 9.8% at 30Mdpta and 15.1% at 50Mdptpa. The corresponding 10th percentile annual flow reductions are predicted to be 16.9% and 24.2%, respectively. It has also been predicted that shallow groundwater inflows to the estuary would increase. Samples taken from the Ward River estuary in the late dry season (December 2008) showed that under conditions of low or no surface water inflows, but strong groundwater inflows, the concentrations of aluminium, iron and manganese in estuarine waters were greatly enhanced compared with other times of the year, and also higher than those found for the Norman Creek estuary at the same time of the year (Section 5). The altered downstream flow regime that would result from the Stage 2 dam development is likely to be analogous to having lower late dry season surface water flows for longer than would otherwise be the case under any given rainfall scenario. Aluminium, iron and manganese concentrations in Norman Creek estuarine waters would likely remain within natural ranges, but at the upper end of that natural range for an increased period. Some alteration of the ecosystems in response to this change to the aluminium regime cannot be ruled out.

The available data on the metal content of SoE ore, and Andoom and Weipa ore and tailings, was evaluated in terms of enrichment of metals (refer **Section 13.3.4**; Rio Tinto 2009a). The Geochemical Abundance Index (GAI) was assessed using the Average Crustal Abundance described in Bowen (1979). The DME/DEH (1995) guideline *Assessment and Management of Acid Drainage* states "a GAI of greater than 3 indicates significant enrichment to a level that warrants further examination". From this assessment, there are no elements that have a GAI greater than 3. Therefore, the following metals are not considered enriched in the Project area and thus not potential constituents of concern: arsenic, chromium, copper, cadmium, lead, nickel, zinc and selenium.

The Project would require the movement and use of large quantities of hydrocarbons in the form of fuel and lubricants during construction and operations. Material would be transported in road tankers via barge to the mine infrastructure areas in accordance with Australian Standard *AS 1940* (refer **Section 19.1**). Potential impacts of hydrocarbons must also be considered – both acute impacts resulting from substantial spills and chronic impacts via low-level releases

and spills from operating machinery, workshops and storage facilities. It should be noted that wetlands, which are key, high value ecosystems in the Project area, tend to be particularly sensitive to hydrocarbon spills. Other toxicant risks, such as sewage effluents would be largely concentrated around the major infrastructure such as the proposed port and beneficiation plant. These areas would largely be remote from any substantial natural watercourses or wetlands, but the potential for impacts from these areas on aquatic ecosystems should be considered in environmental management planning.

8.15.2 Mitigation Measures

8.15.2.1 Elevated catchment sediment loads

The Project proponent's experience in managing sediment runoff risks posed by mining operations in this environment provide the foundation for mitigating the significant risks that are associated with the inherent vulnerabilities of the Project area's aquatic ecosystems. The persistence of aquatic communities equivalent to the Project area's in drainage systems of the Weipa Peninsula to the north of the Project area attests to the impact mitigation capacity of appropriate management approaches for sediment runoff. These mitigation measures include three key areas of operation:

Buffer Maintenance

The retention of effective development "setback" vegetation buffer systems (refer **Section 7.9.2**) around and adjoining surface drainage lines and wetland features represents the frontline in the effective management of elevated sediment load risks confronting aquatic ecosystems. The buffer retention practices currently employed in the Weipa area to the north and proposed for the Project area generally out-perform those associated with many other land uses including agriculture and urban development.

Controlled Drainage Systems

The very high water clarity in most Project area surface waters and the dependence of the existing aquatic ecosystems on this water clarity require that high standards of sediment retention would be required for any discharges. All mine pit development would be required to adhere to sediment run-off management practices including the retention of surface runoff from mine pits within the pit before it reports to surface drainage networks. In limited situations where the topography does not facilitate internally draining mine pits, sediment control would be maintained by use of sediment retention ponds and vegetation buffers. Where haul roads and other infrastructure intersect sensitive environmental areas, environmental management planning would require the implementation of sediment control traps to intersect surface runoff before it reports to surface drainage systems. Clearing of riparian vegetation to facilitate infrastructure crossings of surface drainage lines would be minimised by careful route selection in association with mine planning. These mitigation measures are expected to effectively reduce catchment sediment loads.

Development Cycle Timing

Native vegetation removal presents soil erosion risks; however, these can be managed in a seasonal environment by careful consideration of development timing and location. All clearing of vegetation for development would be controlled by contractor permit requirements for "ground disturbance". Clearing and soil stripping would be scheduled in the dry season so that mine pit development is generally underway by the onset of the wet season, providing a basin to capture surface runoff, which minimises the risk of runoff from disturbed areas entering stream drainage networks.

Monitoring of Performance Measures

Environmental management planning would be underpinned by effective monitoring of performance measures and adaptive management. Monthly monitoring of turbidity in receiving waters of the Project area throughout the wet season would be undertaken (refer **Section 5.5.1** and **Table 5-32**). It is proposed to set a Project trigger value for turbidity based on the 80th percentile baseline value (refer **Section 5.5.1**).

8.15.2.2 Contaminants derived from Mining, Processing and Handling Operations

Mitigation options to address aquatic ecosystem risks posed by catchment runoff containing potential contaminants derived from mining, processing and stockpiling include minimisation at source, containment using infrastructure layout design and controlled drainage, effective monitoring and adaptive management responses.

Source Management

Leachate analyses of metals in SoE crude ore samples show that none are elevated to a degree that would pose a risk to the natural environment (Rio Tinto 2009b). However, if elevated metal levels were to be found in ore, the primary management approach would be the use of internal drainage routes for mine pit runoff. The routeing of mine runoff via groundwater aquifers would provide opportunities for potentially elevated soluble metals to be reabsorbed by the aluminosilicate structure of bauxite in the host laterite. Monitoring of surface waters in receiving drainage systems would provide ongoing assessment of this management approach.

Mitigation measures for other potential contaminants primarily relate to refuelling, fuel/chemical storage and spill response protocols, structures and procedures and are discussed in **Section 19.1** and **Section 19.3.1**. These measures would include bunded fuel storage and refuelling areas, spill emergency response measures and controlled drainage of runoff from industrial plant areas.

Infrastructure Layout and Controlled Drainage

Key considerations from a runoff contaminant management perspective include the locations of potential contaminant sources in relation to contributory catchment area, wet season runoff rates and inundation levels. Runoff from industrial plant areas would be controlled via collection to the site water management system. The design criteria and operation of the system is discussed in **Section 5.2.2**. The tailings storage facilities are located within previously mined and internally draining pit areas and are remote from major drainage lines; this mitigates the potential risks associated with runoff potentially high in soluble aluminium to receiving surface waters.

Performance Monitoring

The locations, parameters and frequency of the proposed surface water and groundwater monitoring program are detailed in **Section 5.5**, which concentrates on pH, EC, dissolved oxygen, turbidity, certain metals and hydrocarbons (in specific locations). If water quality monitoring or other evidence indicates that elevated metal bio-availability has occurred due to mining activities then bio-monitoring of tissue metal concentrations in selected tissue of fish and other aquatic organisms (i.e. crabs, crayfish) would be used to identify possible sources.

8.16 Potential Impacts and Mitigation measures – Loss of Aquatic Habitat Connectivity

8.16.1 Potential Impacts

8.16.1.1 Water Supply Dam Wall and Stream Crossing Infrastructure

The reasons why a freshwater tributary of Norman Creek was chosen as a dam site for water supply for the Project over other alternatives is summarised in **Section 5.2.3**. While the majority of the freshwater fish communities within the Project area have been found to comprise few migratory species, the extreme seasonality of freshwater habitats imposes a requirement for movement and recruitment from restricted dry season refugia and suitable nursery areas to seasonally abundant aquatic habitats. A few species, including the Plotosidae catfish are potamodromous, i.e. migrate within freshwater reaches to find suitable spawning habitats (in their case flowing riffle reaches), and several others including key fishery species (e.g. Tarpon, Barramundi and Mangrove Jack) are catadromous and move between estuarine and/or marine spawning and/or nursery areas and freshwater reaches. The limited availability of some spawning habitats, such as aquatic plant beds utilised by some species within the

Project area, may also require otherwise sedentary species to move between reaches for recruitment and spawning success.

Infrastructure constructed within or across stream drainage lines including the proposed water supply dam wall (8m for 10.9GL storage capacity, 12m for 29.0GL storage capacity) and more innocuous haul road stream crossings has the potential to create fish passage barriers and to disrupt the recruitment and movement of species from dry season refugia or downstream estuarine habitats, therefore impacting the distribution of fish species and the composition of fish communities within the Project area. In the case of some cornerstone species (e.g. key predators some of which, including Barramundi, are also species of fishery importance) impacts of reduced fish passage may cause flow-on effects in terms of changes in fish community structuring or reduced recruitment levels to fisheries. However, the potential for the latter is very limited given the relatively small component of the fish community above the proposed water supply dam site was observed to comprise catadromous species such as Barramundi. Alternatively, the artificial habitat created by the water supply dam would be suitable for species such as Barramundi and the maintenance of fish passage access to this habitat would provide an opportunity to support fishery recruitment (helping to balance other potential impacts to fishery recruitment) and to maintain naturally structured prey communities.

8.16.1.2 Hydrological and Geomorphological Impacts to Connectivity

Besides physical structures associated with in-stream infrastructure, altered hydrological and/or geomorphological conditions that may potentially occur at a sub-reach scale due to impacts associated with catchment development (e.g. shorter duration stream base flows, less perennial aquatic refugia, sedimentation of stream channels and/or pools) could also potentially impact upon aquatic habitat connectivity and fish passage opportunities in the Project area. This could generate similar natured impacts (though at an order of less magnitude) to those described above for physical passage barriers including localised extinctions of some aquatic community members associated with reach scale losses of or reduction of access to aquatic refugia. Importantly, it needs to be recognised that not all potential impacts on aquatic habitat connectivity would be unidirectional. Predicted increases in deep base flow and potentially increased or more rapid catchment discharges associated with mining impacts could also serve to extend perenniality of some pools and reaches and generate deeper stream channels and scour pools which improve aquatic habitat perenniality and/or connectivity between aquatic refugia. Ultimately, aquatic habitat connectivity impacts associated with altered hydrological and geomorphological conditions are not anticipated to be significant at a catchment scale due to the limited magnitude of predicted changes and the likelihood for compensatory impacts.

8.16.2 Mitigation Measures

8.16.2.1 Water Supply Dam Wall and Stream Crossing Infrastructure

To mitigate the potential for impacts to aquatic habitat connectivity associated with the dam wall and stream crossing infrastructure there would need to be a fish passage structure incorporated into the water supply dam and other in-stream infrastructure, sensitive management of surface drainage and implementation of potential hydrological impact mitigation measures (described above). Any structure that may act as a fish barrier needs a permit from the Department of Employment, Economic Development and Innovation (DEEDI) under the *Fisheries Act 1994* (Qld). The requirements for maintaining fish passage through road crossings in Queensland have a legislative basis under the Act, and are well described in available technical literature (e.g. Cotterell 1998). The design of the spillway for the water storage dam would be at low gradient (<3%) and incorporate an allowance for fish passage (refer **Figure 5-11**). Road culverts would be designed so as to avoid becoming a fish barrier and design would consider the technical literature on maintaining fish passage (e.g. Cotterell 1998).

The design of Dam C would be required to address fish passage needs as part of required waterway barrier permits under the *Fisheries Act.* The fish passage needs of the fish community at the dam wall location are not considered to be overly critical to the community as a whole. This is because the dam is likely to form large artificial refugia rich in macrophyte habitat that

would suit the majority of obligatory freshwater fish species present; these species would be able to recruit to upstream habitat during flow events and downstream during spillway overflows and/or environmental releases (assuming appropriate outlet works design). Catadromous species (Barramundi, Tarpon, Mangrove Jack) are currently only a small component of the fish community above the proposed dam wall location, though other large bodied species including some of interest to Traditional Owners and recreational fishers, such as Fork-tailed catfish, are observed to seasonally move from lower reaches (predominantly below the proposed dam location) to upper freshwater reaches. While the ecological impacts of not facilitating fish passage at Dam C may not be substantial, there is still sufficient justification to seek to do so from both ecological and social/fishery perspectives.

The proposed water supply dam wall height is too great for the effective use of vertical slot fishways commonly employed for Australian fish communities and engineering constraints and cost prohibitions would prevent the use of other mechanical fishways (i.e. locks, lifts) considered for high dam walls (Worley Parsons 2008). A "hybrid" low gradient rock ramp / constructed channel (Wildman *et al.* 2005) bypass is currently being developed as part of the spillway design. Observations at the Ely Dam spillway constructed on a bauxite catchment stream in the Pine River basin to the north of Weipa indicate that at least one catadromous species (Tarpon) was capable of moving up spillway flows through the hydrological environment created by spillway flow energy dissipaters formed by gabion rock baskets steps. Further development of this type of spillway design to incorporate the lower gradient, turbulence and flow velocity needs of other fish species would appear to offer the best prospect of serving fish passage at these sites. Although such a fishway would only facilitate fish passage during spillway overflow events, this passage opportunity is considered adequate to maintain full representation of potential upstream migrant species in upstream fish communities.

The proposed low gradient rock ramp fishway is considered an effective and adequate mitigation measure for migratory species occurring or potentially occurring within Norman Creek freshwater reaches, including the threatened Sawfish *Pristis microdon.* All catadromous fish species recorded in Norman Creek are known to negotiate rock ramp fishways in eastern Qld drainages (Kapitzke 2010) and the hydraulic conditions provided by the fishway will at least match or exceed the fish passage opportunity provided by higher gradient riffle run bedrock controlled reaches of Norman Creek downstream of the proposed impoundment. Sawfish *Pristis microdon* are also recognised to be capable of negotiating bedrock controlled riffle run sequences (Thorburn *et al.* 2003), and rock ramp fishways are a recommended fish passage barrier mitigation option in drainages occupied by Sawfish *Pristis microdon* (Marsden and Stewart 2005).

8.16.2.2 Hydrological and Geomorphological Impacts to Connectivity

Viable mitigation options for the potential hydrological and geomorphological impacts to aquatic habitat connectivity that may be associated with mining and infrastructure associated changes to catchment hydrology are limited to the range of options generally nominated for minimising the driving hydrological changes, i.e. considering hydrological aspects in post-mine rehabilitation in the case of altered catchment hydrology and environmental flow strategies for water supply dam construction and operation.

8.16.2.3 Monitoring of Impacts to Aquatic Habitat Connectivity

To monitor the potential impacts to aquatic habitat connectivity within the Project area over the mine life RTA would undertake periodic (3–5 year) survey-based monitoring of the freshwater aquatic community within the Project area. Specific foci for such monitoring would include community composition within each drainage system, particularly within dry season refugia. Compositions of the fish community above and below the water supply dam wall prior to construction and following commissioning of the spillway incorporating the fish passage structure would also be undertaken to assess fishway effectiveness and to facilitate adaptive design management if required.

8.17 Summary of EPBC Act Significance of Impact Assessments for Threatened Fauna

The summary "assessments of significance of impact" in this section are based on the *Significant impact guidelines* (DEWHA 2009a) and draws on discussion provided in **Sections 8.13 to 8.16**.

Individual significant impact assessments based on the proposed disturbance of aquatic habitat within the Project area are provided for each of the EPBC Act listed threatened aquatic fauna species assessed as likely to occur in the Project area (as identified in **Section 8.10)**.

These include:

- Critically Endangered species
    - Speartooth Shark (*Glyphis* sp A)
- Vulnerable species
    - Freshwater Sawfish (*Pristis microdon*)
    - Green Sawfish (*Pristis zijsron*);
    - Dwarf Sawfish (*Pristis clavata*).

Key definitions from the DSEWPaC guidelines that apply to this assessment are as follows:

- "Population of a species" is an occurrence of the species in a particular area. In relation to critically endangered, endangered or vulnerable threatened species, occurrences include but are not limited to:
    - a geographically distinct regional population, or collection of local populations; or
    - a population, or collection of local populations, that occurs within a particular bioregion.
- "Habitat critical to the survival of a species or ecological community" refers to areas that are necessary:
    - for activities such as foraging, breeding, roosting, or dispersal;
    - for the long-term maintenance of the species or ecological community;
    - to maintain genetic diversity and long-term evolutionary development; or
    - for the reintroduction of populations or recovery of the species or ecological community.

  Such habitat may be, but is not limited to:
    - habitat identified in a recovery plan for the species or ecological community as habitat critical for that species or ecological community; and/or
    - habitat listed on the Register of Critical Habitat maintained by the Minister under the EPBC Act.
- An "invasive species" is an introduced species, including an introduced (translocated) native species, which out-competes native species for space and resources or which is a predator of native species. Introducing an invasive species into an area may result in that species becoming established. An invasive species may harm listed threatened species or ecological communities by direct competition, modification of habitat or predation.

Due to their utilisation of marine habitats, the Green Sawfish (*Pristis zijsron*) and the Dwarf Sawfish (*Pristis clavata*) are discussed in further detail and an assessment of the significance of impacts provided in **Section 6.9.5.1**. An assessment of the significance of impacts on the Freshwater Sawfish and the Speartooth Shark are provided below.

Freshwater Sawfish (*Pristis microdon*), and Speartooth Shark (*Glyphis sp.)* have not been recorded in surveys of the Project area but are considered likely to occur in the estuarine and lower brackish reaches of the Project area's main drainage systems. If present, these species could potentially be affected by:

- physical disturbance of sedimentary habitats and fauna from dredging for the barge/ferry terminals in the Embley and Hey Rivers; and
- creation of a turbidity plume, spoil deposition and re-suspension of fine sediments.

The fish assemblage is exposed to periodic but significant physical disturbance and elevated turbidity during extreme weather events. Fish species are also mobile and as such can move away from any local areas that are affected by a disturbance (e.g. dredging and dredge spoil deposition). Given the minor scale and short duration of dredging, at each of the barge/ferry terminal facilities it is unlikely that habitat in the Embley and Hey Rivers would be significantly affected.

Freshwater streams within the Project area have extremely low conductivity as their catchments are highly weathered bauxite landscapes which do not contribute salts (Tait 2011). Recorded conductivity values approach those of distilled water. It is hypothesised that these extremely low conductivity values present an osmoregulation constraint on the freshwater fish community that occur in these systems. This is evidenced by the complete absence of records within the Project area for otherwise ubiquitous families, genera and species of freshwater fishes found throughout tropical Australia including in adjoining river systems of the Project area. It is suggested that the extremely low conductivities of the Project area's freshwaters would present an osmoregulation constraint on both the Freshwater Sawfish and Speartooth Shark as they possess a more primitive osmoregulation capacity than modern ray finned fishes.

While the estuarine and possibly lower tidally influenced freshwater reaches of the Norman Creek system do provide potentially suitable habitat for both species, the seasonal freshwater reaches upstream of the proposed Dam C do not. Freshwater reaches of Norman Creek upstream of the proposed impoundment wall have been assessed as not suitable habitat for threatened elasmobranch species, including the Sawfish *Pristis microdon.* They are small and highly seasonal habitats that lack large permanent pools required for these species, lack known prey species particularly schooling fish such as freshwater herring, grunters or mullets (Thorburn and Morgan 2005, Thorburn *et al*. 2003, 2004) or an abundance of even potentially suitable prey species. Further information relating to listed threatened Sawfish and Glyphis A. species is provided in **Appendix 8C**.

Recreational fishing activity as a result of the Project is expected to be no higher than in recent years as the population in Weipa is not expected to increase significantly (refer to **Table 16.3** for projected changes in population). Therefore it would be unlikely that recreational fishing impacts on sawfish and Glyphis species would increase as a result of the Project. Recreational fishing is regulated by Queensland agencies. A permit to enter the South of Embley area must be obtained from the Aurukun Shire Council (refer to **Section 16.3.2**).

Freshwater Sawfish (*Pristis microdon*): Vulnerable

The DSEWPaC SPRAT database indicates that the Freshwater Sawfish may potentially occur in all large rivers of northern Australia from the Fitzroy River, Western Australia, to the western side of Cape York Peninsula (DSEWPaC 2010). It is mainly confined to the main channels of large rivers. Anecdotal evidence suggests that the Freshwater Sawfish may also be found in closed systems and that they enter and leave the closed system during the wet season (Thorburn *et al*. 2003). Small specimens of this species have been caught in remote ponds that have been isolated for a number of years, which suggests that they can survive if their habitat is not connected for a period of time (DSEWPaC 2010). The distribution of the Freshwater Sawfish outside of Australia is uncertain, but it is known to occur in several major river basins of Indonesia and Papua New Guinea. The total population of the Freshwater Sawfish is unknown.

The Freshwater Sawfish is highly vulnerable to gillnet fishing. Other known threats have been identified as Indigenous harvest, habitat modification and recreational 'trophy' fishing.

Speartooth Shark (*Glyphis* sp. A): Critically Endangered

The DSEWPaC SPRAT database indicates that the Speartooth Shark has been recorded in tidal rivers and estuaries within the Northern Territory and Queensland. Within the Northern Territory the Speartooth Shark has been recorded in the Adelaide River, South, East and West Alligator Rivers, Murganella Creek and Marrakai Creek (DSEWPaC 2010). In Queensland the Speartooth Shark has been found in the Wenlock and Ducie Rivers, Port Musgrave (the mouth of these two rivers) and the Bizant River. The Speartooth Shark has also been recorded close to Port Romilly and the Fly River in New Guinea.

The population size of the Speartooth Shark remains unknown, but is thought to be small based on current knowledge and the apparent rarity of the species. There is insufficient data regarding the Speartooth Shark to suggest a decline in population size and information in the SPRAT database indicates that the species may be naturally rare.

The main threats to the Speartooth Shark have been identified by DSEWPaC (2010) as being recreational line fishing, gillnetting, and habitat degradation or modification.

The potential impacts on this species from associated Project related disturbance associated with Dam C on a freshwater tributary of Norman Creek and the ferry/barge terminals in the Hey and Embley Rivers is considered minimal for the following reasons.

- The potential area of occupancy of the Speartooth Shark is restricted from the mouth of a river to the point where the river ceases to be perennial (Stevens *et al.* 2005). The proposed Dam C on a freshwater tributary of Norman Creek will be located in an ephemeral reach of one branch of Norman Creek. Therefore, it is unlikely that if present in Norman Creek, this species would require passage past the proposed site of the dam. This species prefers highly turbid, weakly saline, tidal or estuarine environments (DSEWPaC 2010).
- The Speartooth Shark prefers a highly turbid, environment (DSEWPaC 2010). Norman Creek is not a highly turbid environment and therefore although the species may occur in Norman Creek, there are more suitable habitats in the area that this species is more likely to inhabit.
- Although there was an unverified report of the presence of this species in the Embley River in 1985, ongoing fish surveys over 20 years in the Embley River have not recorded the Speartooth Shark (Stevens *et al.* 2005). It is therefore suggested that this species is restricted the Wenlock and Ducie Rivers in this region (Stevens *et al.* 2005).

The EPBC Act significance assessment summarised below is based on the potential impacts to the Freshwater Sawfish and the Speartooth Shark associated with Project related disturbance to aquatic ecosystems. Project related disturbance to aquatic ecosystems is limited to the construction and operation of Dam C in a freshwater tributary of Norman Creek and activities (including dredging and the clearing of 400m^2 of Mangrove habitat) associated with the construction and maintenance of the ferry/barge terminals on the Hey and Embley Rivers. Descriptions of these activities and infrastructure are in **Section 2.7.2** and **Section 2.7.3**. A detailed description of the location and size of Dam C on a freshwater tributary of Norman Creek is summarised in **Section 5.2.3**.

Will the proposed works...	**Freshwater Sawfish *(Pristis microdon)***
....lead to a long-term decrease in the size of an important population of a species?	A long term decrease in any population of the species present is unlikely to occur.
....reduce the area of occupancy of an important population?	Sufficient habitat would remain to support this species, if present within the proposed disturbance areas, and the area of occupancy of any population of the species present would not be reduced.
....fragment an existing important population into two or more	Any population present would not be fragmented. Evidence suggests the species would not travel upstream of the proposed Dam C footprint on a freshwater tributary of

Will the proposed works...	**Freshwater Sawfish *(Pristis microdon)***
populations?	Norman Creek (refer to **Table 8.14**).
....adversely affect habitat critical to the survival of a species?	The Project area, or areas that would be disturbed within the Project area, does not include any critical habitat areas for this species. As summarised in **Table 8.14**, the species is unlikely to travel upstream of the proposed Dam C location due to low conductivity and lack of suitable habitat. Therefore the freshwater environment in the freshwater tributary upstream of Dam C would not be considered critical breeding habitat for the species.
....disrupt the breeding cycle of an important population?	The breeding cycle of the species (if present within proposed disturbance areas) would not be disrupted. As summarised in **Table 8.14**, the species is unlikely to travel upstream of the proposed Dam C location. Therefore the freshwater environment in the freshwater tributary upstream of Dam C would not be considered critical breeding habitat for the species.
....modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	The species is unlikely to decline as a result of the Project related disturbance. Evidence suggests the species would not travel upstream of the proposed Dam C location (refer to **Table 8.14**). The impacts on potential habitat associated with dredging activities and clearing of 400m^2 of mangroves associated with the ferry/barge terminals on the Hey and Embley Rivers are considered minor and would not to be to the extent that would cause a decline of the species, if present. The number of bulk carriers proposed to enter the Embley River as a result of the Project would actually decrease, which would result in a positive impact. There is no evidence to suggest that large vessels pose a threat to sawfish species or that large vessels would cause a decline in the species.
....result in invasive species that are harmful to a vulnerable species becoming established in the vulnerable species' habitat?	The Project is unlikely to lead to the introduction of any invasive fauna that could affect this species. RTA would conduct routine monitoring of the port for marine pests, similar to that currently undertaken for Port of Weipa high-risk areas.
.....introduce disease that may cause the species to decline?	Disease is not known as a threat to this species. It is not anticipated that the Project would represent a threat with respect to the introduction of disease.
....interfere with the recovery of the species?	The Project is not expected to interfere with the recovery of this species.

Will the proposed works...	**Speartooth Shark (Glyphis sp. A)**
....lead to a long-term decrease in the size of a population?	A long term decrease in any population of the species present is unlikely to occur.
....reduce the area of occupancy of the species?	Sufficient habitat would remain to support the species, if present within the proposed disturbance areas, and the area of occupancy of any population of the species present would not be reduced.
....fragment an existing population into two or more populations?	Any population present would not be fragmented. Evidence suggests the species would not travel upstream of the proposed Dam C footprint on a freshwater tributary of Norman Creek (refer to **Table 8.14**).
....adversely affect habitat critical to the survival of a species?	The Project area, or areas that would be disturbed within the Project area, does not include any critical habitat areas for the species. As summarised in **Table 8.14**, the species is unlikely to travel upstream of the proposed Dam C location due to low conductivity and lack of suitable habitat. Therefore the freshwater environment in the freshwater tributary upstream of Dam C would not be considered critical breeding habitat for the species.
....disrupt the breeding cycle of a population?	The breeding cycle of the species (if present within proposed disturbance areas) would not be disrupted. As summarised in **Table 8.14**, the species is unlikely to travel upstream of the proposed Dam C location. Therefore the freshwater environment in the freshwater tributary upstream of Dam C would not be considered critical breeding habitat for either species.
....modify, destroy, remove, isolate or decrease the availability or quality of habitat to the extent that the species is likely to decline?	The species is unlikely to decline as a result of the Project related disturbance. Evidence suggests the species would not travel upstream of the proposed Dam C location (refer to **Table 8.14**). The impacts on potential habitat associated with dredging activities and clearing of 400m^2 of mangroves associated with the ferry/barge terminals on the Hey and Embley

Will the proposed works...	**Speartooth Shark (Glyphis sp. A)**
	Rivers are considered minor and would not to be to the extent that would cause a decline of the species, if present. The number of bulk carriers proposed to enter the Embley River as a result of the Project would actually decrease, which would result in a positive impact. There is no evidence to suggest that large vessels pose a threat to the Speartooth Shark species or that large vessels would cause a decline in the species.
....result in invasive species that are harmful to an endangered species becoming established in the endangered species' habitat?	The Project is unlikely to lead to the introduction of any invasive fauna that could affect thespecies. RTA would conduct routine monitoring of the port for marine pests, similar to that currently undertaken for Port of Weipa high-risk areas.
.....introduce disease that may cause the species to decline?	Disease is not known as a threat to the species. It is not anticipated that the Project would represent a threat with respect to the introduction of disease.
....interfere with the recovery of the species?	The Project is not expected to interfere with the recovery of the species.

No specific mitigation measures are required for threatened sharks and sawfish, as the Project related disturbance on aquatic habitat is predicted to pose a low risk to the four sawfish and shark species. Nevertheless, the mitigation measures that have been proposed to minimise potential impacts on all aquatic ecology associated with the construction and operation of Dam C, would also directly relate to threatened sharks and sawfish in the unlikely event that habitat upstream of the dam is utilised by these species. In particular, the proposed low gradient rock ramp fishway would be effective.

Mitigation measures for impacts to catchment hydrology, elevated sediment and contaminant loads, and loss of aquatic habitat connectivity which may also relate to either the Freshwater Sawfish or the Speartooth Shark are provided in **Section 8.14.2**, **Section 8.15.2**, and **Section 8.16.2**, respectively. Mitigation of dredging impacts are discussed in **Section 6.9.2.8** and monitoring in **Section 6.9.3.1**.

8.18 Potential Impacts and Mitigation Measures – Aquatic Habitat Summary

Detailed descriptions of freshwater and estuarine aquatic habitats occurring within the Project area are provided in **Section 8.6**. The key environmental values of the aquatic habitats are shown in **Table 8-20**, along with proposed mitigation and monitoring measures associated with areas to be disturbed by Project related activities.

Table 8-20 Aquatic Habitat Key Values, Potential Impacts, Mitigation and Monitoring Measures

Aquatic Habitat Type	Key Values	Potential Impacts	Mitigations and Monitoring Measures
Perennial Streams	○ Aquatic refugia ○ Recreational / Indigenous Fisheries ○ Fishery nursery ○ Primary productivity driver / exports ○ Threatened species habitat ○ Aquatic vertebrate habitat (frogs, snakes)	Alteration of surface runoff flow volumes and duration with potential for channel geomorphology impacts. Alterations of contributing groundwater flow volumes or duration with potential for alteration of perennial stream reach extent or location. Elevated suspended and bed sediment loads with potential for pool infilling and alteration of water quality. Clearing and/or altered fire regime impacts on riparian vegetation In-stream structures and/or flow regime impacts on reach connectivity.	1. Environmental flows would be released from water supply dam to match the timing of dam inflows. Flow rates would be monitored upstream and downstream of each dam. Spillway overflows would provide large flows during the wet season. 2. Post-mining drainage paths would be configured as far as practicable to match pre-mine surface drainage pattern. Hydrological monitoring would be undertaken in representative sub-catchments affected by mining. 3. Vegetation buffers would be established which provide "setback" distances of mining areas from riparian, wetland and estuarine vegetation in order to minimise sediment transport into streams and to protect sensitive vegetation types (refer **Section 7.9.2**). Mining pits would be internally draining in most instances in order to retain surface runoff. Retention ponds would be installed in cases where mine pits are not internally draining or for haul road crossings of sensitive riparian vegetation. Mine development work would be completed prior to the wet season where possible. Turbidity monitoring would be undertaken in representative sub-catchments upstream and downstream of representative mining areas. 4. Fishway structures would be incorporated into water supply dam spillway to provide aquatic habitat connectivity. Fish species composition would be surveyed above and below the dam after one year of operation and then included into the periodic aquatic fauna program thereafter (see below). 5. Periodic (3-5yr) monitoring of freshwater aquatic fauna would be undertaken in reaches upstream and downstream of the water supply dam. 6. Mapping of representative vegetation ecotonal boundaries (e.g. sclerophyll, riparian/wetland/ estuarine) from aerial photography to detect any long-term (decadal) shift. 7. Fire and Feral Management programs as described in **Section 7.10.2**.
Perennial Coastal Lagoons /Lakes	○ Aquatic refugia ○ Threatened species habitat incl. crocodile breeding ○ Waterbird habitat ○ Aquatic vertebrate habitat (frogs, turtles, snakes)	Alteration of surface runoff flow volume or duration with potential for altered inundation level impacts e.g. riparian tree death and associated ecotonal boundary shifts. Alteration of contributing groundwater flow volumes or durations with potential for truncation of inter/base flows and greater recession of dry season water levels and further intrusion of tidal influence. Elevated suspended and bed sediment loads with potential for pool infilling and alteration of water quality. Clearing and/or altered fire regime impacts to riparian vegetation.	1, 2, 3, 6 and 7 (refer above).
Perennial Pools / Channel Hosted Lagoons	○ Aquatic refugia ○ Aquatic vertebrate habitat (frogs, turtles, snakes) ○ Recreational / Indigenous Fisheries ○ Threatened species habitat ○ Aquatic vertebrate habitat (frogs, turtles, snakes)	Alteration of surface runoff flow volumes and duration with potential for channel geomorphology impacts. Alterations of contributing groundwater flow volumes or duration with potential for alteration of perennial stream reach extent or location. Elevated suspended and bed sediment loads with potential for pool infilling and alteration of water quality. Clearing and/or altered fire regime impacts to riparian vegetation. In-stream structures and/or flow regime impacts to reach connectivity.	1, 2. 3, 4, 5, 6 and 7 (refer above)

Aquatic Habitat Type	Key Values	Potential Impacts	Mitigations and Monitoring Measures
Coastal Swale Swamps	○ Aquatic refugia ○ Potential fishery nursery ○ Threatened species habitat ○ Aquatic vertebrate habitat (frogs, turtles, snakes, crocodiles)	Alteration of contributing groundwater flow volumes and duration including by disturbance of shallow beach ridge aquifers with potential for truncation of inter/base flows and greater intrusion of tidal influence. Elevated suspended sediment loads. Clearing and/or altered fire regime impacts to riparian vegetation.	2, 3, 6 and 7 (refer above)
Tree Swamps	○ Aquatic refugia ○ Threatened species habitat ○ Waterbird habitat ○ Aquatic vertebrate habitat (frogs, turtles, snakes)	Alteration of surface runoff flow volumes and duration with potential for altered inundation level impacts e.g. localised riparian tree death and associated ecotonal boundary shifts. Alteration of contributing groundwater flow volumes and duration with potential for truncation of inter/base flows and altered water level recession rates and associated ecotonal boundary shifts. Elevated suspended sediment loads. Clearing and/or altered fire regime impacts to riparian vegetation.	1, 2, 3, 6 and 7 (refer above)
Seasonal Stream Channels	○ Seasonal aquatic habitat and in-stream productivity ○ Connectivity / dispersion conduits ○ Restricted undescribed species	Alteration of surface runoff flow peaks with potential for channel geomorphology impacts. Alteration of contributing groundwater flow volumes or duration with potential for truncation of inter/base flows and reduced persistence duration of seasonal aquatic habitats. Elevated suspended and bed sediment loads. Clearing and/or altered fire regime impacts to riparian vegetation. In-stream structures and/or flow regime impacts to reach connectivity.	1, 2, 3, 4, 5, 6 and 7 (refer above)
Seasonal Coastal Lakes	○ Seasonal productivity hot spots ○ Primary productivity driver / exports ○ Waterbird habitat ○ Fishery nursery ○ Threatened species habitat ○ Seasonal aquatic vertebrate habitat (frogs, turtles, snakes)	Alterations of catchment runoff volumes or timing with consequent impacts on lake filling frequency or timing. Alteration of contributing groundwater flow volumes or duration with potential for impacts to seasonal water level recession rates and tidal ingress buffering capacity and associated movement of brackish mixing zone.	1 and 2 (refer above)

Aquatic Habitat Type	Key Values	Potential Impacts	Mitigations and Monitoring Measures
Bulkuru Spike Rush swamps	○ Seasonal productivity hot spots ○ Primary productivity driver / exports ○ Waterbird breeding and dry season feeding habitat ○ Threatened species habitat incl. crocodile breeding ○ Seasonal aquatic vertebrate habitat (frogs, turtles, snakes)	Alterations of catchment runoff volumes or timing with consequent impacts on swamp filling frequency or timing. Alteration of contributing groundwater flow volumes or duration with potential for impacts to seasonal water level recession rates and tidal ingress buffering capacity and associated movement of brackish mixing zone.	1 and 2 (refer above)
Groundwater Seepage Zones and Springs	○ Aquatic refugia ○ Coastal salinity regime modifier ○ Freshwater invertebrate habitat	Alteration of contributing groundwater flow volumes or duration with potential for impacts to aquatic habitat persistence, fire refugial functions and associated vegetation ecotonal zonation patterns.	2 and 6 (refer above)
Drainage Depressions / Flood Runners	○ Seasonal aquatic habitat and food resources ○ Seasonal aquatic vertebrate habitat (frogs, turtles, snakes) ○ Connectivity / dispersion conduits	Alteration of surface runoff flow peaks with potential for geomorphology impacts i.e. loss of scour pools. Alteration of contributing groundwater flow volumes or duration with potential for truncation of interflows derived from the bauxite profile and reduced duration of seasonal aquatic habitats. Elevated suspended and bed sediment loads with potential for impacts to invertebrate community and drainage depression infilling. Clearing and/or altered fire regime impacts to riparian vegetation In-stream structures and/or flow regime impacts to reach connectivity.	1, 2, 3, 4, 5, 6 and 7 (refer above)
Estuaries	○ Recreational / Indigenous Fisheries ○ Fishery nursery ○ Primary productivity driver / exports ○ Threatened species habitat ○ Cultural/ spiritual	Alteration of surface runoff flow peaks and duration with potential for changes in sediment transport capacity and associated geomorphology impacts to estuary form and function. Alteration of contributing groundwater flow volumes or durations with potential impacts being realised in terms of altered salinity regimes within the estuary and associated changes to primary productivity, fisheries recruitment and ecotonal vegetation boundary shifts at the fresh–brackish interface.	1, 2, and 6 (refer above)

Environmental Impact Statement

for South of Embley Project

Section 9
Air Quality

9 AIR QUALITY

An assessment of air quality impacts, including particulates, sulphur dioxide (SO_2) and oxides of nitrogen (NO_x), based on current Queensland guidelines, has been made for the Project. Greenhouse gas emissions have also been assessed (refer **Section 9.6**).

The Project is situated in a remote part of Cape York where there are no other significant sources of anthropogenic emissions within the air-shed. Bushfires are common and result in particulate and greenhouse gas emissions. There is unlikely to be other sources within the air-shed in the future with the exception of the proposed Aurukun Bauxite Project. Since the area is not urban and unlikely to become so in the future, it is not considered necessary to undertake an airshed assessment.

The mining and beneficiation of bauxite does not involve the use of chemical reagents and does not give rise to odours. Odour is therefore not considered relevant to this study. Ozone depleting substances would not be used on the site.

9.1 Ambient Air Quality

The Project area is situated in a mostly undeveloped and remote part of Cape York. To the north of the Project area are the townships of Weipa and Napranum, which are approximately 4km from the closest mining areas and 40km from the Boyd infrastructure area and proposed port (refer **Figure 9-1**). To the south of the Project area is the township of Aurukun, which is 15km from the nearest mining areas and 35km from the Norman Creek infrastructure area. There are several homesteads on the remote cattle stations more than 50km to the east of the Project area. The site itself is vegetated and does not currently contain significant dust sources. Potential sources of particulate emissions from the environment surrounding the proposed mine primarily comprise:

- unsealed roads;
- smoke from bushfires;
- existing RTA mines and processing plants at East Weipa and Andoom; and
- cattle station activities.

Since particulate exposure is highest close to the source of the particulates it is expected that vehicle movement on unsealed roads would be the most significant source of dust in the remote areas, although the actual dust exposure would be low. Closer to Weipa and Napranum the existing RTA mines and associated infrastructure would contribute to the dust exposure levels. Particulates in smoke from bushfires are occasionally elevated in the dry season.

Typically, airborne dust is referred to as "particulate matter" and is characterised by its size. The usual particle size ranges referred to are total suspended particulate (TSP), particulate matter with an aerodynamic diameter of less than 10 microns (PM_{10}), and particulate matter less than 2.5 microns in diameter ($PM_{2.5}$). By definition, TSP includes both the PM_{10} and $PM_{2.5}$ fractions, and PM_{10} includes the $PM_{2.5}$ fraction. Concentrations of suspended particulate matter are measured in micrograms per cubic metre of air ($\mu g/m^3$).

Normally, dust particles with an aerodynamic diameter of more than PM_{10} will typically fall out and be deposited onto the ground within several minutes of becoming airborne. This is referred to as "dust deposition" and is measured in milligrams per square metre per day ($mg/m^2/day$).

Dust exposure in Weipa has been monitored previously (PAE 2004) and the following results were found:

- the annual average PM_{10} concentration measured was $23.3\mu g/m^3$;
- the highest PM_{10} (24-hour) concentration measured was $116.2\mu g/m^3$ at the Scherger RAAF base;
- typical maximum PM_{10} (24-hour) concentration was measured in the range 25 to $70\mu g/m^3$ at various sites, including the RAAF base and North Napranum;

South of Embley Project

Fig 9-1: Sensitive Receptor Locations

N

5 0 5 10km

Datum/Projection: GDA94/MGA Zone 54 Date: 14/07/2010

- for 99% of the time, the 24-hour average PM_{10} concentration was below 60μg/m³; and
- for 50% of the time, the 24-hour average PM_{10} concentration was below 22μg/m³.

The monitoring was undertaken at various sites near the now decommissioned calcination plant. The calcination plant was, at the time of the monitoring, perceived as a significant dust source.

It is considered that these dust measurements would be representative of the highest dust exposure in occupied areas such as Weipa, Napranum or Aurukun. It is proposed to adopt these measurements as the background exposure level at all sensitive sites.

Further monitoring and assessments were carried out over a short period in 2008 during the construction of the East Weipa tailings storage facility, which is close to the suburb of Nanum in Weipa. The construction involved significant disturbance of an old tailings storage facility with high fraction of very fine material. This is unrepresentative of the Project operations and, as a consequence, it is not appropriate to use this monitoring data.

The ambient dust levels for $PM_{2.5}$ and PM_{10} that have been adopted are based on PAE (2004) data for PM_{10} and are summarised in **Table 9-1**.

The levels for $PM_{2.5}$ have been derived based on the *Queensland 2007 air monitoring report* (EPA 2008b), which shows that the ratio of $PM_{2.5}$ to PM_{10} in ambient air is approximately 1:2.4 for urban areas where motor vehicles are a large source of $PM_{2.5}$ emissions. For rural areas a ratio of 1:3 has been adopted.

The ambient air quality values for TSP and deposited dust are conservative estimates, based upon the consultant's knowledge of monitoring in north Queensland, and are also shown in **Table 9-1**.

Table 9-1 Ambient Air Quality

Indicator	Ambient Air Quality	Averaging Period
$PM_{2.5}$	7 μg/m³	24 hours
PM_{10}	22 μg/m³	24 hours
TSP	23 μg/m³	Annual average
Deposited dust	50 mg/m²/day	30 days ± 2 days

The ambient levels for Napranum and Aurukun are likely to be lower than Weipa due to the increased distance from existing dust sources. However, as air quality criteria are based on health protection criteria rather than ambient levels, the higher the ambient level assumed for the modelling, the more conservative the approach. Therefore, the ambient levels are assumed to be the same across Weipa, Napranum and Aurukun.

There have not been any measurements of existing levels of NO_2 or SO_2 in Weipa. The existing power station and vehicle fleet in the region will be the main contributors. The *Queensland 2007 air monitoring report* (EPA 2008b) states the annual mean for NO_2 is between 4 parts per billion (ppb) and 8ppb for various industrial locations in Queensland. For SO_2 the annual mean is reported to be between 1 and 2ppb. The maximum 1-hour NO_2 level is typically 40ppb. The SO_2 level is typically 5ppb for the maximum 1-hour and 3ppb for the maximum 24-hour average. These values have been adopted as ambient concentrations for the Project area. Given they mostly relate to industrial areas (Townsville, Gladstone, etc) they are likely to be elevated compared to existing levels in Weipa. As for particulates, this is a conservative approach to the modelling given that air quality criteria are based on health protection criteria rather than ambient levels.

9.2 Guidelines, Policies and Legislation

9.2.1 Environmental Protection (Air) Policy

The *Environmental Protection (Air) Policy 2008* (Qld) (EPP (Air)) commenced on 1 January 2009 and sets out a framework for:

- identifying environmental values for the air environment;
- setting air quality objectives for sensitive receptors; and
- avoiding, minimising or managing air emissions.

The relevant environmental values to be enhanced or protected under this policy are:

(a) the qualities of the air environment that are conducive to protecting the health and biodiversity of ecosystems; and

(b) the qualities of the air environment that are conducive to human health and wellbeing.

Schedule 1 of the EPP (Air) nominates air quality indicators and objectives and incorporates the goals recommended in the *National Environment Protection (Ambient Air Quality) Measure* for $PM_{2.5}$. Relevant indicators and objectives for the Project are as shown in **Table 9-2**.

9.2.2 DERM Guidelines

The Department of Environment and Resource Management (DERM) Guideline *Preparing an environmental management overview strategy (EMOS) for non-standard mining projects* requires that the release of dust or particulate matter or both resulting from the mining activity must not cause an environmental nuisance at any sensitive or commercial place. The maximum dust levels, measured downwind of the operation at a sensitive or commercial place suggested in the Guideline are shown in **Table 9-2**.

9.2.3 Project Air Quality Criteria

The applicable air quality criteria for the Project are therefore summarised in **Table 9-2**.

Table 9-2 Proposed Project Air Quality Criteria

Indicator	Receptor	Air Quality Objective	Units	Averaging Period	Comment	Source
$PM_{2.5}$	Residences	8	$\mu g/m^3$	1 year		EPP (Air)
	Residences	25	$\mu g/m^3$	24 hours		EPP (Air)
PM_{10}	Residences	50	$\mu g/m^3$	24 hours	Not to be exceeded on more than 5 days/yr	EPP (Air)
PM_{10}	Residences	150	$\mu g/m^3$	24 hours		DERM Guideline
TSP	Residences	90	$\mu g/m^3$	1 year		EPP (Air)
Dust deposition	Residences	120	mg/m^2/ day	1 month		DERM Guideline
NO_2	Residences	120	ppb	1 hour	Not to be exceeded on more than 1 day/yr	EPP (Air)
	Residences	30	ppb	1 year		EPP (Air)
	Natural ecosystems	16	ppb	1 year		EPP (Air)
SO_2	Residences	200	ppb	1 hour	Not to be exceeded on more than 1 day/yr	EPP (Air)
	Residences	80	ppb	1 day	Not to be exceeded on more than 1 day/yr	EPP (Air)
	Residences	20	ppb	1 year		EPP (Air)
	Agriculture	11	ppb	1 year		EPP (Air)
	Ecosystems	7.5	ppb	1 year		EPP (Air)

9.3 Emission Sources

The main operations associated with the Project comprise:

Construction

Preparation of the site for construction of infrastructure involves clearing and burning the vegetation. The dust emissions from these activities have not been included as they are localised and relatively short in duration. The predicted annual rate of vegetation clearing during construction is less than the predicted annual rate of clearing at the 30Mdptpa and 50Mdptpa production rate scenarios. In addition, fewer heavy vehicles would be in use during construction. Therefore, the air quality impacts during construction are likely to be appreciably less than the predicted operational levels.

Operations

Vegetation would be cleared by bulldozers following the wet season when the ground is sufficiently moist to allow tree roots to pull clear of the ground rather than breaking. The cleared vegetation would be left on the ground for approximately 12 months before being burnt. The particulate dust (and smoke) emissions from these operations have not been included as it is of a relatively short duration.

Following vegetation clearing, front-end loaders and rear-dump trucks are used to strip soil, which would be returned directly to mined-out areas undergoing rehabilitation, where possible, or stockpiled for later respreading. This activity would be one of the main dust sources from the Project.

Mining comprises extraction of bauxite ore by front-end loaders and loading into dump trucks. The dump truck takes the bauxite to a dump station on unsealed roads. Where haul distances are long, this can be a significant source of dust. The dump stations near the beneficiation plants are also significant dust sources.

The bauxite ore is conveyed a short distance from the dump station to the beneficiation plant. The conveyor is a minor source of dust.

The beneficiation plant area includes run-of-mine (ROM) stockpiles, the beneficiation plant, conveyors, stackers and reclaimers, product stockpiles, and tailings storage facilities. The dust emissions from the beneficiation plant are comparatively low since the bauxite is washed to remove the fines. However, the exposed areas surrounding the plant are potential sources of dust due to vehicle movement and wind-blown dust. Product stockpiles are not a main source of dust, as after beneficiation the product is free of fine particulates. Tailings storage facilities have the potential to be a source of dust if the surface is dry.

Ship loading involves reclaimers, conveyors and ship loaders. The bauxite has high moisture content during these processes. As a result, ship loading is only a minor source of dust.

Rehabilitation would involve replacing the topsoil and revegetation. Replacing topsoil generates a similar amount of dust to stripping topsoil.

The diesel-fired power station (and mobile equipment) are sources of SO_2 and NO_2. RTA currently uses low sulphur diesel in the existing power station; however, high sulphur diesel has been used in the Project model to provide a conservative estimate. The fuel consumption is assumed to be at a steady rate throughout the year.

9.4 Air Dispersion Modelling

The types of dust particles are described in **Section 9.1**. Aerodynamic diameters account for the density of the dust involved. The PM_{10} fraction does not have a significant settling velocity component and will tend to behave in a gaseous fashion – that is, the fall out time is significantly longer than a few minutes.

The air quality modelling comprised:

(a) development of an emissions database using both *AP-42* (US-EPA 1995) and the *Emission Estimation Technique Manual for Mining Version 2.3* (NPI 2001); and

(b) modelling of the likely downwind ground level concentrations using The Air Pollution Model (TAPM).

TAPM draws on Bureau of Meteorology (BoM) Limited Area Prediction System (LAPS) analyses to solve the equations of motion to predict the meteorology and dispersion of pollutants hour by hour without needing any local meteorological data. Terrain and land use information are employed in the simulations and are in-built into the model.

TAPM predicts meteorology and concentrations for a range of contaminants important for air quality applications. The model consists of coupled prognostic meteorological and air pollutant concentration components, eliminating the need to have site-specific meteorological observations. Instead, the model predicts the flows important to local-scale air quality, such as sea breezes and terrain induced flows, against a background of larger-scale meteorology provided by synoptic analyses.

Some limitations of TAPM include the following:

- It is not suitable for horizontal domain sizes above approximately 1,000km by 1,000km.
- It cannot be used to accurately represent deep atmospheric circulations or extreme weather events (cyclones).
- It cannot be used for very steep terrain because of the use of a terrain following coordinate system in the model. Thus the model cannot represent discontinuities in terrain height (for example, cliffs or bluffs).
- It assumes that cloud processes are resolved by the typical inner grid spacings used in the model (i.e. 3km or less). Therefore no large-scale cloud convection parameterisation is included.

These limitations are of minor significance to the modelling of air quality for the Project. The area of interest is much smaller than the maximum horizontal domain size. Extreme weather events (such as cyclones) are not of interest from an air quality perspective. The terrain does not have significant cliffs or bluff bodies within the region and it is expected that the inclusion of large-scale cloud convection would only slightly change the radiation and moisture balances.

TAPM is well regarded by DERM and a verification study carried out by the CSIRO (the developers of TAPM) found:

> TAPM performs well in a variety of regions throughout Australia (e.g., coastal, inland and generally complex terrain for sub-tropical to mid-latitude conditions). The pollution results show that TAPM performs well for a range of important phenomena (e.g. concentration variance and fluctuation intensity; building wakes; nocturnal inversion break-up fumigation; stable, neutral, and convective dispersion; shoreline fumigation; and general dispersion in complex rural and urban conditions). In particular, TAPM performs very well for the prediction of extreme pollution statistics, important for environmental impact assessments, for both non-reactive (tracer) and reactive (nitrogen dioxide, ozone and particulate) pollutants for a variety of sources (e.g. industrial stacks and/or general surface or urban emissions) (Hurley et al. 2005).

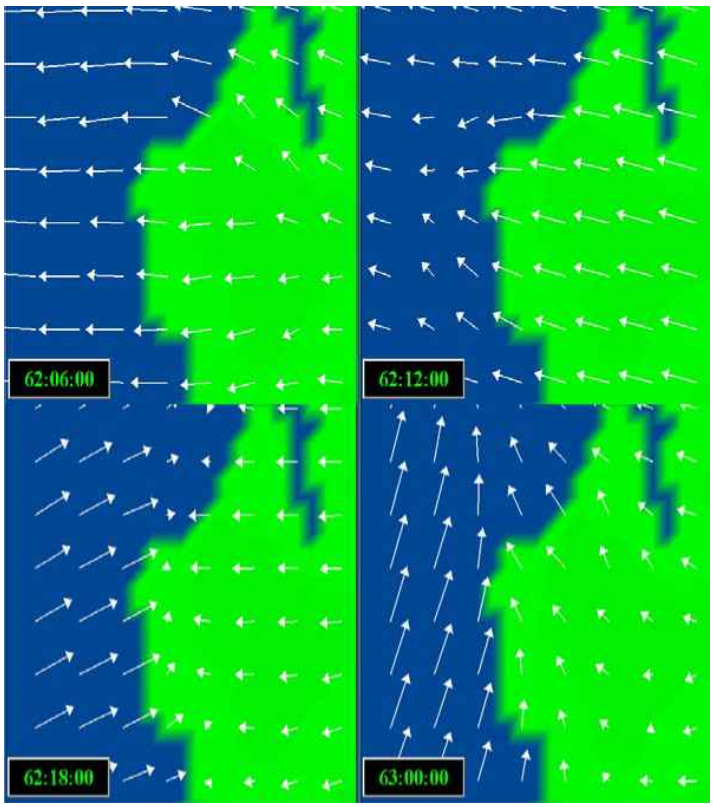
TAPM was used to determine the downwind ground level concentrations for all pollutants and dusts (including photochemistry). The gas-phase photochemistry included in TAPM is based on the semi-empirical mechanism called the Generic Reaction Set. The gas-phase photochemistry is associated with the NO-to-NO_2-to-NO cycle in sunlight. The cumulative effects of the existing industry, power station and other emission sources in the region have been included the predictions.

9.4.1 Meteorology Conditions

TAPM was used to calculate the meteorology over the entire site. TAPM includes in its database six-hourly observations based on interpretation of the results from all relevant weather stations in Australia. Although not strictly required, the accuracy of TAPM can be improved by incorporating meteorological data from weather stations within the study zone.

The meteorology for Weipa has been observed by BoM since 1959; however, rainfall records from the Weipa area are available from 1914. Since 1992 BoM has maintained an automatic weather station at Weipa Aerodrome to continuously record observations every 30 minutes. A subset of these observations was obtained for this study, specifically, to improve the accuracy of the generation of meteorological data over the entire site by TAPM. The data obtained from BoM comprised hourly wind speed and direction as required by TAPM.

TAPM calculates a wind field over the study area for every hour of the simulation period. An example which shows the variability of the winds is contained in **Figure 9-2**. The figure shows that the winds can vary significantly in terms of both speed and direction.



Notes: Arrows represents wind speed (arrow length) and direction over the study area over one day, with six-hourly time steps.
Green indicates land; blue indicates sea or water.
Weipa is located towards the top of the figure; Aurukun is located towards the bottom.

Figure 9-2 Example of TAPM Wind Calculations over Project Area

The general features of winds that will affect plume dispersion are illustrated in the wind rose diagrams for the years 2004 and 2005 for a location approximately in the middle of the Project area (adjacent to Dam C on Norman Creek). The years 2004 and 2005 were selected as cyclone activity was below average with only two relatively mild cyclones in 2004 and one in 2005 affecting Cape York. The wind roses show the frequency of occurrence of winds by direction and strength. The bars correspond to the 16 compass points – N, NNE, NE, ENE, E etc. The length of the bar represents the frequency of occurrence of winds from that direction, and the

colour of the bar sections correspond to wind speed categories. The wind roses in **Figure 9-3** and **Figure 9-4** summarise the wind statistics at 10m above ground on-site, as calculated by TAPM and adjusted (nudged) by Weipa Aerodrome statistics. It is noted that the predominant wind direction during the year is from the east to the south-east. The meteorological modelling indicates that the inland areas do not experience the full effect of coastal sea breeze influences.

Wet Season

The wet season (November to April) wind roses (**Figure 9-3**) show that from midnight to 6am prevailing winds were generally light and from the east-south-east to east-north-east, approximately 80% of the time. Morning winds (6am to 12pm) showed easterlies increasing in strength. During the afternoons (12pm to 6pm) wind frequency and velocity from the westerly directions increased, representing both the sea breeze and monsoonal influences. During the evenings (6pm to midnight) wind strength generally decreased, with the most common direction from east-south-east.

Wind rarely blows from the south over the Embley River towards Weipa. This implies that dust and contaminants released in the Project area are unlikely to combine with dust or contaminants from existing mining operations in the Weipa area.

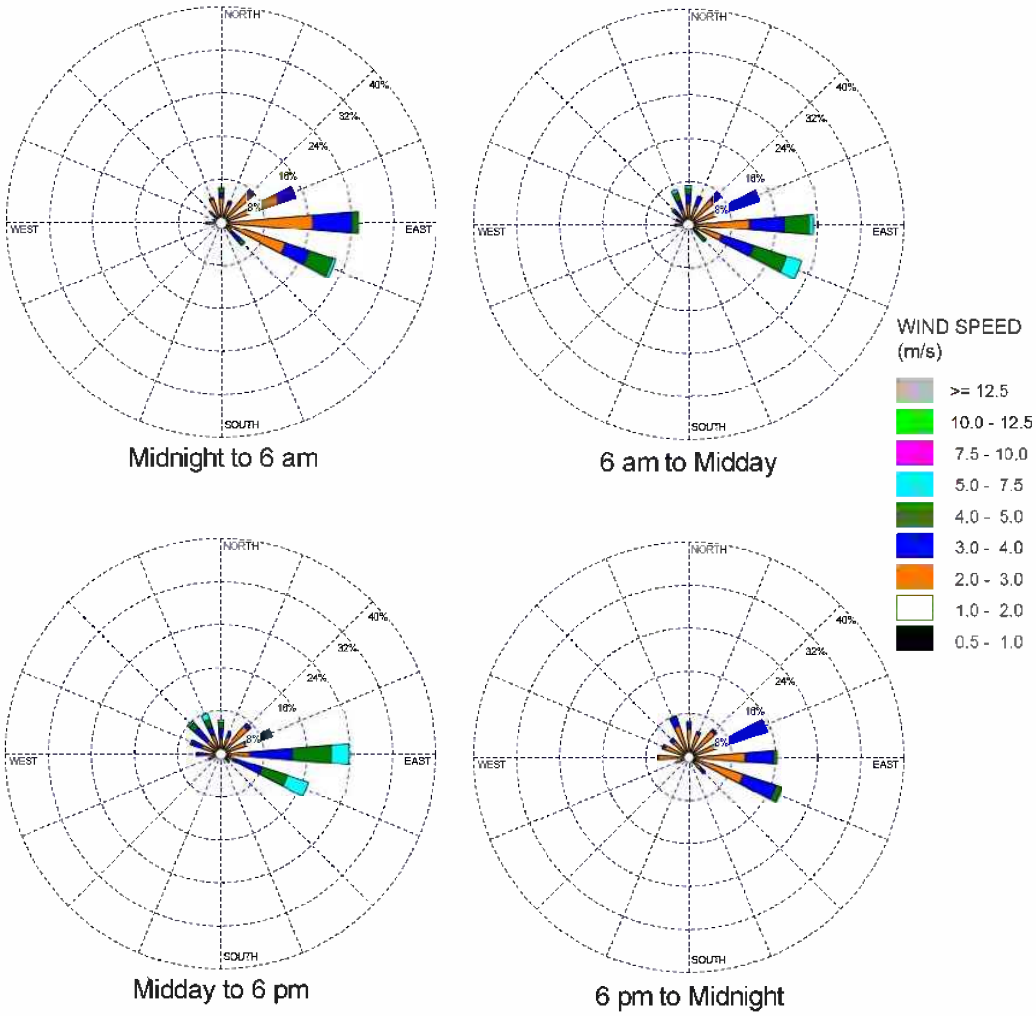


Figure 9-3 Wet Season Wind Roses for Norman Creek Area

Dry Season

The dry season (May to October) wind roses (**Figure 9-4**) show that the winds are almost exclusively from the east. From midnight to 6am, prevailing winds were generally light. Easterlies increased in strength during the morning (6am to 12pm) while during the afternoons (12pm to 6pm) the easterlies marginally increased in strength. During the evenings (6pm to midnight) a general decrease in strength of winds is observed with the most common direction from the east.

The wind rarely blows towards Weipa, Napranum or Aurukun from the Project area.

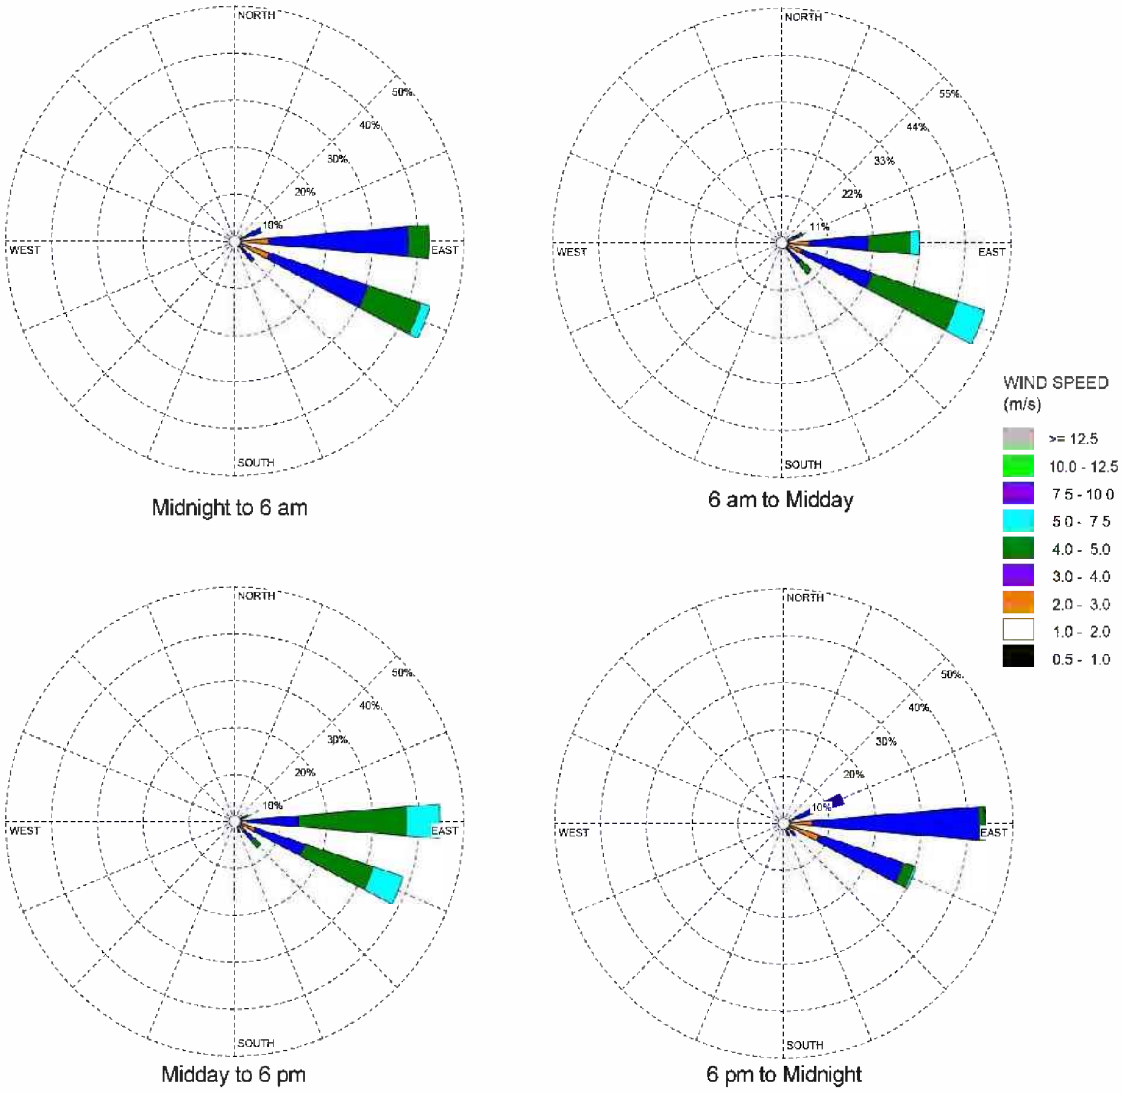

Figure 9-4 Dry Season Wind Roses for Norman Creek Area

9.4.2 Emissions Data

Projected emissions from the Project were modelled using TAPM. This assessment is based on the long-term maximum projected output for the Project of 50Mdptpa.

The emissions data is based on observed current RTA mining, process and shipping operations at Weipa. The operations are described in terms of:

- clearing for mining;
- soil stripping and overburden removal (mine development);
- mining (extraction of the bauxite);
- truck and conveyor haulage;
- process plant (beneficiation);
- stockpiling;
- power generation;
- ship loading; and
- mine rehabilitation.

It is likely the development (stripping soil and overburden prior to mining) areas would be located close to previously mined areas. This is a good operational practice since it limits the total travel distances and cycle time for dump trucks and minimises dust generation on the roads.

In generating the emissions data it is important to recognise that dust emissions are highly dependent on the moisture content of the surface material, be it overburden, roads or bauxite. Dust emissions are lowest during the wet season as the surface material moisture content is very high. However, during the dry season, there is a higher potential for dust emissions to be released.

Rather than adopt a constant emission rate for all hours, the model uses a methodology that determines an emission rate from every operation, for each hour of the year, which includes the effects of dust emission controls due to rainfall and the operation of water trucks. In addition, the emissions from wind-generated dusts have also been included.

The methodology adopted to generate the emissions data is discussed below.

- Initially, each dust source was identified. For each of these dust sources an emission/erosion potential for dry exposed surfaces was calculated based on either the NPI (2001) *Emission Estimation Technique Manual for Mining Version 2.3* or US-EPA AP-42 (1995) 5th Update 2003.
- The dry emission rate (for each source and for every hour of the modelling simulation) was modified to account for the actual moisture content of the overburden, road surface, bauxite stockpiles and tailings storage facilities from both rainfall and water truck usage.

The moisture content of overburden and unmined bauxite due to rain was established through the following methodology:

- The TAPM model was initially run in meteorology mode only and an hourly meteorological file for the entire year extracted. This TAPM calculated and generated file contains inter alia, wind speed and rainfall for each hour.
- If any rain occurred during that hour then the moisture content of the ground was assumed to be 10%.
- If there was at least 1mm of rain during the preceding three hours the moisture content of the ground was assumed to be 10%.
- Otherwise the assumed moisture content for the ground or overburden was assumed to be 4% during the wet season and 2% during the dry season.

The moisture content of roads and haulage routes due to rain and water truck operations was established through the following methodology:

- If any rain occurred during that hour then the moisture content of the road was assumed to be 5%.
- If there was at least 1mm of rain during the preceding three hours the moisture content of the road was assumed to be 5%.
- For all other hours the moisture content of the road was assumed to vary randomly between 0% and 1.66%. Thus the maximum control efficiency of watering by water trucks was 50% (1.66% moisture content).

9.4.3 Construction

The construction phase has not been modelled because the modelled operational phase has a higher impact than construction (refer **Section 9.3**).

9.4.4 Operations

For the purposes of impact assessment, three production scenarios have been considered over the life of the mine:

- 15Mdptpa;
- 30Mdptpa; and
- 50Mdptpa.

The 15Mdptpa production scenario covers the early years of the Project when the mining areas would be located close to the Boyd infrastructure area and furthest from sensitive receptors. Under the 30Mdptpa production scenario the mining areas would be more remote from the Boyd infrastructure area and also occur near the Norman Creek infrastructure area and extend further away over time. Under the 50Mdptpa production scenario the mine would extend from the north to the south of the lease area over a distance of approximately 60km. The equipment and plant utilisations expected for each production scenario are shown in **Table 9-3**. The air quality model incorporates plant and equipment operating at 50Mdptpa production rate with a spatial distribution representative of operations likely to cause the highest dust levels at all sensitive locations. The distribution of the dust sources comprise:

- a mining and development area approximately 5km west of the Hey River barge/ferry terminal and 6.4km south-west of Napranum (Hey River A);
- a mining area 23km south-south-west of Napranum (Hey River B);
- a mining and development area 17km north of Aurukun (Norman Creek A);
- a mining area 35km north of Aurukun (Norman Creek B); and
- haul roads, conveyors, beneficiation plants, power station and shiploaders.

For modelling purposes, mobile equipment fleet have been located in mining areas, on haul roads, and at dump stations, as would occur in a realistic mining situation.

For wind generated dust, the default emission rate applies for all hours where the wind speed exceeds 1m/s, except when raining, or hours when there has been more than 1mm of rain in the past three hours. The dust emissions from an exposed area depend on the surface area and the number of disturbances per year. An exposed surface has a thin layer of particulates that are light enough to be liberated by the wind. Once these surfaces have emitted dust there are no more particulates available until the surface is disturbed, usually by the action of vehicles, bringing fine particulates to the surface. After rain or watering of exposed surfaces, the fine particulates tend to bind together and to the heavier particulates to form a crust. This model assumes that an actively disturbed area is available to emit dust for every hour wind speeds are high enough to liberate dust from a surface.

Table 9-3 Summary of Equipment

Production Rate	**15Mdptpa**	**30Mdptpa**		**50Mdptpa**	
Work Area	**Boyd**	**Boyd**	**Norman Creek**	**Boyd**	**Norman Creek**
Plant	Beneficiation plant 4.7km of conveyors 16 conveyor drives Power station (12MW) Stacker and reclaimer 1 bulldozer	Beneficiation plant 6.4km of conveyors 19 conveyor drives Power station (26 MW) Stacker and reclaimer 1 bulldozer	Beneficiation plant 0.5km of conveyors 2 conveyor drives Stacker and reclaimer	Beneficiation plant 8.9km of conveyors 29 conveyor drives Power station (46 MW) Stacker and reclaimer 1 bulldozer	Beneficiation plant 1km of conveyors 4 conveyor drives Stacker and reclaimer

Overland Conveyor	-		15km of conveyor 4 conveyor drives		15km of conveyor 4 conveyor drives

The actively disturbed area comprises:

- 30ha for each development area (60ha in total);
- 20ha for each mining area (80ha in total);
- 5ha for the area surrounding each of the beneficiation plants;
- 435ha for each of the tailings storage facilities (three out of four cells assumed to be dry); and
- 25ha for the product stockpiles.

It should be noted that the exposed areas would be significantly larger.

Annual dust emissions from each activity in each active area are shown in **Table 9-4**. The most significant source of all the dust fractions is vehicles on haul roads. A summary of the total annual emissions is contained in **Table 9-5**. It should be noted that there is only limited measured data available for $PM_{2.5}$ emissions. Based on review of the literature, the quantity of $PM_{2.5}$ released is taken to be 12% of the quantity of PM_{10}. TSP is expressed as PM_{30} in TAPM.

Table 9-4 Dust Emissions by Area and Source at 50Mdptpa

Location	Activity	Annual dust emissions (tonnes per annum)		
		$PM_{2.5}$	PM_{10}	TSP
Mining and development (Hey River A)	Excavator on overburden	2	18	38

Source	Annual dust emissions (tonnes) from operations for particle diameters		
	$PM_{2.5}$	PM_{10}	TSP
Dust from haul roads	231	1,925	9,385
Dust from mining areas (development, mining operation, and rehabilitation)	119	993	3,249
Dust from two beneficiation plants, conveyors, stockpiles, tailings storage facilities and shiploaders	185	1,153	3,363
Annual Total [tonnes]	**535**	**4,071**	**15,997**

Both the power station and the mobile equipment are diesel powered. The main emissions from these sources are presented in **Table 9-6**. The emissions are based on annual diesel consumption of 101,000kL. The percentage sulphur assumed is 1,000 parts per million (ppm) or 0.1%. By comparison, retail fuel has a sulphur content of 10ppm.

Although the EPP (Air) provides air quality objectives for nitrogen dioxide (NO_2), the amount of NO_2 released by combustion of diesel is very low. However, NO_2 is formed from nitric oxide (NO) through photochemical reactions in the atmosphere. Therefore, NO emissions have been calculated as a conservative estimate of NO_2 emissions using the *Emission Estimation Technique Manual for Mining* (NPI 2001).

Table 9-6 Annual NO_x and SO_2 Emissions at 50Mdptpa

Contaminant	Annual Emissions [tonnes] from Diesel Operations	
	Power Station	Mobile Equipment
NO_X (taken to be all NO)	2100	1125
SO_2	111	54

9.4.5 Air Quality Modelling Outputs

The predicted particulate, SO_2 and NO_2 concentrations at the sensitive places close to the Project are shown in **Table 9-7** and **Table 9-8**. The ground level concentrations at the sensitive places include the ambient background concentrations. The modelling was carried out using TAPM for both the meteorology and pollution aspects of the Project. Since the simulation includes two years of meteorology, the model incorporates all likely and expected meteorological conditions, including adverse meteorological conditions (such as inversions) and various likely mixing heights. The model is a thorough and realistic simulation of the expected meteorological and operational conditions for the Project.

The NO_2 concentrations levels shown in **Table 9-8** include the effect of photochemistry and are therefore a conservative estimate.

Table 9-7 Predicted Particulates at Sensitive Residential Receptors at 50Mdptpa

Receptor	Predicted Particulate Levels For Sensitive Receptors (including ambient levels)				
	Maximum PM_{10} (24 hour) – Fifth highest in a year [$\mu g/m^3$]	Maximum $PM_{2.5}$ (24 hour) [$\mu g/m^3$]	$PM_{2.5}$ (annual average) [$\mu g/m^3$]	TSP (annual average) [$\mu g/m^3$]	Dust deposition (highest month) [$mg/m^2/day$]
Proposed Criteria	**50**	**25**	**8**	**90**	**120**

9.5 Predicted Impacts and Mitigation Measures

The particulate emissions from the Project readily comply with all particulate air quality objectives at the nearest sensitive receptors.

The NO_2 and SO_2 concentrations from the Project comply with all air quality objectives at the nearest sensitive places.

9.5.1 Local Impacts

The impacts associated with the Project are entirely local. The modelling generally shows that the greatest impacts occur to the north-west of the operations. The dust concentration levels at sensitive receptors in Weipa, Napranum and Aurukun are expected to readily comply with all DERM guidelines.

The predicted NO_2 and SO_2 concentrations at all sensitive receptors (Weipa, Napranum and Aurukun) are much lower than the objectives to protect health and wellbeing. The predicted incremental increase to annual average NO_2 and SO_2 concentrations is zero at Weipa, Napranum or Aurukun as a result of the Project. In addition, the predicted annual increase does not exceed the EPP (Air) quality objectives for the protection of agriculture and natural ecosystems.

It is noted that the highest concentrations, as expected, occur close to the operations and within the mining lease.

The PM_{10} model indicates that the prevailing wind in the vicinity of the Embley River is easterly (parallel to the Embley River) and southerly winds rarely occur. However, at the southern end of the study area there are sufficient northerly winds to slightly increase the maximum PM_{10} concentrations at Aurukun above Weipa concentrations (refer **Figure 9-5**); however, the resulting concentrations are still well below the proposed criteria.

Levels of $PM_{2.5}$ are sensitive to winds that sustain direction and strength for an extended period of time (e.g. 24 hours). This is indicated as "lobes" in the contour lines shown on **Figure 9-6**, which are most noticeable in the 1 $\mu g/m^3$ contour. The lobes represent unusual winds and may only occur once or twice per year. For instance, in the north there are noticeable lobes to the north, north-east, and east, while in the south there are lobes to the east and south. These lobes represent unusual winds rather than high dust levels, since the total maximum 24-hour $PM_{2.5}$ concentrations are still less than 40% of the proposed criteria.

Modelled dust deposition levels in Weipa, Aurukun and Napranum from the Project are minor and likely to be no more than 1mg/m^2/day averaged over one month (51mg/m^2/day including ambient) for the highest month in a 12-month period (refer **Figure 9-9**). This readily complies with the dust deposition guideline.

Apart from the conventional haul road watering and water sprays on chutes where trucks dump crude ore at the beneficiation plant, which were incorporated into the modelling, no further mitigation measures are required. Water sprays would also be used to clean the ship-loading conveyor belt, which would reduce build-up of fine material.

9.5.2 Regional Impacts

The Project is situated in a remote region. Dust mostly falls out of the air within a few hundred metres of the source. The very fine dust fraction ($PM_{2.5}$) remains aloft for the longest period, yet even this dust quickly becomes less significant than the estimated regional ambient concentration. Therefore the northern Cape York regional air quality is not expected to deteriorate as a result of the Project.

The levels throughout the Project area and surrounding region are also lower than the EPP (Air) objectives to protect agriculture and health and biodiversity of ecosystems.

9.6 Greenhouse Gas Emissions and Abatement

This subsection provides an inventory of projected greenhouse gas (GHG) emissions for the Project and proposed abatement measures.

9.6.1 Projected Emissions

Methodology

The Department of Climate Change and Energy Efficiency delivers the majority of programs under the Australian Government's climate change strategy. The methods and emission factors contained within the *National Greenhouse Accounts (NGA) Factors* (DCCEE 2010a) workbook were used to calculate GHG emissions from the Project. The NGA factors are designed to estimate greenhouse gas emissions for reporting under various government programs, including the *National Greenhouse and Energy Reporting* (NGER) scheme.

The greenhouse gases covered by this assessment include: carbon dioxide (CO_2); methane (CH_4); nitrous oxide (N_2O); perfluorocarbons (PFC); hydrofluorocarbons (HFC); and sulphur hexafluoride (SF_6). The global warming potential is an index for each greenhouse gas which is used to convert emissions to carbon dioxide equivalents (CO_2-e). This allows the atmospheric warming effect of the different greenhouse gases to be compared.

The methodology for estimating the GHG inventory used the NGA Factors listed below.

- Scope 1 emissions – or direct emissions at point of release for diesel electricity generation – were calculated using the factors of 38.6 gigajoule per kilolitre (GJ/kL) and 69.2 kilograms of carbon dioxide equivalents per gigajoule (kg CO_2-e/GJ).
- Scope 1 emissions – or direct emissions at point of release for diesel for transport – were calculated using the 2.7 tonnes CO_2-e/kL factor.

The biomass carbon for the Weipa eucalypt tall open forest to be cleared ahead of mining was estimated as 44.5 tonnes/ha cleared using Full Carbon Accounting Model, a tool within the National Carbon Accounting Toolbox (AGO 2005).

An average growth rate of 1.07t carbon/ha/year was assumed for Weipa eucalypt tall open forest revegetation in the Project area, which has been derived for the area based on productivity rates in the Weipa region using default values from the National Carbon Accounting Toolbox (AGO 2005).

Note that while vegetation clearing and revegetation has been included in the greenhouse gas assessment for completeness, land management is not included under NGER and therefore would not be the subject of annual reporting under the NGER scheme.

Inputs

This GHG assessment accounts for direct Scope 1 emissions for the three production scenarios of 15Mdptpa, 30Mdptpa and 50Mdptpa.

Primary sources of GHG emissions included in this assessment are:

- the on-site generation of electricity (diesel-fired power station) which is used to power the beneficiation plants, conveyors, stackers, reclaimers and shiploader, as well as support facilities such as the water treatment plant, pumps, workshops, and offices;
- heavy vehicle transport (diesel) including mobile equipment for mining bauxite and haulage; and
- vegetation clearing prior to mining.

Secondary sources of GHG emissions include:

- light vehicles and buses (diesel);
- barge and ferry movements (diesel); and

- a proportion of the fuel used in the existing Lorim Point power station to power Project support facilities located in Weipa. Half of the emissions attributable to electricity use in warehouses, offices, residences and commercial premises in Weipa have been included in Project emissions at 15Mdptpa increasing to 100% at 30 and 50Mdptpa.

The CO_2 absorbed by vegetation in rehabilitation areas has been subtracted from the calculated emissions.

To minimise on-site generation of electricity, the following energy efficiency measures have been adopted to increase energy efficiency:

- generating power at the load source to avoid transmission line losses;
- reducing height in the beneficiation plants minimising the energy needed to lift ore;
- fit for purpose design (lower excess capacity margins to reduce unused electric motor capacity) resulting in higher electrical efficiency (power factor); and
- High-density polyethylene (HDPE) tailings line to reduce pumping energy due to lower friction losses.

Emissions

A summary of the projected GHG emissions is shown in **Table 9-9**. The estimate of emissions from all Project components at 50Mdptpa production is 508kt CO_2-e per annum. By comparison, GHG emissions in Australia were estimated to be 537,000kt CO_2-e in 2009 (DCCEE 2010b) and 181,000kt CO_2-e from Queensland in 2007 (DERM 2009d).

Greenhouse gas emissions vary considerably from year to year at the current Weipa operations, depending on production rate and activities carried out (e.g. the amount of land clearing). The amount of land cleared per tonne of ore is higher at Andoom and East Weipa operations than it would be for the Project due to thinner bauxite layers.

Table 9-9 Projected Annual Energy Use and Greenhouse Gas Emissions

	Source	Units	Production rate		
			15Mdptpa	30Mdptpa	50Mdptpa
Input Data	Diesel used for power generation*	kL	26,100	46,100	70,100
	Diesel used for transport	kL	11,700	23,100	38,400
	Cleared land	ha	500	850	1,360
	Rehabilitated land	ha	290	850	1,360
Greenhouse Gas Emissions	Power generation	t CO_2-e	69,740	121,100	187,400
	Transport	t CO_2-e	31,600	62,300	103,500
	Vegetation cleared	t CO_2-e	81,700	138,800	222,100
	Less vegetation sink (rehabilitation)	t CO_2-e	1,100	3,300	5,300
	Annual Total	t CO_2-e	181,840	318,900	507,700
	Intensity	t CO_2-e / t bauxite	0.0121	0.0106	0.0102

* Includes electricity supply for Weipa, which would be supplied from the existing East Weipa power station.

Note: Conversion factors and methodology described in DCCEE (2010a)

Environmental Impact Statement

for South of Embley Project

Section 10

Noise and Vibration

10 NOISE AND VIBRATION

This section provides an assessment of noise impacts based on current Queensland guidelines. This assessment considers the construction phase as well as ongoing mining, processing and ship-loading operations. This assessment is based on three mine production rates, namely:

- 15 million dry product tonnes per annum (Mdptpa);
- 30Mdptpa; and
- 50Mdptpa.

There are no significant vibration sources associated with the operations. The operations do not require that blasting be carried out. Nor are there any vibration sensitive receptors within or close to the lease area. As a result, vibration issues will not be addressed further.

10.1 Existing Noise Environment

10.1.1 The Land Environment

An environmental noise survey was conducted in Evans Landing, adjacent to the Department of Primary Industries Fisheries building. This site was considered to be representative of the residential areas along the Embley River, namely Napranum and the accommodation areas in Evans Landing, which would be the nearest sensitive receptors to the Project area (refer **Figure 9-1**). The measured noise levels are shown in **Table 10-1**. The noise levels recorded at Evans Landing included noise from recreational boating and activities in the boat ramp car park. During the night, noise from the Lorim Point ship loader was noted. No rain fell during the monitoring period, which was hot and dry. There were light winds, mostly from the east, during the day and the nights were still.

The noise level survey was carried out using a calibrated Rion NL-22 sound level meter in accordance with AS1055.1 and AS1055.2. The equipment was configured to record the fast "A" weighted noise levels over a period of one week. The noise levels in **Table 10-1** are expressed in terms of the $L_{A90\ (1\ hour)}$, $L_{Aeq\ (1\ hour)}$ and the $L_{Aeq\ (24\ hour)}$. The L_{Aeq} is the average noise energy during a measurement period. The L_{A90} is the noise level that is exceeded 90% of the time and is commonly referred to as the background noise level.

By way of comparison, the results of an earlier survey commissioned by RTA at Nanum are presented in **Table 10-2** (Moore and Associates 2007). Nanum is approximately 3km north of Evans Landing and closer to Weipa.

The results of the noise monitoring for both Nanum and Evans Landing are similar. The background noise levels are almost identical, while the $L_{Aeq\ (1\ hour)}$ shows that Evans Landing is exposed to slightly higher overall noise levels.

Table 10-1 Environmental Noise Survey at Evans Landing

Date	$L_{A90\ (1\ hour)}$ Background Noise Level [dB(A)]			$L_{Aeq\ (24\ hour)}$ [dB(A)]	$L_{Aeq\ (1\ hour)}$ Noise Level [dB(A)]

10.1.2 The Underwater Environment

The noisy background environment must be considered when evaluating the various noise sources and their impacts on the marine environment (SVT, 2009). Ambient underwater noise levels are frequency dependent, as follows (SVT, 2009):

- seismic activity is in the first 10 Hz;
- shipping and meteorological effects, including rain and wind, dominate the spectrum from 10 to 100 Hz;
- wave action, rain and wind dominate the spectrum up to almost 100 kHz; and
- molecular thermal effects dominate above 100 kHz.

10.2 Guidelines, Policies and Legislation

10.2.1 Environmental Protection (Noise) Policy 2008

The *Environmental Protection (Noise) Policy 2008* (Qld) (EPP (Noise)) came into effect on 1 January 2009 and sets out a framework for:

- identifying environmental values for the acoustic environment;
- setting acoustic quality objectives for sensitive receptors;
- avoiding, minimising or managing noise; and
- controlling background creep.

Schedule 1 of the EPP (Noise) contains acoustic quality objectives for sensitive receptors, including dwellings, hospitals, schools and parks.

For dwellings, the acoustic quality objectives are expressed as indoor noise level goals at Night (10pm to 7am) and indoor and outdoor noise level goals during the Day (7am to 6pm) and Evening (6pm to 10pm). The EPP (Noise) also includes acoustic quality objectives for critical habitats (as defined in a conservation plan under the *Nature Conservation Act 1992* (Qld) and marine parks under the *Marine Parks Act 2004* (Qld)). These objectives are shown in **Table 10-3**.

When setting limits it is not intended that the acoustic environment be permitted to deteriorate and this is achieved by controlling background creep. To the extent that it is reasonable to do so, noise from an activity must not be:

- for noise that is continuous noise measured by $L_{A90,T}$ – more than nil dB(A) greater than the existing acoustic environment measured by $L_{A90,T}$; or
- for noise that varies over time measured by $L_{Aeq,adj,T}$ – more than 5dB(A) greater than the existing acoustic environment measured by $L_{A90,T}$.

Table 10-3 EPP (Noise) Acoustic Quality Objectives

Location	Time of Day	Acoustic Quality Objectives (measured at the receptors) dB(A)			Environmental Value
		$L_{Aeq, adj, 1 hr}$*	$L_{A10, adj, 1 hr}$*	$L_{A1, adj, 1 hr}$*	
Dwelling outdoors	Day & Evening	50	55	65	Health and wellbeing – for outside areas
Dwelling indoors	Day & Evening	35	40	45	Health and wellbeing – for indoor areas
Dwelling indoors	Night	30	35	40	Health and wellbeing in relation to the ability to sleep
Protected area, or an area identified under a conservation plan under the *Nature Conservation Act 1992* as a critical habitat or an area of major interest	Anytime	The level of noise that preserves the amenity of the existing area or place			Health and biodiversity of ecosystems
Marine park under the *Marine Parks Act 2004*	Anytime	The level of noise that preserves the amenity of the existing area or place			Health and biodiversity of ecosystems

* $L_{Aeq,adj,1hr}$ is the A-weighted sound pressure level of a continuous steady sound, adjusted for tonal character, that within a 1-hour period has the same mean square sound pressure of a sound that varies with time.

L_{A10} and L_{A1} is the A-weighted sound pressure level, adjusted for tonal character or impulsiveness, which is exceeded for 10% and 1% respectively of the 1-hour measurement period.

10.2.2 DERM Ecoaccess Guideline - Low Frequency Noise

DERM's Ecoaccess Guideline *Assessment of Low Frequency Noise* categorises items such as boilers, pumps, transformers, cooling fans, compressors, oil and gas burners, foundries, wind farms, electrical installations, diesel engines, ventilation and air-conditioning equipment, wind turbulence and large chimney resonance as noise sources that have a proportionally high level of frequency content less than 200Hz.

These sources exhibit a spectrum that characteristically shows a general increase in sound pressure level with decrease in frequency. Annoyance can be caused by low frequency noise even though the total noise level measured is relatively low. Typically, annoyance is experienced in the otherwise quiet environs of residences adjacent to, or near, low frequency noise sources. Generally, low frequency noises become annoying when the masking effect of higher frequencies is absent.

This loss of high frequency components may occur as a result of transmission through the fabric of a building or in propagation over long distances. Where a noise emission exhibiting unbalanced frequency spectra occurs, the overall sound pressure level inside residences should not exceed 50dB (Linear) to avoid complaints of low frequency noise annoyance.

10.2.3 enHealth Guideline – Health Effects of Environmental Noise

The enHealth Council (2004) Guideline *The Health Effects of Environmental Noise – Other than Hearing Loss* provides a review of the health effects (other than hearing loss) of environmental noise and reviews measures aimed at the management of environmental noise. The document addresses annoyance and quality of life, sleep disturbance, low frequency noise, performance

and learning with school children, cardiovascular disease, mental health and neuro-physiological stress. The goals adopted in this report address all relevant aspects of this document

10.2.4 Proposed Noise Level Criteria for Human Receptors

The proposed noise level criteria for the Project have been derived taking into consideration the acoustic quality objectives for health and wellbeing as well as the control of background creep. The criteria are expressed as outdoor noise levels, measured 4m from dwellings.

The EPP (Noise) indoor noise quality objectives for health and wellbeing at dwellings have been adjusted so they can all be expressed as outdoor noise levels and are presented in **Table 10-4**. The equivalent external noise levels measured at least 4m from the residence would be 5dB higher, and therefore the indoor criteria for health and wellbeing has been adjusted by 5dB to allow comparison for measurements to be undertaken outdoors.

It is not uncommon for bedrooms in tropical areas to be air-conditioned. For air-conditioning to be effective it is necessary to keep the windows closed. Having the windows closed further reduces outside noises and the reduction of external noise from outside to inside can be as high as 20dB; i.e. the equivalent external noise levels measured at least 4m from the residence would be 20dB higher than the acoustic quality objectives noted in **Table 10-3**. However, for the purposes of this assessment, it is conservatively assumed that the residences have open windows.

Table 10-4 Adjusted Acoustic Quality Objectives for Dwellings

Location	Time Period	Acoustic Quality Objectives [dB(A)]		
		$L_{Aeq,\ 1\ hour}$	$L_{A10,\ 1\ hour}$	$L_{A1,\ 1\ hour}$
4m from Residential Receptors	Day and Evening	50	55	65
	Day and Evening*	40	45	50
	Night*	35	40	45

* indoors criteria adjusted for outdoors by adding 5dB

It is difficult to model the L_{A10} and the L_{A1} since there is no accurate calculation method available. Since the noise sources are not of very short duration but occur throughout the monitoring period it is expected that if the L_{Aeq} goals are met then the L_{A10} and L_{A1} would be met as well. As a consequence it is not proposed to model or report either the L_{A10} or L_{A1}.

The noise level criteria to avoid background creep is based on the median background level measured at Evans Landing and are shown in **Table 10.5.** The noise from most plant and equipment at the Project varies over a short time period. Furthermore, the noise propagation characteristics over large distances always results in fluctuating noise levels. Since all the noise sensitive locations are located at large distances from the operations it was considered reasonable to apply the limits for time variable noise. The noise level criteria to avoid background creep have been calculated using the method specified in the EPP (Noise) and is equal to $L_{Aeq,T} = L_{A90,T} + 5$ dB(A). The $L_{A90,T}$ is the median background noise level calculated in **Table 10.1**.

Table 10-5 Calculated Noise Levels to Avoid Background Creep in Residential Areas

Location	Noise Level to Avoid Background Creep $L_{Aeq,\ 1\ hour}$ [dB(A)]		
	Day	Evening	Night
4m from Residential Receptors	46	43	43

It is noted that the noise level criteria to avoid background creep are higher than the indoor acoustic quality objectives for health and well-being (adjusted for outdoors) (refer **Table 10-4**). This is due to the existing noise levels being considerably higher than the acoustic quality objectives.

The "acoustic quality objectives" seek to protect the amenity of an acoustic environment. The indoor night-time objectives effectively address sleep disturbance and sleep awakenings, while during the day the objectives protect conversation. The acoustic quality objectives are not individual point source emission standards but are total levels of noise in the surrounding environment. Currently the existing ambient levels are much higher than the acoustic quality objectives.

The controlling background creep objective seeks to avoid intrusiveness. When setting limits it is not intended that the acoustic environment be permitted to deteriorate and this is achieved by controlling background creep.

Thus the noise level criteria proposed for the project are designed to avoid background creep and are shown in **Table 10-6**.

Table 10-6 Proposed Noise Level Criteria for Residential Areas

	Noise Level Criteria to Avoid Background Creep [$L_{Aeq,\ 1\ hour}$ dB(A)]			Low Frequency Noise [$L_{eq,\ adj,\ 1\ hr}$ dB(Linear)]
Time Period	**Daytime**	**Evening**	**Night**	**Night**
Measured 4m from Residential Receptors	46	43	43	50

10.2.5 Sensitivity of Fauna to Noise

There are no designated Marine Parks or Protected Areas in the vicinity of the Project area, and therefore the objectives provided by the EPP (Noise) are not relevant to the Project.

There are no other regulatory criteria relating to noise impacts on terrestrial or marine animals. Sensitivities to noise vary among species and potential effects also depend on a number of factors including the type of noise, whether or not the noise source is stationary or moving, or if it is constant or sporadic.

Underwater noise is likely to occur as a result of construction of the proposed port, tug berths and barge/ferry terminals (predominantly due to pile driving activities), and later in operation of these facilities. The marine animals expected to occur in the vicinity of the Project area are described in **Section 6.6**. Marine turtles and mammals, such as whales, dolphins and dugongs, are known to be sensitive to underwater noises that are louder (greater intensity) than normal background levels. It should be noted that underwater noise is converted to the decibel ratio using a reference pressure of one micro-Pascal (µPa). In air the reference pressure is 20µPa. Thus sound pressure underwater would appear to be 26dB greater than the equivalent pressure in air due to the difference in the reference pressures.

No study to date has shown injury in marine mammals from pile driving (Erbe 2009). However, physical damage to the auditory system of dolphins and whales, which is understood to be the onset of permanent threshold shift, may occur at noise levels of greater than 230dB re 1µPa (Gausland 2000, Erbe 2009, SVT 2009).

Temporary threshold shift in mid-frequency cetaceans was observed at 224dB re 1 µPa at a sound exposure level (SEL) of 183dB re 1µPa^{2}s (Erbe 2009). These same levels were recommended by Southall *et al.* (2007) as criteria for temporary threshold shift in dolphins. Avoidance behaviour begins to occur at around 110–130dB re 1µPa (McCauley 1994).

There is lack of data to determine injury thresholds (including temporary threshold shift) for low frequency sensitive mammals (e.g. brydes whale). However it is recommended that injury and avoidance threshold levels for mid-frequency sensitive mammals (e.g. dolphins) be accepted for low-frequency mammals (SVT 2009, Southall *et al.* 2007). SVT (2009) proposed that the

criteria for seismic survey activities be accepted for piling activities due to the lack of known avoidance thresholds for piling. The relevant criteria proposed were:

- possible physical injury may occur at peak pressure levels greater than 230dB re 1 μPa at a sound exposure level (SEL) of 198dB re 1μPa^{2}s; and
- avoidance behaviour was estimated to occur at peak pressure levels greater than 224dB re 1 μPa at a SEL of 160dB re 1μPa^{2}s;

SVT (2009) conducted underwater noise modelling and assessment for pile driving activities proposed for the Cape Lambert Port B Development in Western Australia. The following conclusions were made regarding marine turtles:

- physical injury would be likely to occur at peak pressure levels greater than 222dB re 1μPa at a sound exposure level (SEL) of 198dB re 1μPa^{2}s;
- hearing damage may occur at peak pressure levels greater than 222dB re 1μPa;
- avoidance behaviour was estimated to occur at peak pressure levels greater than 120dB re 1μPa based on the auditory bandwidth of turtles; and
- there is no supporting literature to establish acceptable levels of continuous noise to prevent threshold shift in marine turtles.

Underwater noise criteria have not currently been developed specifically for Dugong to manage potential temporary threshold shift. However previous anatomical studies of dugong suggest that their overall hearing sensitivity would likely to be less than that of dolphins. Therefore adopting the same underwater noise criteria for Dugongs as for dolphins, would provide a conservative management basis for Dugongs.

As there is no critical breeding or feeding habitat for these species close to the construction areas, an avoidance response is unlikely to have a significant impact.

10.3 Noise Sources

The main activities associated with the Project comprise:

- Construction of mine facilities, beneficiation plant and supporting infrastructure
- Clearing for mining
- Soil stripping and overburden removal (mine development)
- Mining
- Truck and conveyor haulage
- Process plant and stockpiling
- Power generation
- Ship loading
- Barge and ferry transport
- Mine rehabilitation.

Construction of the mine facilities and beneficiation plants consist of earthworks, erection of buildings and structures, and installation of plant and equipment. The construction of the proposed port would involve dredging and driving more than two hundred 800–1200mm raked steel piles for the wharf into the sea floor in a manner similar to that which has been previously carried out at the Port of Weipa. The construction of the ferry/barge terminals are comparatively minor building works (including limited piling of 600mm piles). Once the terminals are constructed, the operation of the ferry and barge would be a potential noise source.

Land clearing involves the pushing over of trees and other vegetation with a bulldozer during the dry season. Land clearing, like mine rehabilitation, is considered a minor noise source.

Following removal of the vegetation, topsoil is stripped using front-end loaders or scrapers. Overburden is then loaded into haul trucks, with front-end loaders. Typically these development activities take place close to the active mining areas.

Mining comprises the extraction of bauxite by front-end loader and loading haul trucks. The trucks travel to the dump station situated close to the beneficiation plant. In each development area there is a fleet of loaders and trucks stripping and placing overburden. In each mining area there are likely to be several loaders and a fleet of haul trucks.

The mine industrial area comprises the beneficiation plant (including crushers), conveyors, power station and stacker/reclaimers. Ships are loaded via a dedicated ship loader fed by a conveyor from the stockpile.

10.3.1 Plant and Equipment Sound Power Survey

The sound power levels for the plant and equipment proposed for the operational aspects of the Project was obtained by measuring similar equipment at the current RTA operations. These measurements were obtained during September 2008 using a calibrated Norsonic NOR118 real-time 1/3 Octave band analyser in accordance with AS 1055.1, 1997 Acoustic – Description and Measurement of Environmental Noise Part 1: General Procedures and Part 2: Application to Specific Situations. A summary of the measured noise levels is presented in **Table 10-7**.

Rear dump trucks operate between the development area and the recently mined areas. This is a relatively short journey as the development operations are normally closely followed by mining. For mining areas, haul trucks are expected to operate between the mining areas and the dump station. However, for the more remote mining areas, prime movers with multiple trailers or side dump trucks are likely to be employed.

10.3.2 Underwater Noise from Pile Driving

Noise emitted from a pile during pile driving operations is a function of its material type, its size, the force applied to it and the characteristics of the substrate into which it is being driven. The action of driving the pile into the sea floor would create a mixture of compression and transverse waves within the pile. The transverse waves would propagate into the ocean while the compression waves would propagate into the sea floor (SVT 2009).

Most of the energy from pile driving activities would normally transfer into the sea floor. Once in the sea floor, the energy would then move outwards. The waveform normally generated from pile driving activities produces a substantial peak Sound Pressure Level (SPL). However, the pulse duration and pulse rise time during pile driving activities is longer than that of an explosion. As a result, the effect of a pile driving activities on marine fauna would not be as damaging as a pulse from an explosion of equal peak SPL (SVT 2009).

The piles that would be used for the construction of the port would range from 329mm to 1050mm in diameter. Approximately 300 piles would be used. A hydraulic piling hammer would be used for pile driving. The hammer would be sized according to seabed geotechnical conditions. Preliminary investigations indicate that a hammer between 30 tonnes and 45 tonnes would be required. Drilling may also be used to install some piles, which would reduce the noise impact.

The piles used for the ferry and barge terminals would be 600mm in diameter. There would be 14, 10, and 20 piles for Humbug, Hornibrook and Hey River Terminals respectively. The hammer size would be smaller than that required for the Port. Approximately 28 piles (610mm - 1050mm) would also be required for navigational aids.

Pile driving activities would closely follow the completion of dredging activities and may occur at any time of the year.

Table 10-7 Summary of Sound Power Levels for Operational Noise Sources

Source	Configuration when measured	Octave Sound Power Level [dB] in Octave Band Centre Frequency (Hz)								Overall Sound Power Level [dB(A)]	Sound pressure level at 100m [dB(A)]
		63	125	250	500	1000	2000	4000	8000

10.4 Noise Modelling

Noise Model

A digital terrain noise model of the site and surroundings has been developed using PEN3D. The PEN3D General Prediction Model (GPM) is based on the method by Bies and Hansen (1988).

The PEN3D software was originally developed in 1993 and has been in constant development and review. The basic equation adopted by the GPM is:

$$Lp = Lw - 20\log_{10}(r) - 10\log_{10}(4\pi) + AE$$

Where:

- Lp is the sound pressure level at an observer
- Lw is the sound power level of the source
- $20\log_{10}(r) + 10\log_{10}(4\pi)$ is the distance attenuation (spherical)
- AE is the excess attenuation factor

The excess attenuation factors (AE) comprise:

$$AE = Aa + Ag + Am + Ab + Af$$

Where:

- Aa = excess attenuation due to air absorption
- Ag = excess attenuation due to ground reflection
- Am = excess attenuation due to meteorological effects
- Ab = excess attenuation due to barriers
- Af = excess attenuation due to forests.

The noise model developed for this Project incorporates three-dimensional terrain data. Since there is considerable coverage of natural vegetation, the noise model also incorporates the noise attenuation effects from tree zones. The effects of the tree zones are minimal within approximately 500m of the haul roads and conveyors and within approximately 1,250m of the bauxite processing, mining and development areas. It should be noted that the noise attenuation effect from tree zones is typically minor at night or down-wind since the noise adopts a downward curved path, well above the height of the trees. However, under neutral conditions, or upwind, the attenuation effects can be substantial.

Meteorology

The meteorology for Weipa was reviewed (refer **Section 9.4.1**) and four representative modelling cases were developed where meteorological conditions may be expected to lead to elevated noise levels in Weipa and Napranum. The modelling cases are summarised in **Table 10-8**. Each of these modelling cases occurs at least 10% of the time over the duration of a year.

Table 10-8 Noise Modelling Cases

Modelling Case Name	Wind Speed [m/s]	Wind Direction [degrees]	Vertical temperature gradient [°C/100m]	Temperature [°C]	Humidity [%]	Stability Class
Day	3.0	125	–1	27	75	C
Evening	2.3	129	1	24	75	E
Night	0	0	2	22	75	F
Night with Wind	2.6	113	2	22	75	E

10.4.1 Construction

During the construction phase of the Project the most significant sources would be the construction of the proposed port and the ferry and barge terminals. Construction sounds that have the potential to affect both human receptors and marine animals include pile-driving and jack hammers.

The proposed port is approximately 38km from Weipa. The Hornibrook ferry terminal is more than 1km from Napranum and the Humbug barge terminal is more than 1km from Evans Landing. It is therefore unlikely there would be significant impact to sensitive human receptors as a result of construction of these facilities and these impacts have not been modelled.

Underwater noise generated by piling has the potential to impact individual marine animals, however the potential impact of Project pile driving activities on threatened and migratory species is considered low. Although the areas where pile driving activities would be conducted may be traversed by some species, or utilised by some species for foraging, there is no critical breeding or feeding habitat for these species (refer **Table 6.34**) close to these construction areas. Specific quantitative analysis has not been conducted on the potential underwater impacts on threatened marine fauna associated with pile driving activities. However a number of recent studies have been conducted on this subject, the results of which are summarised below.

Measurements taken at the Port of Melbourne during piling in 13m of water with cylindrical steel piles found that the mean sound pressure level underwater was 179dB re 1µPa at 30m and 170dB 1µPa at 206m (McCauley 2008). Measurements taken by Erbe (2009) during pile driving activities (750mm and 1500mm diameter piles) in Moreton Bay found:

- 750mm piles at a distance of 14m produced a sound pressure level peak of 207+/-2dB re 1µPa. At a distance of 320m the peak sound pressure level produced by these piles was measured at 181+/-1dB re 1µPa. At a distance of 1290m the peak sound pressure level produced by these piles was measured at 126+/-1dB re 1µPa;
- 1500mm piles at a distance of 14m produced a sound pressure level peak of 205+/-2dB re 1µPa. At a distance of 360m the peak sound pressure level produced by these piles was measured at 180+/-1dB re 1µPa. At a distance of 1330m the peak sound pressure level produced by these piles was measured at 133+/-1dB re 1µPa.

The measurements from Moreton Bay also show that at a distance of 14m, underwater noise from both 750mm and 1500mm pile driving activities are below the peak pressure levels considered to cause hearing loss in both marine turtles and cetaceans. The measured levels for both sized piles were greater than the avoidance and behavioural thresholds (refer **Section 10.2.5**) for both marine turtles and cetaceans. An exclusion zone of 200m was implemented during the piling (Erbe 2009).

Underwater noise modelling (SVT 2009) of the driving of 1600mm piles undertaken for the Cape Lambert Port B Development in Western Australia found:

- physical injury could occur to marine turtles within 20m (piling close to shore) and 30m (piling in deeper water); and
- avoidance behaviour by marine turtles could occur within 300m (piling close to shore) and 400m (piling in deeper water).

In addition to the above studies, the recent approval relating the Cape Lambert Port B Development (EPBC Approval 2008/4032) imposed the requirement to develop and implement both marine turtle (Biota 2010) and cetacean (SKM 2010) management plans that are approved by DSEWPaC, which were to include mitigation measures for underwater noise impacts on marine fauna associated with pile driving activities. The management plans committed to a 500m exclusion zone for marine turtles during pile driving activities, however remained silent on exclusion zones for dolphins. However it is assumed that the 500m exclusion zone would also apply to dolphins as the turtle management plan states that observers would look for marine turtles and other marine fauna within 500m of piling operations (Biota 2010).

The construction of the ferry/barge terminals are minor building works compared to the construction of the port (including limited piling of 600mm piles) of short duration. Pile driving activities for the ferry/barge terminals is anticipated to take approximately 15 days. The impacts would be limited to the day-time period and localised to the immediate area. The works are not of sufficient size to be addressed further other than by a Construction Management Plan of sufficient detail as is usual for works of this nature.

The operation of the ferry and barge would be a potential noise source once the terminals are commissioned, which would be at least six months into the construction period. This has been modelled in the operations phase of the project.

10.4.2 Operations

For the purposes of impact assessment, three production scenarios have been considered over the life of the mine:

- 15Mdptpa;
- 30Mdptpa; and
- 50Mdptpa.

The 15Mdptpa production scenario covers the early years of the Project when the mining areas would be located close to the Boyd infrastructure area and furthest from sensitive receptors. Under the 30Mdptpa production scenario would be more remote from the Boyd infrastructure area and also occur near the Norman Creek infrastructure area and extend further away over time. Under the 50Mdptpa production scenario the mine would extend from the north to the south of the lease area over a distance of approximately 60km. The equipment and plant utilisations for each production level are shown in **Table 10-9**. The noise model incorporates plant and equipment operating at 50Mdptpa production rate with a spatial distribution representative of operations likely to cause the highest noise levels in all noise sensitive locations as follows:

- a mining and development area approximately 5km west of the Hey River barge/ferry terminal and 6.4km south west of Napranum;
- a mining area 23km south-south-west of Napranum;
- a mining area 35km north of Aurukun;
- a mining and development area 17km north of Aurukun; and
- haul roads, conveyors, beneficiation plant, power station, and ship loaders.

For modelling purposes, mobile equipment fleet have been located in mining areas, on haul roads, and at dump stations, as would occur in a realistic mining situation.

A barge would be used to transport equipment, cargo and fuel from the Humbug Terminal to the Hey River Terminal (refer **Section 14.4** for full description of barge and ferry operations). At maximum production approximately six trips would occur each day, with each trip taking approximately 30 minutes.

A ferry would transport the workforce from the Hornibrook Terminal to the Hey River Terminal. At maximum production, it is estimated that four to six crossings per day would be required, each taking approximately 12 minutes.

The route for the barge and ferry is approximately mid-channel and at least 1km from the banks of the Embley River at Napranum. For the purposes of modelling it is conservatively assumed there would be two barge/ferry passages in the hour. The noise level would be representative of a barge or passenger ferry with standard mufflers.

The calculated noise levels (including the low frequency noise levels) for Weipa, Napranum and Aurukun for the four meteorological cases are shown in **Table 10-10, Table 10-11** and **Table 10-12** respectively. Since the 50Mdptpa production scenario is likely to produce the highest noise levels, only this case is modelled. Refer to **Figure 10-1, Figure 10-2, Figure 10-3,** and **Figure 10-4** for the $L_{Aeq,\ adj,\ 1\ hr}$ noise levels during the day, evening, night and night with wind respectively for the 50Mdptpa production scenario.

The existing $L_{A90,\ 1hour}$ noise levels are 41dB(A), 38dB(A), and 38dB(A) respectively for the day, evening and night periods. These existing background noise levels are well above the calculated noise levels from the Project. The existing $L_{Aeq,\ 1\ hour}$ are even higher. Adding the calculated Project noise levels to the existing levels would not change the noise levels in the sensitive areas. Furthermore, the noise levels comply with the noise level objectives; therefore, health and amenity are unlikely to be adversely affected if there are periods of the year with very low ambient levels.

There are homesteads on the cattle stations to the east of the mining areas (refer **Figure 9-1**). The separation distances between the project and the homesteads are at least 50km. The noise levels at these homesteads from the Project are expected to be inaudible under all circumstances.

10.5 Potential Impacts and Mitigation Measures

Construction Phase

Most construction operations take place at large distances away from noise sensitive locations. Napranum is the closest noise sensitive area to the Project.

The main construction noise sources affecting Napranum would be the construction of the Hornibrook ferry terminal and subsequent operation of the ferry and barge. Baseline noise monitoring would be carried out at Napranum prior to the commencement of construction.

Piling activities for the ferry terminal would be temporary activities that would be carried out during the day. Therefore this activity is unlikely to cause nuisance at these sensitive receptors.

The construction of the wharf at the proposed port between Boyd Point and Pera Head would involve pile driving. The underwater noise that is generated by the hammer hitting the top of the pile is of short-term duration and therefore can be described as impulsive noise. Noise generated from driving a pile is broadband and does not have any tonal characteristics. The time taken to drive each pile would depend on the hardness of the seabed in each location.

Based on the noise measurements conducted for similar sized pile driving operations by McCauley (2008), Erbe (2009) and SVT (2009), marine turtles and cetaceans in the vicinity of the pile driving activities may experience changes in behavioural patterns.

It is anticipated that the construction activity would deter most turtles and marine mammals from the immediate area. However, for precautionary purposes, it is proposed that a "soft start" approach would be used to disperse animals in the vicinity prior to normal pile driving. The "soft start" involves commencing pile driving with a partial capacity strike, or giving a warning with an underwater airgun prior to normal pile driving. It is proposed that an exclusion zone be established and monitored by an observer around pile driving activities and that a soft start approach be undertaken prior to normal pile driving. Normal pile driving would not be conducted while threatened marine fauna species are indentified within the nominated exclusion zone. The extent of the exclusion zone would be defined based on further literature review and quantitative analysis of the potential underwater noise impacts from pile driving relating to threatened marine fauna. The final extent of the exclusion zone would be defined in consultation with DSEWPaC.

With the implementation of the proposed mitigation measures, the impact of noise and vibration on sensitive receptors during the construction phase of the Project is considered to be low.

Operational Phase

The modelling has demonstrated that the noise levels from mining are expected to comply with all noise level objectives and criteria in Weipa, Napranum and Aurukun during the day, evening and night, as shown in **Table 10-10**, **Table 10-11** and **Table 10-12**. The expected $L_{Aeq,adj,1hr}$ noise level from the ferry and barge is calculated to be less than 31dB(A) in Napranum during the day, evening, night and "night with wind" modelling cases.

Furthermore, the low frequency noise level limit of 50dB(Linear) is likely to be met at all locations during the night. It should be noted that noise from the ferry is likely to be the main source of low frequency noise from the Project at both Napranum and Weipa. The noise from the ferry has been modelled at 50dB(Linear) at Napranum at night with wind; however, this is based on a conservatively high noise emission from the ferry and barge. Smaller passenger ferries would be significantly quieter.

The vessels using the proposed port would also produce underwater noise. In Australia, dolphin species co-exist with coastal development, including extensive port facilities, and therefore noise from operation of the port is not expected to have a significant impact. Further discussion on impacts to marine fauna is provided in **Section 6.9.4**.

The manufacturer's sound power level specifications for major equipment items would be used as guidance when purchasing equipment. A noise monitoring campaign, including attended monitoring at Napranum, would be conducted after operation commences to validate the noise model. Where it is determined that actual noise levels exceed applicable noise limits, action would be taken to reduce noise levels.

The impact of noise from the operation on the natural terrestrial animals and avifauna is best assessed by the noise from operations compared with the existing noise levels. The existing background noise levels (close to the Embley River) are 41dB(A) during the day and 38dB(A) during the evening and night. Coastal areas are often noisy environments due to the action of birds and wildlife, wind and waves. The areas around Boyd Point are likely to be noisier than that measured near Hornibrook ferry terminal as it is more exposed to the Gulf. The noise modelling shows that these existing noise levels are typically met between 1km and 1.5km from roads, mining and the processing plant. Close to Boyd Point, these levels are typically met at a much larger distance, typically 5km along the shoreline and out to sea.

Blasting is not proposed, and therefore there would be no impact from blasting noise, ground vibration, or flyrock. Off-site impacts from increased road or other transportation are addressed in **Section 14**.

The impact of noise and vibration on sensitive receptors during the operational phases of the Project is therefore considered to be low.
